MISSION OVERVIEW, SCIENCE OBJECTIVES AND RESULTS

CASSINI FINAL MISSION REPORT 2019

DEDICATION

Volume One of the Cassini Mission Report is dedicated to the thousands of engineers, scientists, technicians, administrators, storytellers, and artists that took the vision of a few and transformed that vision into the Cassini-Huygens Mission to Saturn and Titan, a 20-year voyage of exploration and discovery and a gift for all of humanity.

The research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

MISSION OVERVIEW, SCIENCE OBJECTIVES, AND RESULTS

1 INTRODUCTION

On September 15, 2017, at about 10:45 a.m. Saturn local time, the Cassini-Huygens mission ended with a high-velocity entry of the Cassini orbiter into Saturn's upper atmosphere. The spacecraft's speed guaranteed destruction, effectively precluding any inadvertent encounter with Saturn's moons, particularly Enceladus and Titan. Intentionally guided to its fiery demise by the flight team at NASA's Jet Propulsion Laboratory, this final mission event represented a triumphant end to one of humanity's greatest missions of deep space exploration.

The Cassini-Huygens spacecraft were launched on October 15, 1997. After a 6.5-year interplanetary cruise with gravity assists from Venus (2), Earth, and Jupiter, the spacecraft entered into orbit around Saturn on June 30, 2004. The ESA-supplied Huygens probe was released from Cassini on December 24, 2004, and made its historic landing on the moon Titan on January 14, 2005. The Cassini orbiter then went on for another 12¾ years exploring the Saturn system.

As a fitting end to 13 incredible years of exploring the Saturn system, the mission concluded with the Grand Finale, a gambit so daring that it could not have been considered during any other phase of the mission. These 22 orbits darted through the gap between the rings and planet itself revealing more unseen wonders and a collection of brand-new puzzles.

Christened a "discovery machine" by its scientists, the Cassini-Huygens mission will be considered one of the most productive chapters in humankind's exploration of the planets. From the moment Cassini-Huygens began science operations until its final moments as it was overcome by the Saturn's encroaching atmosphere, the mission was returning invaluable information on the Saturn system. Cassini-Huygens time and time again shocked and amazed both the science community and the general public.

Using data from the mission, scientists have written nearly 4,000 science publications across five interrelated disciplines: Titan, Icy Satellites, Rings, Magnetosphere and Plasma Science, and Saturn. The Cassini Mission has produced such a wealth of data that the science community will be analyzing the results for decades. While this report attempts to tell the Cassini-Huygens story,

we are aware that no single report can completely cover the history, challenges, successes, results, and lessons learned from the mission. We encourage the reader to seek out the many publications on the mission that we have captured in the references.

The Cassini Mission Report's seven volumes contain an overview of the mission and a science summary and assessment, a performance assessment of the different systems that formed parts of the project, and the major lessons from the mission team during the development and operations phases.

Content for each volume of the Mission Report:

- Volume 1 describes the Cassini Mission and the major systems that formed part of the project, provides an assessment of success in achieving its scientific objectives, summarizes the accomplishments and successes of the project's public and educational outreach program, lists archive locations of project records, and provides a bibliography of scientific and engineering papers, articles, and publications in the appendices.
- Volumes 2 and 3 contain the performance assessment of the spacecraft and the instrument payload, respectively. Spacecraft performance is discussed at the system level, as well as for each of the engineering subsystems. Volume 3 contains the performance assessment for each of the scientific instruments that formed Cassini's payload. These two volumes describe in detail the challenges and successes that the spacecraft, instruments, and flight team went through during the operations phases. Volumes 2 and 3 also provide an overview of the main spacecraft and instrument anomalies and idiosyncrasies that took place during operations.
- Volume 4 contains a performance assessment of the navigation portion of the mission. It includes an overview of the navigation objectives, a detailed description for each navigation model used during operations, the navigation strategies used to predict and reconstruct the spacecraft's trajectory, as well as the methodology for determining the ephemerides (i.e., the positions at a given time) of Saturn and its moons.
- Volume 5 contains a performance assessment for the ground-based Mission Operations System (MOS) used to operate the flight system from the beginning of the cruise phase through end of mission. For each of the major operations processes, this volume also includes a system-level description and a performance assessment.
- Volume 6 contains the lessons that the project and the flight team learned during mission operations, as well as an explanation of the event (or events) that led to each lesson learned. Some of the lessons learned also contain the event's impact on the project or the overall mission.
- Volume 7 contains the end-of-mission Planetary Protection Report. This volume details the Cassini Project's final disposal of launched hardware and the project's compliance with the planetary protection requirements established by NASA policy directive (NPD) 8020.7G and as directed by the NASA Planetary Protection Officer.

2 MISSION DESCRIPTION

> The Cassini-Huygens mission was designed to reveal Saturn's mysteries … using the largest and most sophisticated interplanetary spacecraft that … (NASA) had ever launched.

Perhaps no other place in the solar system is so rich an environment for exploration and scientific discovery as the expansive Saturn system. The planet, its rings, and its several dozen moons have lured and mystified scientists from all over the world. While the solar system's other giant planets—Jupiter, Uranus, and Neptune—have rings, Saturn's are unique in their breadth and brightness. They are the main feature by which Saturn is known. Scientists treat Saturn and its ring system as a physical model for the Sun and the disc of gas and dust from which the planets formed because when humans search for planetary systems elsewhere in the galaxy, their success depends partly upon how well we understand the early stages of planet formation. The Cassini-Huygens mission was designed to reveal Saturn's mysteries by exploring the entire Saturn system in greater detail than ever before, using the largest and most sophisticated interplanetary spacecraft that the National Aeronautics and Space Administration (NASA) had ever launched.

2.1 Program Summary

When Cassini-Huygens left Earth on October 15, 1997, to begin a journey covering 3.5 billion km, it was the most highly instrumented and scientifically capable planetary spacecraft ever flown. The Cassini orbiter carried 12 instruments, and the Huygens probe carried six, for a total of 18 instruments. The mission represented the best technical efforts of thousands of engineers and over 260 scientists from the United States and 18 European countries.

The Cassini-Huygens mission was an enterprise that, from initial vision to mission completion, spanned 30 years. The formal beginning was in 1982, when the European Science Foundation's Space Science Committee and the Space Science Board of the U.S. National Academy of Sciences formed a joint working group. The group's charter was to study how the United States and Europe might cooperate in the field of planetary science. Their precept was that the mission would benefit the scientific, technological, and industrial sectors of their countries. As a result of the studies, European scientists proposed a Saturn orbiter and Titan probe mission to the European Space Agency (ESA), suggesting collaboration with NASA.

The Cassini-Huygens mission became an international venture involving NASA, ESA, the Italian Space Agency (Agenzia Spaziale Italiana (ASI)), and several separate European academic and industrial partners. The large Cassini spacecraft, consisting of an orbiter and the attached ESA Titan probe, carried scientific sensors to support 27 different investigations.

2.1.1 Historical Astronomical Observations Important to Cassini-Huygens

The mission was named in honor of the French-Italian astronomer Jean Dominique Cassini, with the Titan probe named in honor of the Dutch scientist Christiaan Huygens. Those two scientists so enriched human understanding of the Saturn system that the Program was inspired to select their names for the mission.

The Italian astronomer Galileo Galilei was the first to observe Saturn through a telescope in 1609–10. The earliest known record of any telescope is dated to only a year or so before Galileo began studying the night sky. Viewed through Galileo's crude instrument, which he constructed himself, Saturn was a puzzling sight. Unable to make out the rings, Galileo thought he saw two sizable companions close to the planet. Having recently discovered the major moons of Jupiter, he supposed that Saturn could have large moons, too. "... [to] my very great amazement, Saturn was seen to me to be not a single star, but three together, which almost touch each other," Galileo wrote at the time.

Galileo was even more astonished when, two years later, he again looked at Saturn through his telescope only to find that Saturn's companion bodies had apparently disappeared. "I do not know what to say in a case so surprising, so unlooked for and so novel," he wrote in 1612. The rings were simply "invisible" because he was now viewing them edge-on. Two years later, they again reappeared, larger than ever. Galileo concluded that what he saw were some sort of "arms" that grew and disappeared for unknown reasons. He died not knowing that he had been the first person to observe Saturn's (or any planet's) rings.

Nearly half a century later, optics had improved, allowing Dutch scientist Christiaan Huygens to solve the puzzle that had baffled Galileo. Huygens pronounced in 1659 that the companions or arms decorating Saturn were not appendages, but rather the planet "is surrounded by a thin, flat ring, which nowhere touches the body." Some in the science community were opposed to his theory, but the notion of Saturn's rings was later confirmed by the observations of British physicist Robert Hooke and Italian-French astronomer Jean Dominique Cassini.

While observing Saturn, Huygens also discovered Saturn's largest moon Titan. A few years later and using new telescopes, Cassini added several other key Saturn discoveries, including Saturn's four other major moons—Iapetus, Rhea, Tethys, and Dione. In 1675, Cassini discovered that Saturn's rings are split largely into two parts by a narrow gap—known since as the "Cassini Division." In the 19th century, J. E. Keeler, pursuing theoretical studies developed by James Clerk Maxwell, showed that the ring system was not a uniform sheet but is instead made up of small particles orbiting Saturn. Each of those realizations was game-changing. Yet it was only when humans began sending spacecraft to observe the Saturn system up close that the planet, rings, and moons began to truly reveal themselves.

The first detection of Saturn's magnetic field came with the flyby of Saturn by NASA's Pioneer 11 spacecraft in 1979. Then, in 1980 and 1981, the NASA Voyager 1 and Voyager 2

spacecraft flew through Saturn's system to reveal several additional small moons, storms and subtle latitudinal banding in the planet's atmosphere, and a breathtaking collection of thousands of ringlets. The Voyagers found ring particles ranging in size from nearly invisible dust to icebergs the size of a house. The spacing and width of the ringlets were discovered to be orchestrated at least in part by gravitational tugs from a retinue of orbiting moons and moonlets, some near ring edges but most far beyond the outermost main rings. Voyager instruments confirmed what ground-based instruments had suggested—that the rings contain water ice, which may cover rocky particles.

The Hubble Space Telescope then joined the effort, making Saturn a frequent target and producing stunning views of long-lived hurricane-like storms in the planet's atmosphere. The world's major telescopes, including Hubble, have been trained on Saturn to observe phenomenon known to astronomers as a Saturn ring plane crossing. The rings were seen edge-on from Earth's perspective on May 22 and August 10, 1995, and on February 11, 1996. Ring plane crossings provide astronomers with unique views of Saturn's system.

These observations showed that the ring plane was not absolutely flat. Instead, the tilt of the F-ring distorts the appearance of the rings, causing one side to appear brighter than the other during ring plane crossings. Astronomers used observations from the space telescope to search for new moons and turned up several suspects, most of which are now believed to be bright "knots" in the F-ring. Of particular interest were ring arcs, natural "satellites" in the F-ring that appeared cloud-like and spread over a small area, instead of sharp pinpoints. The origin of these clumps of material in the F-ring is not well understood.

Viewing Saturn's ring system edge on also made the faint, outermost E-ring easier to detect due to the greater amount of material in the line of sight. That effect also allowed scientists to get better information about the overall thickness of Saturn's rings. Mission designers used the new information gathered about the location and density of material in the rings to plan the most advantageous and safest course for Cassini's flight through the gap between Saturn's F- and G-rings during Saturn arrival in 2004.

The Hubble Space Telescope not only helped designers plan the spacecraft's trajectory for the Cassini-Huygens mission, but also guided and supported the mission's observations of Saturn, its rings, moons, and magnetosphere. Hubble observations of Saturn's atmosphere were made after storms were discovered by ground-based observers. First in 1990 and again in 1994, apparent upwellings of ammonia clouds appeared and then were spread around the planet by prevailing winds.

Scientists also compared Voyager and Hubble observations of Saturn's moon, Titan. They found that color differences in Titan's hemispheres seen during the Voyager flybys in 1980 and 1981 had reversed themselves by the time Hubble observed the moon.

Some Hubble observations have studied chemical processes in Titan's atmosphere. Images made in the infrared have looked through Titan's clouds (which are opaque in visible wavelengths of light), allowing some mapping of Titan's surface. Hubble has also contributed new information about processes in Saturn's magnetosphere through ultraviolet measurements of Saturn's auroras.

As with any proper science endeavor, Cassini-Huygens used knowledge acquired by its predecessors to refine not only the questions to be asked, but also the best places and times to ask those questions.

2.1.2 HISTORY OF THE EVOLUTION AND DEVELOPMENT OF THE CASSINI MISSION

In 1983, the U.S. Solar System Exploration Committee recommended that NASA include a Titan probe and radar mapper in its core program and also consider a Saturn orbiter. NASA/ESA completed a joint assessment of a Saturn orbiter/Titan probe mission in 1984–85. Then in 1986, ESA's Science Program Committee approved Cassini for initial Phase A study, with conditional start in 1987.

In 1987–88, NASA carried out further work to design and develop the standardized Mariner Mark II spacecraft and a set of outer planets missions to be accomplished with the new line of spacecraft. The program was an early effort to reduce the costs of planetary exploration by producing multiple spacecraft for different missions with the same basic spacecraft components off the same assembly line. Cassini and the Comet Rendezvous/Asteroid Flyby (CRAF) were the first two missions chosen for further study. At the same time in Europe, a Titan probe Phase A study was carried out by ESA in collaboration with a European industrial consortium led by Marconi Space Systems. The Titan probe was named Huygens by ESA as its first medium-sized mission of its Horizon 2000 space science program.

In 1989, the U.S. Congress approved funding for Cassini and the comet-asteroid mission. NASA and ESA simultaneously released announcements of opportunity for scientists to propose scientific investigations for the missions. In 1992, a funding cap was placed on the Mariner Mark II program, effectively ending the new spacecraft line and, at the same time, canceling the CRAF mission. To cut the cost of the mission and simplify the spacecraft and its operation, designers restructured the Cassini spacecraft.

Mission planners performed extensive tradeoff studies considering cost, mass, reliability, durability, suitability, and availability of hardware, which resulted in Cassini's eventual design. They eliminated moving parts from the spacecraft wherever the functions could be performed satisfactorily without them. As a result, early designs that included moving science instrument platforms or turntables were discarded in favor of instruments fixed to the spacecraft body, whose pointing requires rotation of the entire spacecraft. Also, tape recorders were replaced with solid-state recorders, mechanical gyroscopes were replaced with hemispherical resonator gyroscopes, an articulated probe relay antenna was discarded in favor of using Cassini's high-gain antenna to capture the radio signal of the Huygens probe, and a deployable high-gain antenna of the type used for the Galileo mission was considered and abandoned.

Project engineers, both those who designed and built the hardware and those who operated the spacecraft, relied heavily on extensive experience to provide a spacecraft design more

The Cassini-Huygens design also came with a side effect: new spacecraft technology that benefited future missions.

sophisticated and reliable than any other spacecraft ever built for exploration of the planets. That careful design allowed the Cassini spacecraft to return more scientific data about its targets than had been possible in any previous planetary mission.

The Cassini-Huygens design also came with a side effect: new spacecraft technology that benefited future missions.

2.1.3 NEW TECHNOLOGY

A wealth of new technology was developed and qualified for spaceflight by or for the Cassini program. Much of the new technology has already been adopted by other space science programs, in some cases at a reduced cost directly attributable to Cassini, which enabled the development of new classes of low-cost, high-efficiency spacecraft, such as the Discovery and New Millennium spacecraft.

The Cassini orbiter also advanced and extended the technology base of the United States and its partners with several innovations in engineering and information systems. Though they may not seem so today because the pace of technology is so fast, each of the innovations described below was revolutionary at the time of Cassini's launch in 1997.

Cassini pioneered the use of solid-state data recorders with no moving parts. This is now standard hardware on all spacecraft.

Similarly, the main onboard computer that directs operations of the orbiter used an innovative design that employed new types of electronic chips, such as the very high-speed integrated circuit (VHSIC) chips developed under a U.S. government-industry research and development initiative. The Cassini generic VHSIC spaceborne computer (GVSC) 1750A was the first civilian spacecraft to use this technology. Cassini's computer system also used new application-specific integrated circuit (ASIC) parts; each component replaced one hundred or more traditional chips. The ASIC chips allowed the development of a data system for Cassini 10 times more efficient than earlier spacecraft designs, and with less than one-third the mass and volume. Two spacecraft under NASA's Discovery program—Mars Pathfinder and the Near-Earth Asteroid Rendezvous mission—used these chips directly off the Cassini production line.

Also, on the Cassini orbiter, the power system benefited from an innovative solid-state power switch developed for the mission. The switch had a significantly improved component lifetime and eliminated rapid fluctuations called transients that usually occurred with conventional power switches. The Cassini program also developed a low-mass, low-power, radiation-hardened X-band radio transponder (a combined receiver and transmitter). Both the Mars Pathfinder and the Near-Earth Asteroid Rendezvous missions used radio transponders built on the Cassini mission's production line.

The inertial reference units (IRUs) used on Cassini represented the first space version of a revolutionary new gyro called the hemispherical resonator gyroscope. At the time, gyros that were commonly used in spacecraft, aircraft, and ships were large, very delicate mechanical devices whose many moving parts made them susceptible to failure. The new hemispherical resonator gyroscope was more reliable and less vulnerable to failure because it used no moving parts. The new gyroscope relied instead on waves traveling through a hemispherical quartz shell similar to how a note is produced when running a wet finger around the rim of a wine glass, but using electricity instead of one's finger. The Near-Earth Asteroid Rendezvous spacecraft used a slightly modified Cassini gyro.

2.1.4 THE CASSINI-HUYGENS PROGRAM

The Cassini-Huygens program was a cooperative international effort involving NASA, ESA, and ASI, as well as numerous American and European academic and industrial contributors—a partnership that represented an undertaking whose scope and cost would not likely be borne by any single nation, but was made possible through shared investment and participation.

Figure 2.1-1. Flags of the Participating Nations in Cassini-Huygens Development.

Over the course of nearly 30 years, the structure and names of the internal and external structure of the Cassini-Huygens program changed several times but the basic structure remained the same. In the United States, the mission was managed by NASA's Jet Propulsion Laboratory (JPL), a division of the California Institute of Technology (Caltech). Leadership at NASA was provided by the Cassini program executive and program scientist.

The European Space Technology and Research Center (ESTEC) managed the development of the Huygens Titan probe. Many European countries supplied the probe equipment, which were then assembled by ESTEC's prime contractor, Aerospatiale (now Alcatel) in Cannes, France. The U.S. supplied Huygens' batteries and two of its scientific instruments.

ASI supplied Cassini's high-gain and low-gain antenna. ASI also contributed components to the radio frequency instrument subsystem, the Cassini radar, and the visible and infrared mapping spectrometer.

The U.S. Department of Energy provided Cassini's radioisotope thermoelectric generators.

The U.S. Air Force provided the Titan IV/Centaur launch vehicle that was built by Lockheed-Martin. Launch operations were managed by the 45th Space Wing, Cape Canaveral, FL.

2.2 Mission Objectives

Cassini's instrument payload represented a carefully chosen suite of interrelating instruments to address major scientific questions about the Saturn system. The data they returned were, and will continue to be, analyzed by a team of nearly 260 scientists from the United States and Europe.

Following is the set of major science objectives that the Cassini-Huygens mission was charged with accomplishing.

2.2.1 Saturn

The major science objectives for Saturn (Figure 2.2-2) included:

- Determine the temperature field, cloud properties, and composition of Saturn's atmosphere.
- Measure the planet's global wind field, including waves and eddies; make long-term observations of cloud features to see how they grow, evolve, and dissipate.
- Determine the internal structure and rotation of Saturn's deep atmosphere.
- Study daily variations and the relationship between the ionosphere and the planet's magnetic field.

- Determine the composition, heat flux, and radiation environment present during Saturn's formation and evolution.
- Investigate the sources and nature of Saturn's lightning.

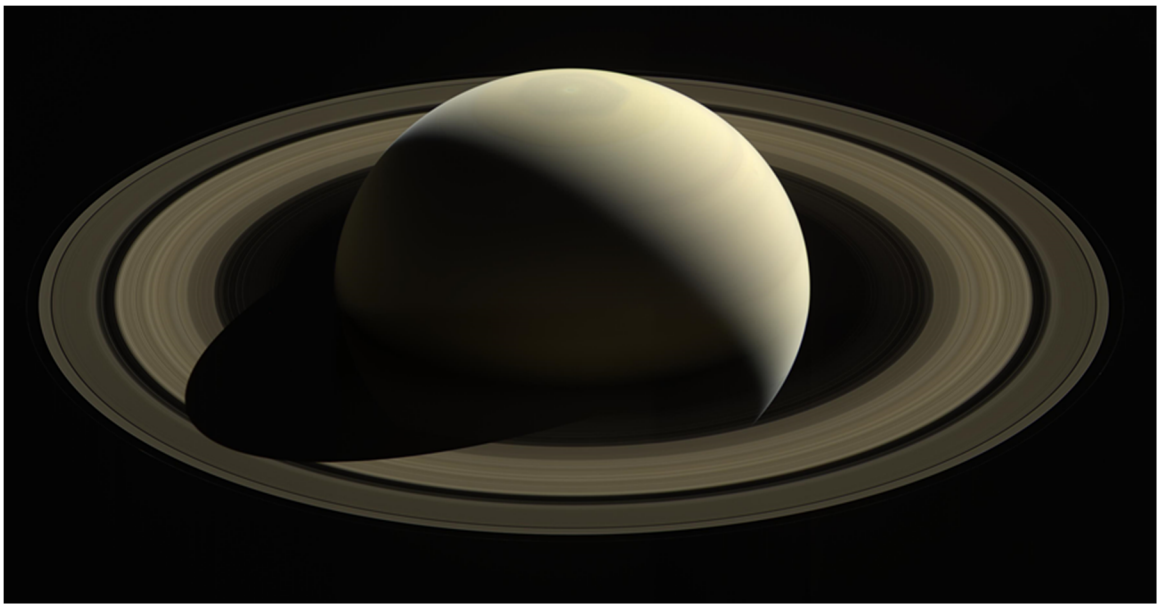

Figure 2.2-2. Saturn.

2.2.2 THE RINGS

The major science objectives for the rings (Figure 2.2-3) included:

- Study configuration of the rings and dynamic processes responsible for ring structure.
- Map the composition and size distribution of ring material.
- Investigate the interrelation of Saturn's rings and moons, including moons embedded in the rings.
- Determine the distribution of dust and meteoroid distribution in the vicinity of the rings.
- Study the interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.

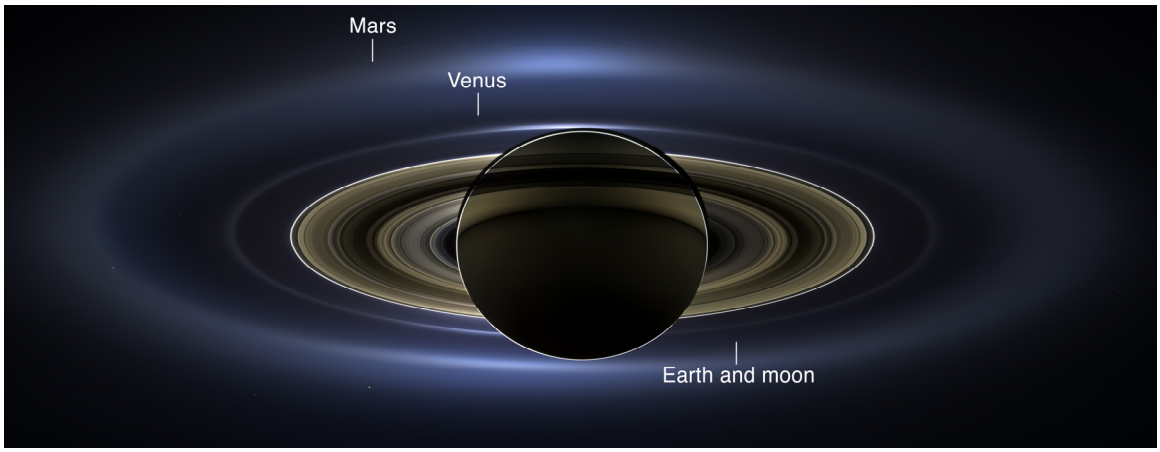

Figure 2.2-3. The Rings.

2.2.3 TITAN

The major science objectives for Titan (Figure 2.2-4) included:

- Determine the relative amounts of different components of the atmosphere; determine the mostly likely scenarios for the formation and evolution of Titan and its atmosphere.
- Observe vertical and horizontal distributions of trace gases; search for complex organic molecules; investigate energy sources for atmospheric chemistry; determine the effects of sunlight on chemicals in the stratosphere; study formation and composition of aerosols (particles suspended in the atmosphere).
- Measure winds and global temperatures; investigate cloud physics, general circulation, and seasonal effects in Titan's atmosphere; search for lightning.
- Determine the physical state, topography, and composition of Titan's surface; characterize its internal structure.
- Investigate Titan's upper atmosphere, its ionization and its role as a source of neutral and ionized material for Saturn's magnetosphere.

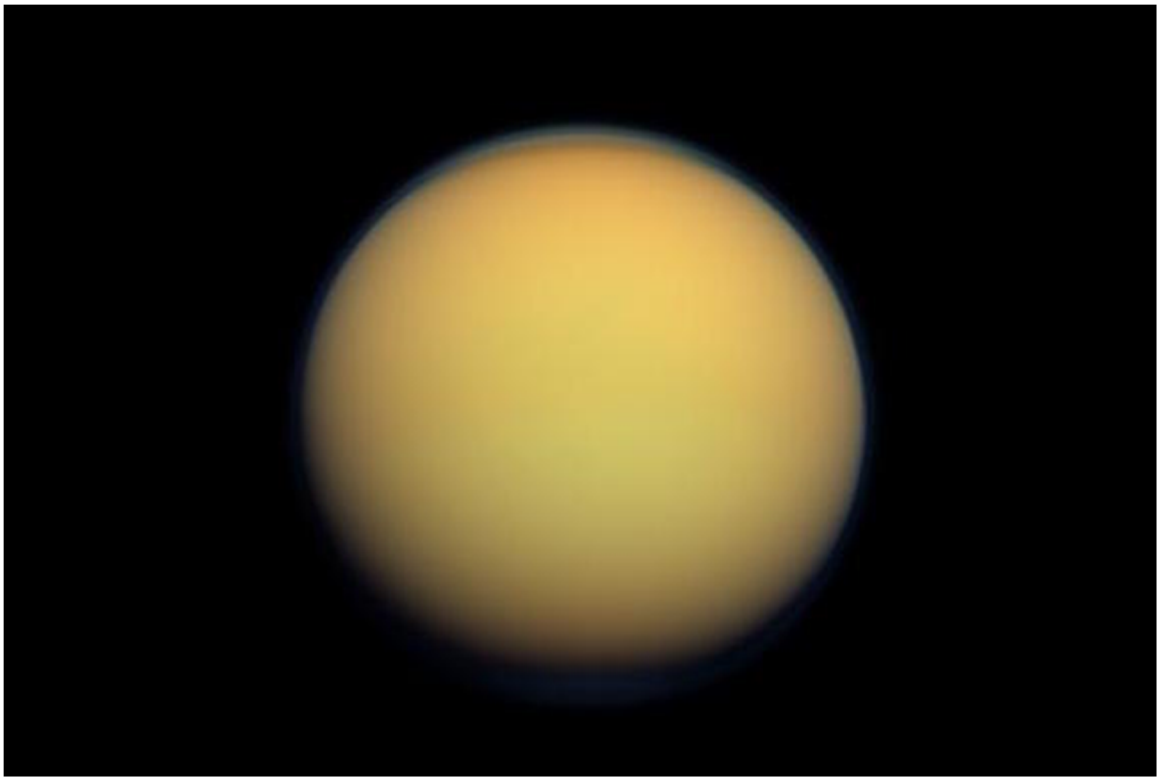

Figure 2.2-4. Titan, Saturn's largest moon.

2.2.4 MAGNETOSPHERE

The major science objectives for the magnetosphere (Figure 2.2-5) included:

- Determine the configuration of Saturn's magnetic field, which is nearly symmetrical with Saturn's rotational axis. Also study its relation to the modulation of Saturn kilometric radiation—a radio emission from Saturn that is believed to be linked to the way electrons in the solar wind interact with the magnetic field at Saturn's poles.
- Determine the current systems, composition, sources, and concentrations of electrons and protons in the magnetosphere.
- Characterize the structure of the magnetosphere and its interactions with the solar wind, Saturn's moons, and rings.
- Study how Titan interacts with the solar wind and with the ionized gases within Saturn's magnetosphere.

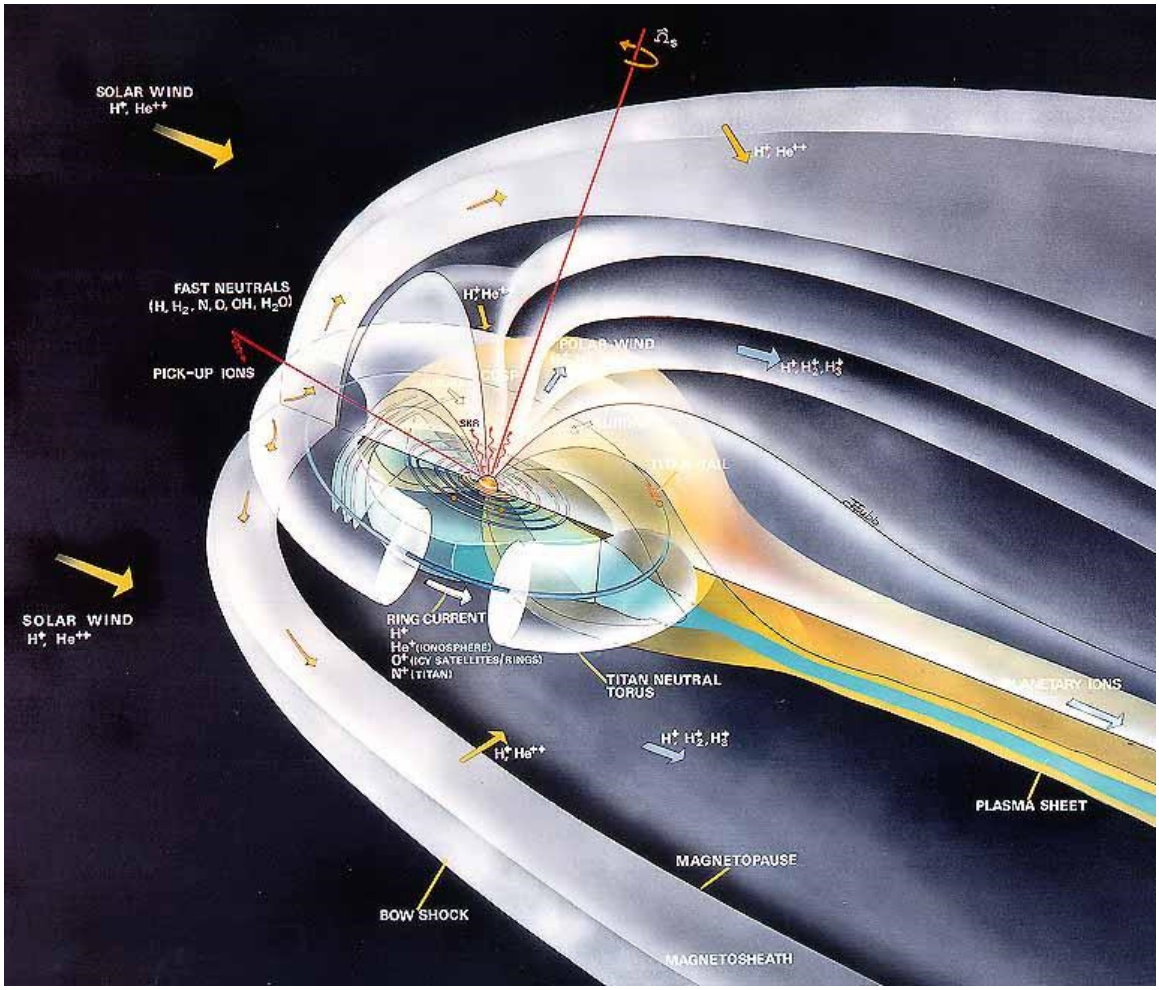

Figure 2.2-5. Magnetosphere.

2.2.5 Icy Moons

The major science objectives for icy moons (Figure 2.2-6) included:

- Determine general characteristics and geological histories of Saturn's moons.
- Define the different physical processes that have created the surfaces, crusts, or sub-surfaces of the moons.
- Investigate compositions and distributions of surface materials, particularly dark, organic-rich materials, and condensed ices with low melting points.
- Determine the bulk compositions and internal structures of the moons.
- Investigate interactions of the moons with Saturn's magnetosphere and ring system and possible gas injections into the magnetosphere.

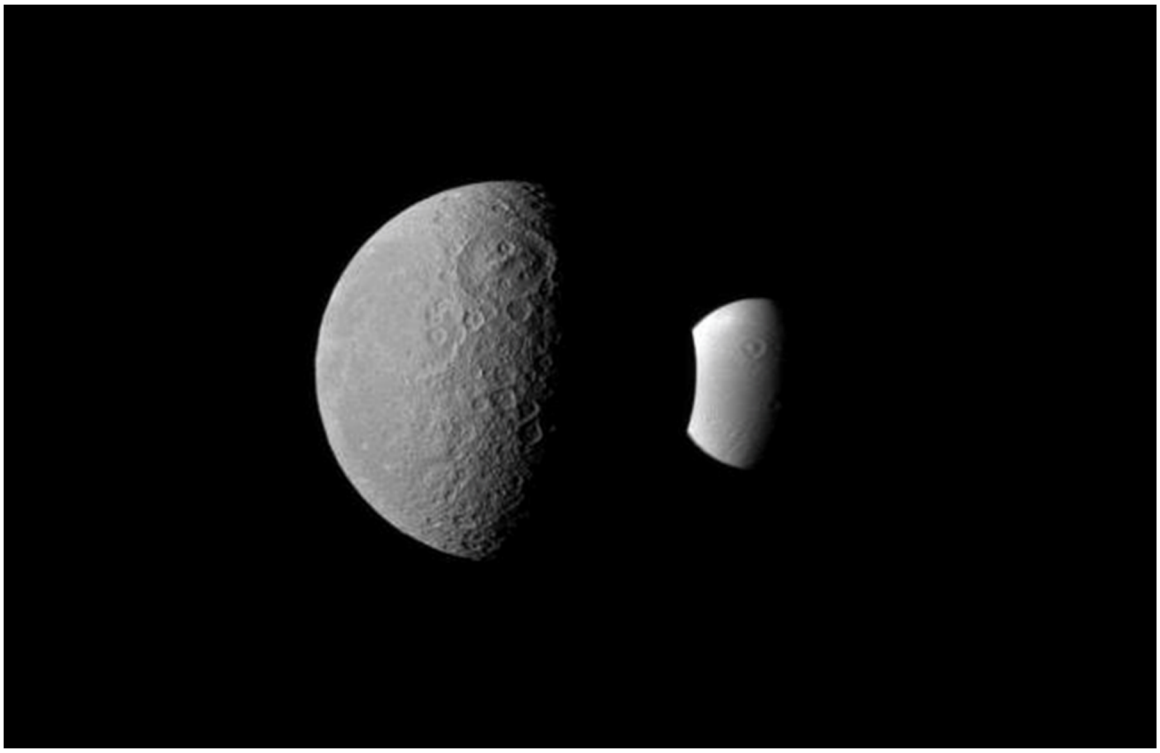

Figure 2.2-6. Saturn's icy moons Rhea (left) and Dione.

In addition to the science objectives at Saturn, the Cassini spacecraft also conducted a gravitational wave search through the ASI-provided high-gain antenna during its interplanetary cruise.

2.3 Mission Overview

The Cassini spacecraft traveled to Saturn for nearly seven years via four planetary gravity assists—two flybys of Venus, and one flyby each of Earth and Jupiter—and in June 2008 completed an outstanding 4-year prime tour of the Saturnian system (Figure 2.3-1). Cassini then embarked on two mission extensions: the Cassini Equinox Mission (completed in 2010) and the Cassini Solstice Mission (completed in 2017). Cassini-Huygens was the fourth spacecraft to visit the Saturnian system but was the first spacecraft to orbit Saturn. In all, Cassini completed 294 Saturn orbits during 13 years.

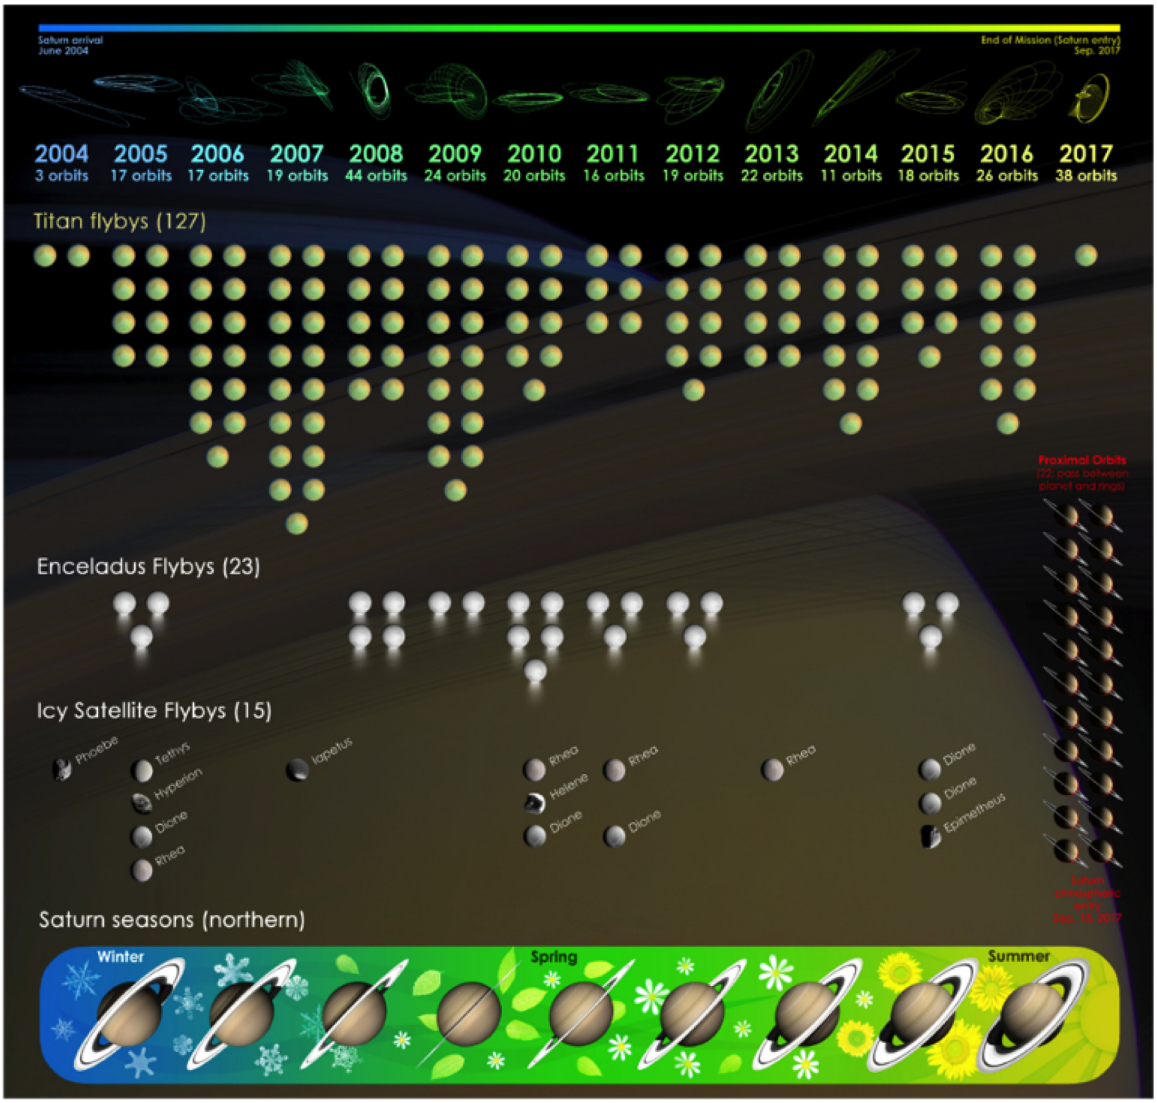

Figure 2.3-1. Cassini Mission overview.

2.3.1 LAUNCH

Cassini's journey to Saturn began on October 15, 1997, with launch on a Titan IVB/Centaur rocket from Florida's Cape Canaveral Air Force Station. The upper-stage booster accelerated the spacecraft out of Earth orbit towards Venus for the first of four planetary gravity assists designed to boost Cassini toward Saturn. In a gravity assist, the spacecraft flies close to enough to a planet to use the gravity of the two bodies—the planet and the spacecraft—to transfer some of the planet's orbital momentum to the spacecraft. As a result, the spacecraft accelerates and the planet decelerates. But because of the enormous difference in mass between the planet and the relatively miniscule spacecraft, the spacecraft accelerates by thousands of kilometers per hour while the planet decelerates by immeasurably little. That is what produces the "slingshot" effect to boost the speed of the spacecraft.

2.3.2 VENUS, EARTH, AND JUPITER FLYBYS

Cassini's mass was so large that it was not possible to use any available launch vehicle to send it on a direct path to Saturn. If Cassini had traveled directly toward Saturn, the Sun's gravity would have slowed the spacecraft and curved its trajectory back toward the inner solar system, and it would have never reached Saturn. To gain enough momentum to overcome the Sun's gravity after launch, the mission used four gravity assists to hurl the spacecraft to Saturn. Cassini travelled an interplanetary trajectory that took it by Venus twice, then past Earth and Jupiter (Figure 2.3-2).

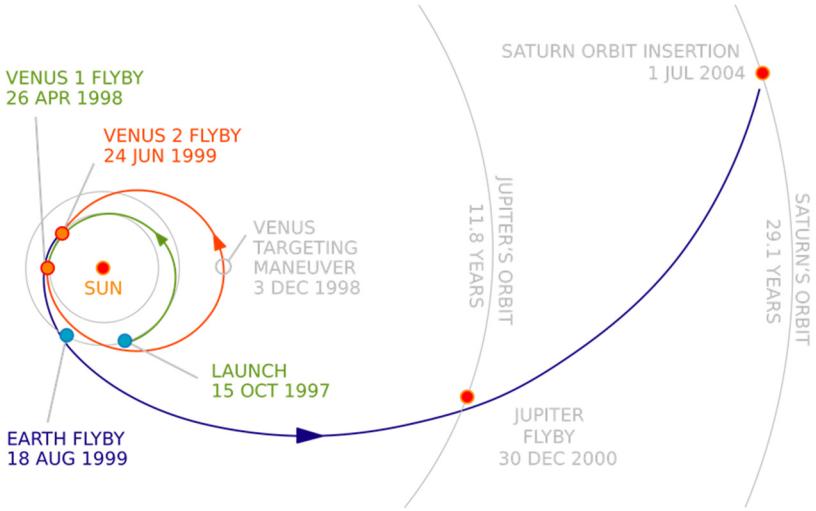

Figure 2.3-2. Venus, Earth, and Jupiter flybys.

2.3.3 PRIME MISSION OVERVIEW

In 1990, NASA announced the selection of seven Principal Investigator (PI) instruments and four facility instruments for the orbiter, and seven interdisciplinary science investigations. The Ion and Neutral Mass Spectrometer instrument was selected in 1992. The assembly, test, and launch operations began in November 1995. NASA received launch approval on October 3, 1997.

Cassini had a 30-day nominal launch period, extending from October 6, 1997 to November 4, 1997, which provided an arrival date at Saturn of July 1, 2004. The launch vehicle was a Titan IV with solid rocket motor upgrades and a Centaur upper stage. After controllers postponed a first attempt on October 13, Cassini successfully lifted off from the Cape Canaveral Air Force Station complex 40 on October 15, 1997 at 08:55 Coordinated Universal Time (UTC).

During the nearly seven years en route to Saturn, ground controllers checked out, calibrated, and maintained the science instruments. They also characterized the instruments and performed limited science observations.

The interplanetary trajectory design was a Venus–Venus–Earth–Jupiter gravity assist. The inner cruise phase spanned the time period from November 14, 1997 through November 7, 1999.

This phase included two Venus flybys (April 26, 1998 and June 24, 1999) and one Earth flyby (August 18, 1999). The outer cruise phase extended from November 8, 1999 to July 7, 2002, and included a flyby of Jupiter on December 30, 2000.

The science cruise phase began on July 8, 2002, and continued through May 15, 2004. As Cassini approached Saturn, it executed the first targeted flyby of the tour, of Phoebe, on June 11, 2004.

Cassini-Huygens entered Saturn orbit (called Saturn Orbit Insertion, or SOI) on July 1, 2004. In January 2005, after the Huygens probe descent to the surface of Titan, Cassini went on to complete its 4-year tour of Saturn, its rings, satellites, and magnetosphere via 75 orbits about Saturn, which included 45 close Titan flybys, four Enceladus flybys, and nine close flybys of other icy satellites along with dozens of Saturn, rings, and Titan radio and solar occultations. Due to the highly successful execution of the 4-year prime tour, NASA approved funding for a mission extension called the Equinox Mission, so named because the spacecraft would observe Saturn's equinox—the period when the planet's equator and the rings face the Sun edge-on.

2.3.4 EQUINOX MISSION OVERVIEW

The Equinox Mission was an aggressive 2-year 3-month extended mission that began on July 1, 2008, and continued to explore the Saturnian system's rings, magnetosphere, and icy satellites, especially Enceladus. The extension also allowed scientists to make observations during Saturn's northern vernal equinox. The Equinox Mission trajectory consisted of 64 more orbits of Saturn, 28 more Titan flybys, and 11 more close icy moon flybys, seven of which were Enceladus flybys.

2.3.5 SOLSTICE MISSION OVERVIEW

At the conclusion of the Equinox Mission, the Cassini team initiated a 7-year mission extension named the Solstice Mission, stretching the tour to September 15, 2017. The overarching goal of the Solstice Mission was to observe the complex and dynamic Saturn system over a wider range of geometries and conditions, including Saturn's May 2017 northern summer solstice. By end of mission, Cassini observed most of the northern winter season and all of the northern spring season (Figure 2.3-3).

On November 30, 2016, Cassini began the penultimate phase of the mission, the ring-grazing orbits. This 20-week phase consisted of 20 high-inclination orbits with apoapses near Titan's orbit and periapses just outside the main ring system, shown in Figure 2.3-4. The final, targeted Titan flyby on April 22, 2017, set Cassini on the Grand Finale—a series of 22 orbits with periapses that passed between Saturn and its rings; a region no spacecraft had explored before.

On September 11, 2017, Titan gave Cassini a "goodbye kiss," a distant non-targeted flyby that put Cassini on its impact trajectory with Saturn. End-of-mission occurred at 11:56 UTC on

September 15, 2017, when Cassini plunged into Saturn's atmosphere and Earth lost the spacecraft's signal forever.

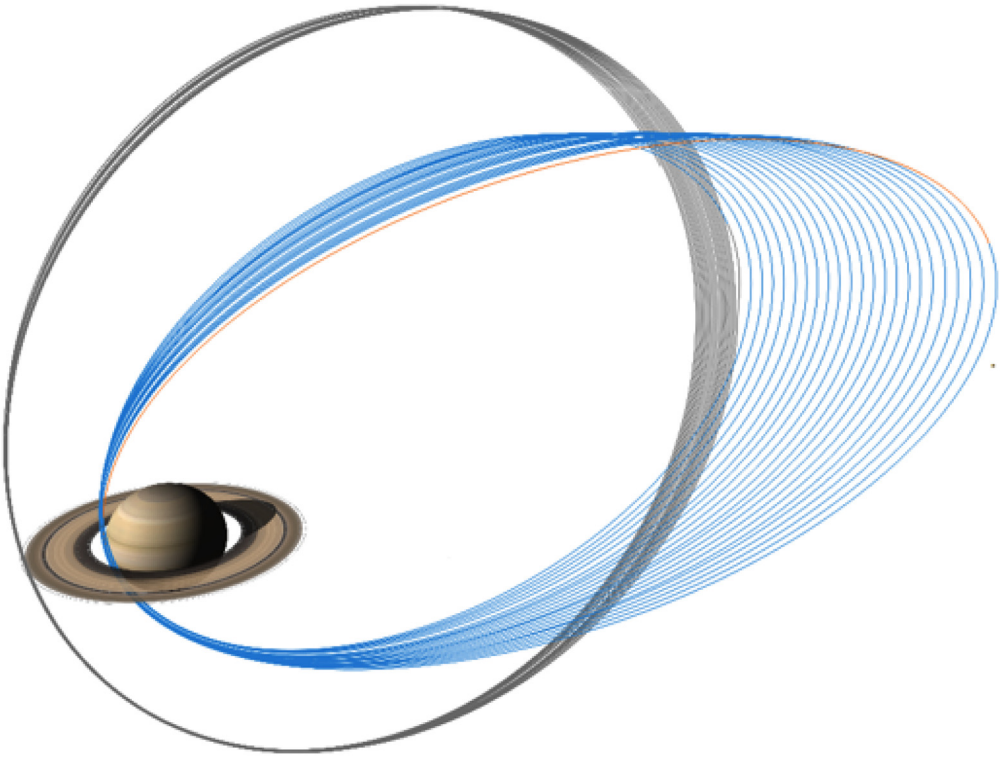

Figure 2.3-4. Ring-grazing orbits (gray), grand finale (blue), and final plunge (orange).

2.4 Flight System Description

2.4.1 SPACECRAFT OVERVIEW

The Cassini orbiter is the largest and most sophisticated outer planet spacecraft built to date (Figure 2.4-1). At launch, the orbiter with the Huygens probe weighed 5,574 kilograms. Over half of that mass was the liquid propellants needed to perform the main engine maneuvers. Right before the end of mission, the spacecraft weighed 2,780 kilograms, having used up the bulk of its propellants and having ejected the 320-kilogram Huygens probe.

The Cassini design had to accommodate a wide range of solar output, from the equivalent of 2.2 Suns at Venus distances to the 0.01 Sun available at Saturn. It was electromagnetically “quiet” to enable sensitive science investigations. The spacecraft’s telecommunications system was designed to function at near-Earth distances and at 1.6 billion kilometers from Earth, in Saturn orbit.

Cassini was a three-axis stabilized spacecraft using reaction wheels and small thrusters for control (Figure 2.4-2). Unlike Galileo, the mission to Jupiter, Cassini had no articulating platform that would allow the imaging instruments to target objects of interest while the spacecraft remained at a fixed attitude. Instead, the entire Cassini spacecraft had to be turned as one for instrument pointing, resulting in more complex design and sequencing of science opportunities. Much of the instrument pointing required the high-gain antenna to point away from Earth, so Earth communications were carefully balanced with data collection in order to maximize science return.

Figure 2.4-1. The Cassini-Huygens orbiter during thermal-vacuum testing.

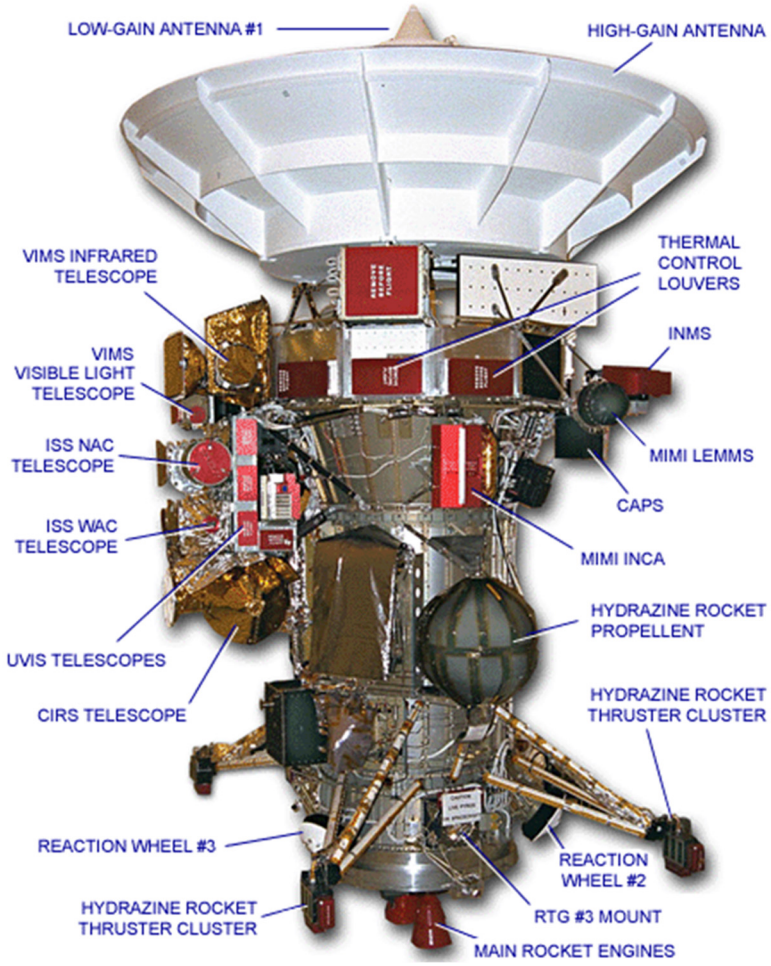

Figure 2.4-2. The Cassini-Huygens orbiter and some of its components.

2.4.2 SPACECRAFT ENGINEERING SUBSYSTEMS OVERVIEW

The Cassini spacecraft was composed of eight engineering subsystems that controlled spacecraft features and functions:

1. Spacecraft structure subsystem
2. Power subsystem
3. Command and data subsystem
4. Attitude and articulation control subsystem
5. Propulsion subsystem
6. Telecommunications subsystem

7. Thermal control subsystem

8. Fault protection

All of the main engineering subsystems had redundant units to serve as a backup in case the main unit failed. This was typical design at JPL when a single spacecraft is planned for a major mission like Cassini.

2.4.2.1 Spacecraft Structure Subsystem

Cassini used the classic JPL multisided ring bus derived from the early Mariner-Mark II spacecraft design. The Cassini bus had 12 sides, or bays, that held most of the engineering subsystems and some of the instrument electronics.

The spacecraft contained five main stacked modules. At top was the 4-meter parabolic high-gain antenna, built by the Italian Space Agency. The high-gain antenna sat atop the 12-bay electronics module, which in turn, was attached to the upper equipment module. These three components were then stacked on top of the domed propulsion module, built by Lockheed Martin Astronautics Company. And at the bottom of the stack was the lower equipment module, holding the small thruster cluster pods and completing the spacecraft's structure.

At 6.8 meters tall, the spacecraft was roughly the size of a school bus. With the magnetometer boom fully extended, the spacecraft was over 15 meters wide. The bulk of the spacecraft was made of aluminum, with some titanium and beryllium pieces for structural integrity. The high-gain antenna and the legs of the lower equipment module were a graphite epoxy structure.

2.4.2.2 Power Subsystem

Three radioisotope thermoelectric generators (RTGs) supplied power for the spacecraft. Their combined power at launch was about 875 watts. Planners predicted that the RTGs' total power output by the end of prime mission in July 2008 would be 692 watts, but because the mission was extended to September 2018 (another 10 years and two months), the actual power measured at the end of the Grand Finale was even lower, at 602 watts. The rate of power decay was quite predictable, allowing for routine power operational modes to be used in sequencing.

The RTG power was supplied to 192 solid-state power switches (SSPS), which acted as circuit breakers. Each individual engineering or science load was allocated one or more SSPS depending on the load required and the criticality of the unit. For example, the Huygens probe used five SSPSs to carry its 260 watts, and the main engineering computers had two redundant SSPSs, each capable of supplying the entire 10 watts.

2.4.2.3 Command and Data Subsystem (CDS)

Cassini had redundant IBM 1750A computers, called engineering flight computers (EFCs) that provided command, data handling, telemetry and timekeeping services. Each EFC had a 7.4 megahertz quartz crystal clock for timekeeping services. The EFC flight code was written in Ada, and the load image had some 45,000 lines of code for each EFC. The flight code was stored in radiation-hardened static random-access memory (SRAM).

As the telecommunication subsystem received commands, they were processed and routed over a MIL-STD-1553B bus to the appropriate instrument or engineering subsystem. There were two 1553B buses (for reliability and redundancy), but only one was active at a time. Each instrument or engineering subsystem had a bus interface unit (BIU) to receive commands from the computer and to send telemetry packets when requested. The 1553B bus was a mostly serial master bus, commanding and collecting data from only one instrument or engineering subsystem at a time, with the exception being broadcast messages, which were transmitted to all BIUs at the same time.

2.4.2.3.1 Solid-State Recorders

Two solid-state recorders (SSRs) handled data storage for the spacecraft, and each had approximately 2.2 gigabits of storage capacity. The SSRs had two functions, the primary one being to store the science and engineering telemetry until the data were downlinked to Earth. The second function was to store copies of the flight software for the attitude and articulation control subsystem (AACS), CDS, and the instruments. Each SSR was able to hold two different flight software loads for each instrument and the engineering computers. That allowed an instrument or the CDS or AACS to uplink and check out a new flight software load while still maintaining an older copy to fall back on if needed.

2.4.2.4 Attitude and Articulation Control Subsystem

The basic system architecture for the AACS flight computer was the same as the CDS. AACS also had a redundant MIL-STD-1553B bus and redundant IBM 1750A computers, called AACS flight computers (AFCs). The AFC received commands from and sent telemetry to the CDS EFC through a special BIU on the CDS buses. It used its own internal AACS 1553B bus to communicate with the sun sensors, stellar reference units (SRUs), IRUs, accelerometer, and the propulsion drive electronics. The AFCs had their own flight software and fault protection routines to always maintain proper attitude knowledge and control. The code was also in Ada, but larger than the EFC, with some 55,000 lines of code.

2.4.2.4.1 Attitude Determination

The prime sensor for attitude knowledge was the SRU, which had a catalog of 3,700 stars that identified up to five of the brightest stars in the field of view at any given time. The SRU was located 90° away from the optical remote sensing platform, on the +X spacecraft orientation. The SRU information was then fed every 5 seconds to the IRU, which propagated the inertial attitude between star updates. Should the SRU star updates be suspended, either by the ground or by some fault on

the spacecraft, the IRU was able to propagate the inertial attitude for many hours before needing a star update from the SRU. The backup, "failsafe" unit was the sun sensor. The two sun sensors were located in cutout holes in the high-gain antenna. The sun sensor was used for initial Sun acquisition and in certain fault protection situations. Should attitude knowledge be lost for any reason, the spacecraft would try to find the Sun and center on it, then it would try to reestablish attitude knowledge.

2.4.2.4.2 Attitude Control

There were two modes of operation for attitude control. One was using the reaction control subsystem (RCS), which used small 1-Newton thrusters to control attitude. The attitude on each axis was allowed to drift within a small range called the "deadband." If the spacecraft's attitude drifted to the edge of that deadband, thrusters would fire to push the spacecraft's attitude back toward its ideal attitude. A typical deadband range was ±2 milliradians. Thrusters provided fairly coarse control of the spacecraft—it was effective for downlink and for large directional instrument control, but not the best for producing good images. For finer control, the spacecraft used three reaction wheel assemblies (RWAs). Each RWA was aligned to be roughly 120° apart and was not co-aligned with the spacecraft X-, Y-, and Z-axes, but rather between any two axes. The RWAs were capable of maintaining a spacecraft attitude to within 40 micro-radians at any given time. In other words, about 50 times finer precision than the thruster system. Now and then, because the RWAs adjusted the spacecraft's attitude by spinning at a higher or lower rate, one or another of the RWAs would become "saturated," or spin excessively fast. To restore the RWAs to a healthier and more useful spin rate, the thrusters held the spacecraft's attitude while the RWAs spun down in a process called "desaturation."

Thrusters provided fairly coarse control of the spacecraft—it was effective for downlink and for large directional instrument control, but not the best for producing good images.

2.4.2.4.3 Propulsive Maneuvers / Trajectory Correction Maneuvers

The AACS used the 445 Newton main engines for all maneuvers with a change in velocity over 0.5-meters per second. The bipropellant system is described below in the propulsion section. Cassini's largest maneuver was the SOI maneuver. With a velocity change of 626 meters per second, the burn used about 27 percent of the total 3,132 kilograms of bipropellant loaded at launch. The main engine gimbals controlled only pitch and yaw direction during actual burns, while the RCS thrusters controlled roll. For very small maneuvers, only the RCS thrusters were used instead of the main engine.

2.4.2.5 Propulsion Subsystem

The propulsion subsystem had two independent systems, the bipropellant and the monopropellant subsystems. The bipropellant system was used strictly for large maneuvers, as described above.

2.4.2.5.1 Bipropellant Subsystem

The bipropellant subsystem consisted of the bipropellant tanks and plumbing to the 445-Newton rocket engine assemblies, also known as the main engines. The bipropellant design used monomethyl hydrazine (MMH) as fuel and nitrogen tetroxide (NTO) as the oxidizer. The separate propellant tanks were pressurized by a common helium system. The plumbing was designed after the Mars Observer loss, and used an extensive pyrotechnic valve ladder configuration to isolate the NTO from the MMH side. The high-pressure helium could also be isolated from both fuel and oxidizer tanks using additional pyro-activated valves. The pyro ladder was used multiple times in flight to pressurize and isolate the NTO tank.

2.4.2.5.2 Monopropellant Subsystem

The monopropellant system was a hydrazine 1-Newton thruster design. Cassini had four thruster clusters on the lower equipment module, each containing two Z–axis facing and two X-axis facing thrusters, for a total of 16 thrusters. Only one thruster in each axis on each cluster was used at a time, the other two were redundant. The thrusters fired in pairs, with the Z-facing thruster used for pitch and yaw control, and the Y-facing thrusters for roll control.

2.4.2.6 Telecommunications Subsystem

The Cassini spacecraft communicated with Earth via an X-band downlink and X-band uplink to and from NASA's Deep Space Network (DSN). The DSN has three main complexes—one near Madrid, Spain, one near Canberra, Australia, and one near Barstow, California. As Earth rotates, at least one of the complexes was able "see" Cassini at any given time. The DSN uses either 34-meter or 70-meter antennas for communication with interplanetary spacecraft, and on a typical day Cassini was allocated a 9-hour DSN pass on one of those antennas. In other words, the spacecraft was transmitting to Earth, and Earth was transmitting to Cassini, for about 9 hours at a time on any given day.

2.4.2.6.1 Antennas

Cassini had three communication antennas. The 4-meter high-gain antenna was used for high-rate telemetry and commanding. Low-gain antenna-1 was located on top of the high-gain antenna and was used for emergency links. A second low-gain antenna, low-gain antenna-2, was located below the Huygens probe and was used extensively for inner cruise communication, when the high-gain antenna was being used as a sunshade and so could not point at Earth without the spacecraft being exposed to dangerously intense sunlight.

2.4.2.6.2 Uplink/Downlink

Commands were routed from JPL to the DSN and uplinked to Cassini via the X-band carrier. The uplink power from the DSN was usually 18 kilowatts. The command uplink rate was from 7.8125 bits per second (bps) over the low-gain antenna to 500 bps over the high-gain antenna. A 20-watt X-band amplifier powered the downlink carrier. The downlink telemetry rate was 5 bps over the low-gain

antenna. Over the high-gain antenna, the bit rate was variable, from 1896 bps up to 165 kilobits per second (kbps). The highest telemetry rates were available only by using the DSN's 70-meter stations.

2.4.2.6.3 Navigation

The downlink carrier was normally made coherent with the uplink carrier to get a two-way Doppler signal. To be coherent, the receiver must lock on the uplink signal, then downlink an exact 880/749 multiple of the uplink carrier. The two-way Doppler signal was used for accurate navigation. The DSN was able to also add ranging or other "tones" on the uplink to obtain radio-metric tracking data for navigation.

2.4.2.7 Thermal Control Subsystem

The thermal control subsystem was distributed all around the spacecraft, using both active and passive components. The spacecraft was covered with thermal multi-layer insulation blankets. The blankets were either gold, from a gold-colored Kapton layer, or black from a black Kapton layer.

Each instrument had its own replacement heater that was normally used when the instrument was turned off. Some of the more isolated instruments had supplemental heaters all designed to keep the electronics within certain temperature limits. The electronics in the 12-bay structure, the upper equipment module, and the propellant control assembly also had supplemental heaters as needed.

The larger heat generators, such as CDS, the Ku-band radar, Radio Frequency Instrument S-band, Ka-band, and X-band amplifiers, all had thermostat-controlled louvers on the outside to actively cool the electronics.

2.4.2.8 Onboard Fault Protection

Because of the billion-plus kilometers between Saturn and Earth, a radio signal from Cassini sometimes took more than an hour to reach Earth. If the spacecraft reported that something had gone wrong (a short-circuit, unusually extreme temperatures in the spacecraft, etc.), it would take an additional hour-plus for commands from the ground to travel the distance back to Cassini. Due to that time-lag, along with the complex nature of spacecraft events, the onboard computers had special sequences that functioned as system fault-protection routines.

Each subsystem had some hardware fault-protection built in, but the system-level fault protection was in the flight software loaded into the CDS EFCs. There were a number of system-level routines that were able to execute a response to any of several monitors if needed. The core system fault protection routine was known as spacecraft safing. Safing refers, literally, to keeping the spacecraft safe for a period of time until the ground is able to intervene. The main purpose of these routines was to establish a safe power-level, attitude reference and attitude control, and a robust telecommunication link to Earth.

2.4.3 HUYGENS PROBE OVERVIEW

The Huygens probe system included the probe itself, which entered the Titan atmosphere, and support equipment that remained attached to the orbiter after the release of the probe. The probe weighed 320 kilograms and consisted of three main elements (see Figure 2.4-3):

1. A **spin-eject device, which was part of the support equipment**, used springs to propel the probe away from the orbiter with a relative velocity of about 0.3 to 0.4 meter per second and simultaneously caused the probe to spin about its axis at 7 revolutions per minute.

2. A **front shield**, 2.7 meters in diameter, protected the probe from the enormous heat generated during entry into Titan's atmosphere. The shield was covered with a special thermal-protection material called AQ60—a low-density mat of silica fibers.

3. An **aft cover** used thermal-protection materials to ensure a slow and stable descent. Its main parachute slowed the probe and allowed the decelerator to fall away when it was released. To limit the duration of the descent to a maximum of 2.5 hours, the main parachute was jettisoned at approximately 900 seconds after atmospheric entry, and was replaced by an approximately 3-meter diameter drogue chute for the remainder of the descent.

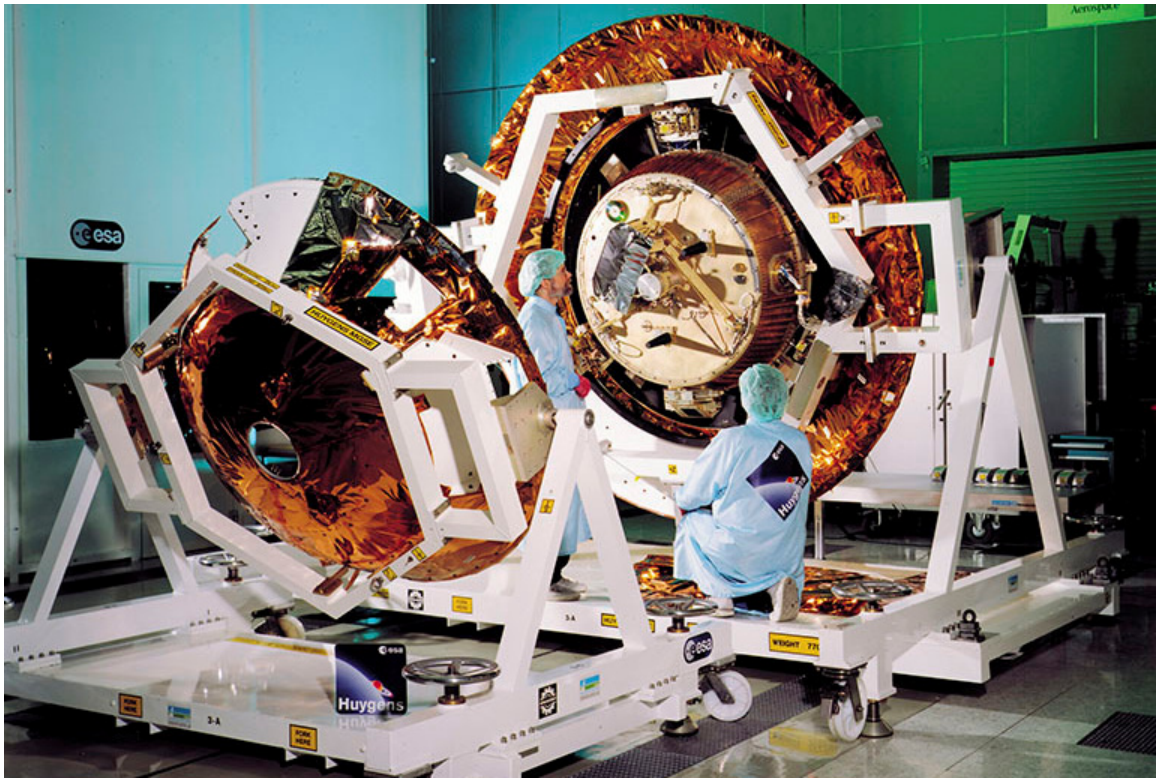

Figure 2.4-3. The Huygens probe during assembly. Image courtesy of the European Space Agency.

The probe's interior consisted of two aluminum honeycomb platforms and an aluminum shell. It was linked by fiberglass struts and pyrotechnically operated release mechanisms to the front shield and aft cover. The central equipment platform carried the boxes containing the electrical subsystems and science experiments. The upper platform carried the stowed parachute and the transmitter used to radio data to the Cassini spacecraft via the microwave S-band.

At different phases of the mission, the Huygens probe was subject to extreme changes of heat and cold requiring a variety of passive controls to maintain the required temperature conditions. When Cassini left the inner solar system, the temperature environment of the probe was greatly reduced. After separation from the Cassini spacecraft, the Huygens probe was at its coldest. To ensure that the equipment stayed operational, 35 radioisotope heater units were placed in the system. Each heater unit contained radioactive plutonium dioxide and produced about 1 watt of heat.

During entry into Titan's atmosphere, the front shield reached temperatures above 1,500° Celsius. Layers of insulation in the probe ensured that the equipment inside stayed below 50° Celsius. Once the chutes were deployed, the probe instruments were exposed to the cold Titan atmosphere at a temperature of approximately −200° Celsius. The probe's internal temperature was kept within operating limits by a thick foam insulation filling the probe and by power dissipation in the experiments and subsystems.

When still attached to the Cassini spacecraft, the probe obtained power from the spacecraft via an umbilical cable. After separation, five lithium-sulfur dioxide batteries provided electrical power, each with 23 cells. A small part of the battery power was used by the Huygens probe's timer for the 21-day coast to Titan.

The Huygens probe's command and data management subsystem controlled the timing and execution of a number of critical events, including the following:

1. Kept time during the coast phase and switched on the probe just before atmospheric entry.

2. Controlled the deployment of various components during descent.

3. Distributed commands to other subsystems and to the experiments.

4. Distributed to the experiments a timeline of conditions that instruments were able to use to schedule operations.

5. Collected scientific and engineering data and forwarded the data to the spacecraft during the cruise to Saturn and during the Huygens mission.

The probe data-relay subsystem provided the one-way communications link between the Huygens probe and the Cassini spacecraft, and included equipment installed in the probe and in the spacecraft. Elements that were part of the probe's support equipment on the Cassini spacecraft included radio-frequency electronics (including an ultra-stable oscillator, USO) and a low-noise

amplifier. For backup, the Huygens probe carried two S-band transmitters, both of which transmitted data during probe descent; each had its own antenna.

2.4.3.1 Huygens Probe Instruments

The Huygens descent probe contained a total of six science instruments, which are shown in Figure 2.4-4 and briefly described below:

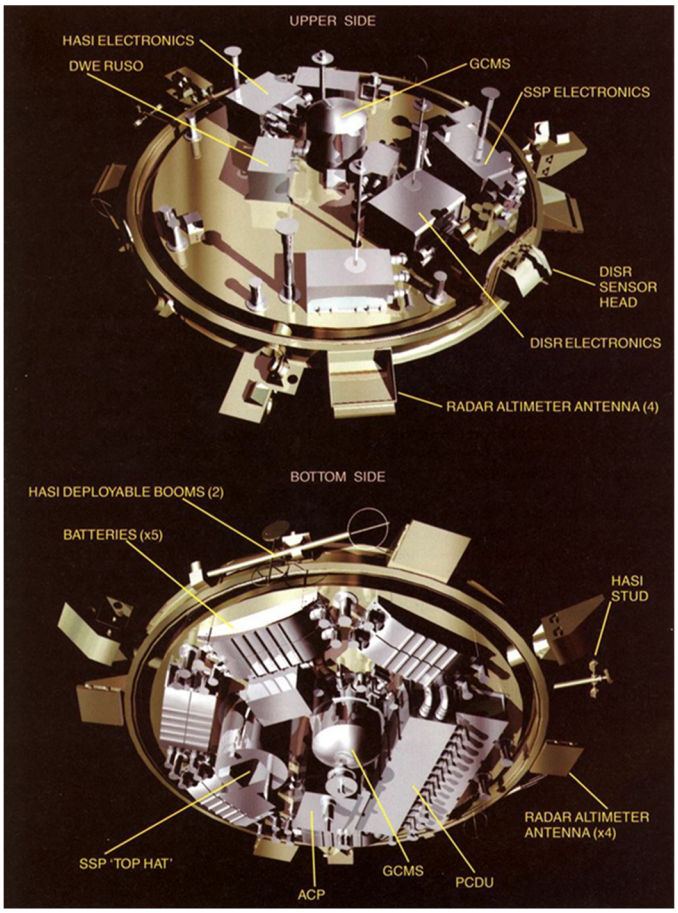

Figure 2.4-4. Huygens probe instruments.

1. **Descent Imager/Spectral Radiometer (DISR).** The imager/spectrometer used 13 fields of view, operating at wavelengths of 350 to 1,700 nanometers, to obtain a variety of imaging and spectral observations: Infrared and visible imagers were used to observe Titan's surface during the latter stages of the descent. By taking advantage of the Huygens probe's rotation, the imagers were able to build a mosaic of pictures around the landing site. A side-looking visible imager was able to view the horizon and the underside of the cloud deck. The spectral radiometer measured concentrations of argon and methane in the atmosphere. It also determined that the

local surface was solid and studied its topography. Solar aureole sensors measured the light intensity around the Sun resulting from scattering by particles suspended in the atmosphere, permitting calculations of their size, number and density. The PI for DISR was Dr. Martin G Tomasko of the University of Arizona, Tucson.

2. **Huygens Atmospheric Structure Instrument (HASI).** This instrument investigated the physical properties of Titan's atmosphere, including temperature, pressure, and atmospheric density as a function of altitude, wind gusts, and liquid surface wave motion. Comprising a variety of sensors, the instrument also measured the ion and electron conductivity of the atmosphere and searched for electromagnetic wave activity. On Titan's surface, the instrument was able to measure the conductivity of surface materials. The instrument also processed the signal from the Huygens probe's radar altimeter to obtain information on surface topography, roughness and electrical properties. The PI for HASI was Dr. Marcello Fulchignoni of the Paris Observatory, Meudon, France.

3. **Aerosol Collector and Pyrolyzer (ACP).** The collector and pyrolyzer instrument trapped particles suspended in Titan's atmosphere using a deployable sampling device. Samples were heated to vaporize the ice particles and decompose the complex organic materials into their component chemicals. The products were then passed to the gas chromatograph/mass spectrometer for analysis. The instrument obtained samples at two altitude ranges. The first sample was taken at altitudes down to about 30 km above the surface. The second sample would be obtained at an altitude of about 20 km. The PI for ACP was Dr. Guy M. Israel of the Service d'Aeronomie du Centre National de la Recherche Scientifique, Verrieres-le-Buisson, France.

4. **Gas Chromatograph Mass Spectrometer (GCMS).** This spectrometer provided a quantitative analysis of Titan's atmosphere. Atmospheric samples were transferred into the instrument by dynamic pressure as the Huygens probe descended through the atmosphere. The mass spectrometer constructed a spectrum of the molecular masses of the gas sampled by the instrument. Just before landing, the instrument's inlet port was heated to vaporize material on contact with the surface. After landing, the instrument was able to determine Titan's surface composition. The mass spectrometer served as the detector for the gas chromatograph, for atmospheric samples, and for samples provided by the aerosol collector and pyrolyzer. The PI for GCMS was Dr. Hasso B. Neimann of NASA's Goddard Space Flight Center, Greenbelt, Maryland.

5. **Doppler Wind Experiment (DWE).** The wind instrument used two ultra-stable oscillators—one on the Huygens probe and one on the Cassini spacecraft—to give the Huygens' radio relay link a stable carrier frequency. Spacecraft measurements of changes in probe frequency caused by Doppler shift provided information on the probe's motion. From this, scientists were able to derive a height profile of wind and its turbulence. The PI for the DWE was Dr. Michael K. Bird of the University of Bonn, Germany.

6. **Surface Science Package (SSP).** This instrument contained a number of sensors to determine the physical properties and composition of Titan's surface. An acoustic sounder measured the rate of descent, surface roughness, and the speed of sound in any fluid. During descent, measurements of the speed of sound provided information on atmospheric composition and temperature. An accelerometer recorded the deceleration profile at impact, indicating the hardness of the surface. Tilt sensors (liquid-filled tubes with electrodes) measured any pendulum motion of the Huygens probe during descent, indicated the Huygens probe orientation after landing, and measured any wave motion. Other sensors measured the surface's density, temperature, refractive index, thermal conductivity, heat capacity, and electrical properties. A group of platinum resistance wires, through which a heating current was passed, measured temperature and thermal conductivity of the surface and lower atmosphere and the heat capacity of the surface material. A transducer, pointed downward and operating at 15 KHz, conducted an acoustic sounding of the liquid's depth. The instrument provided a crude topographic mapping of the surface as the probe descended the last few meters through the atmosphere. The PI for SSP was Dr. John C. Zarnecki of the University of Kent, England.

2.4.4 INSTRUMENTS PAYLOAD OVERVIEW

The Cassini spacecraft carried a total of 12 science instruments, four of which were on the remote sensing experiments pallet, and three of which were on the fields and particles experiments pallet. The other five instruments were fixed at independent locations on the spacecraft. The science instruments are listed and their measurement objectives described in this section. For eight of these instruments, a PI and co-investigators were responsible for their corresponding instrument, as well as for their scientific investigation. The other four instruments were designated as "facility instruments"; these instruments were built at JPL and were used by a Cassini science team. Facility instrument science teams had team leaders rather than PIs.

Following are the PI-led instruments:

1. Cassini Plasma Spectrometer (CAPS)
2. Composite Infrared Spectrometer (CIRS)
3. Cosmic Dust Analyzer (CDA)
4. Ion and Neutral Mass Spectrometer (INMS)
5. Magnetometer (MAG)
6. Magnetospheric Imaging Instrument (MIMI)
7. Radio and Plasma Wave Science (RPWS)
8. Ultraviolet Imaging Spectrograph (UVIS)

Following are the facility instruments:

1. Imaging Science Subsystem (ISS)
2. RADAR
3. Radio Science Subsystem (RSS)*
4. Visible and Infrared Mapping Spectrometer (VIMS)

Note: The INMS was developed as a facility instrument by NASA's Goddard Space Flight Center but was operated as a PI instrument (see Section 2.5.8.2).

2.4.4.1 Optical Remote Sensing Instruments

Cassini was equipped with a set of in situ instruments for studying the environment in the immediate vicinity of the spacecraft (e.g., magnetometers, plasma instruments, cosmic dust analyzer), as well as a set of instruments that studied targets from afar (visible and infrared cameras, spectrometers, etc.) called optical remote sensing instruments (ORS). The ORS instruments were mounted on the remote sensing pallet (RSP) rigidly attached to the upper equipment module (UEM), shown in Figure 2.4-5. These instruments measured properties of targets at a distance and included: CIRS, ISS, UVIS, and VIMS.

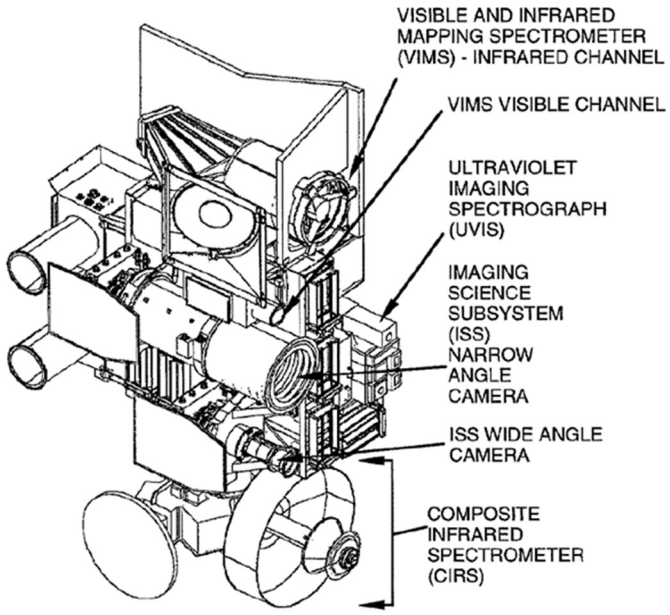

Figure 2.4-5. Remote sensing pallet.

* The RSS was not an instrument, but rather a scientific experiment, which used the capabilities of the radio frequency (RF) subsystem (or telecommunications (telecom) subsystem) onboard the spacecraft to accomplish its science objectives.

Mounted on the RSP, these instruments studied Saturn and its rings and moons in the electromagnetic spectrum:

Composite Infrared Spectrometer (CIRS). The infrared spectrometer functioned as a remote-sensing thermometer. It captured infrared emissions from atmospheres, rings, and surfaces. The instrument then split the light into its component wavelengths (or colors) and then measured the strength of the light at each of those wavelengths primarily to measure the temperature of objects. It also determined the chemical composition of the targets because molecules leave different "fingerprints"—they preferentially absorb and emit infrared radiation at different specific wavelengths in the spectrum. In other words, their presence shows up as different lines in the spectrum.

By analyzing an object's light with a spectrometer, the science community can determine its temperature and some of the materials it is made of. When pointed at Saturn's atmosphere, for example, a spectrometer would reveal a series of bright lines indicating that the spectrometer observed methane gas.

CIRS instrument characteristics:

- Mass (current best estimate) = 39.24 kg
- Peak operating power (current best estimate) = 32.89 W
- Average operating power (current best estimate) = 26.37 W
- Peak data rate (current best estimate) = 6.000 kilobits/sec
- Dimensions (approximate) = 50 cm diameter telescope; 89 × 76 × 52 cm

The PI for CIRS was Dr. Michael Flasar of NASA's Goddard Space Flight Center, Greenbelt, Maryland.

Imaging Science Subsystem (ISS). Cassini's visible-light cameras provided unparalleled images of Saturn, the rings, Titan and the icy moons for various scientific purposes. It would be challenging to overstate how spectacular the images produced by this instrument were. Its images remain iconic (some more than a decade after they were taken) both among the public and among the people who worked on the mission. Yet it was, in both intent and use, a science instrument.

The ISS was one of the facility instruments built at JPL, and one of the six instruments destined to perform scientific investigations of the Saturnian system from a range of remote observing distances. It was also used for optical navigation in order to improve the navigation team's knowledge of the spacecraft's trajectory. The optical navigation method used the known positions of Saturn's moons along with a map of the stars to determine the spacecraft's position based on the images taken of Saturn's moons with stars in the background.

The ISS instrument was composed of two cameras, a wide-angle camera (WAC) and a narrow-angle camera (NAC). Each had its own electronics, detectors, optics, filters wheels, and shutters.

Both were sensitive to visible wavelengths of light and to some infrared and ultraviolet wavelengths. The ISS included spectral filters and imaging capabilities that aided in the attainment of spectacular images of Saturn, its rings, and its numerous icy and rocky moons. In the process, the instrument satisfied several scientific objectives. It studied the contents of Saturn's and Titan's atmospheres, the surfaces of Saturn's moons, and the characteristics and composition of Saturn's rings.

The NAC was a reflecting telescope with a focal length of 2,000 millimeters and a field of view of 0.35°. The WAC was a refractor with a focal length of 200 millimeters and a field of view of 3.5°. Each camera was equipped with a large number of spectral filters which, when used together, spanned the electromagnetic spectrum from 2,000 Angstroms to 1.1 microns. Each of the cameras contained a detector that consisted of a 1,024-square array of pixels each 12 microns. In other words, each of Cassini's cameras was a one mega-pixel camera. The combined spacecraft and instrument data system allowed many options for data collection, including data compression, a method that allowed instrument data reduction to be stored onboard the spacecraft and played back to Earth and expanded to the original set of data collected by the instrument.

Each camera was equipped with a large number of spectral filters which, when used together, spanned the electromagnetic spectrum from 2,000 Angstroms to 1.1 microns.

The WAC captured comprehensive and detailed images of Saturn and its rings from more than 1.5 million kilometers away, and the NAC provided high-resolution images of specific targets, such as craters or fractures on the surfaces of Saturn's moons.

ISS instrument characteristics:

- Wide-angle camera (20 cm f/3.5 refractor; 380–1,100 nm; 18 filters; 3.5° × 3.5°)
- Narrow-angle camera (2 m f/10.5 reflector; 200–1,100 nm; 24 filters; 0.35° × 0.35°)
- Mass (current best estimate) = 57.83 kg
- Peak operating power (current best estimate) = 55.90 W
- Peak data rate (current best estimate) = 365.568 kilobits/sec
- Dimensions (approximate) = 95 × 40 × 33 cm (NAC); 55 × 35 × 33 cm (WAC)

The team leader for ISS was Dr. Carolyn C. Porco of Space Science Institute (SSI) Denver, Colorado.

Ultraviolet Imaging Spectrograph (UVIS). The spectrograph was a set of detectors designed to measure ultraviolet light reflected by or emitted from atmospheres, rings, and surfaces to determine their compositions, distributions, aerosol content, and temperatures. The instrument also measured fluctuations of sunlight and starlight as the Sun and other stars move behind the

rings of Saturn and the atmospheres of Saturn and Titan, and determined the atmospheric concentrations of hydrogen and deuterium.

The instrument included a two-channel, far-ultraviolet and extreme-ultraviolet imaging spectrograph that studied light over wavelengths from 55.8 to 190 nanometers. It also had a hydrogen and deuterium absorption cell and a high-speed photometer. An imaging spectrograph recorded spectral intensity information in one or more wavelengths of light and then outputted digital data that could be displayed in visual form, such as a false-color image. False-color images are not what the eye would see, but are often more useful because enhanced contrast brings out scientifically meaningful details. The hydrogen-deuterium absorption cell measured the quantity of deuterium, a heavier form (isotope) of hydrogen. Hydrogen-deuterium ratio varies widely throughout the solar system and is an important piece of data in understanding planetary evolution. The high-speed photometer determined the radial structure of Saturn's rings by watching starlight that passed through the rings. The PI for UVIS was Dr. Larry L. Esposito of the University of Colorado, Boulder.

Visible and Infrared Mapping Spectrometer (VIMS). The infrared spectrometer mapped the surface spatial distribution of the mineral and chemical features of a number of targets, including Saturn's rings, surfaces of the moons, and the atmospheres of Saturn and Titan. The instrument included a pair of imaging grating spectrometers that were designed to measure reflected and emitted radiation from atmospheres, rings, and surfaces to determine their compositions, temperatures, and structures. A spectrometer is an optical instrument that splits the light received from objects into its component wavelengths; each chemical has a unique spectral signature and thus can be identified. The instrument obtained information over 352 contiguous wavelengths from 0.35 to 5.1 micrometers; it measured intensities of individual wavelengths and used the data to infer the composition and other properties of the object that emitted the light. The mapping function of the instrument provided images in which every pixel contained high-resolution spectra of the corresponding spot on the target body. The team leader for VIMS was Dr. Robert H. Brown of the University of Arizona, Tucson.

2.4.4.2 Fields, Particles, and Waves In Situ Instruments

The fields, particles, and waves (FPW) instruments were mounted in several locations on the spacecraft. The MAG sensors were located on the extensible magnetometer (MAG) boom, attached to the top of the upper equipment module. A small pallet, also mounted on the upper equipment module, carried INMS, MIMI Lower Equipment Module (LEMMS) and Change-Energy-Mass Spectrometer (CHEMS), and CAPS. MIMI Ion and Neutral Camera (INCA), CDA, and the RPWS antennas and Magnetic Search Coils (MSC) were attached elsewhere on the Upper Equipment Module. (Note: MIMI INCA imaged the charged particle population of Saturn's magnetosphere, but despite being a remote sensing instrument rather than an in situ instrument, we included it in this section because it was part of the MIMI instrument and moving it elsewhere might have created confusion.) Figure 2.4-6 depicts the remote sensing pallet and fields and particles pallet.

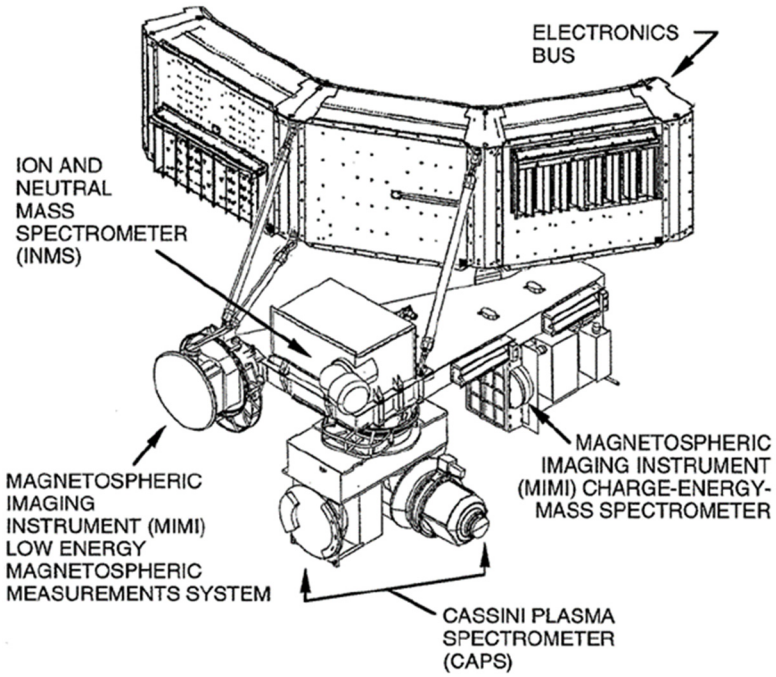

Figure 2.4-6. Remote sensing pallet and fields and particles pallet.

Following is an overview description for each of the FPW instruments.

Cassini Plasma Spectrometer (CAPS). The plasma spectrometer measured the composition, density, flow velocity, and temperature of ions and electrons in Saturn's magnetosphere. CAPS consisted of three sensors: an electron spectrometer, an ion beam spectrometer, and an ion mass spectrometer. A motor-driven actuator rotated the sensor package to provide 208° scanning in the azimuth of the Cassini orbiter. The electron spectrometer performed measurements of the energy of incoming electrons; its energy range was 0.7 to 30,000 electron volts. The ion beam spectrometer determined the energy-to-charge ratio of an ion; its energy range was 1 electron volt to 50 kilo-electron volts. The ion mass spectrometer's energy range was 1 electron volt to 50 kilo-electron volts. The PI for CAPS was Dr. David T. Young of the Southwest Research Institute (SwRI), San Antonio, Texas.

Cosmic Dust Analyzer (CDA). The dust analyzer provided direct observations of small ice or dust particles in the Saturn system to investigate their physical, chemical, and dynamic properties, and to study their interactions with the rings, icy moons, and magnetosphere of Saturn. The instrument measured the amount, velocity, charge, mass, and composition of tiny dust and ice particles. It had two types of sensors—high-rate detectors and a dust analyzer. The two high-rate detectors, intended primarily for measurements in Saturn's rings, counted up to 10,000 impacts per second. The dust analyzer determined the electric charge carried by dust particles, the flight direction and impact speed, mass and chemical composition, at rates up to 1 particle per second, and for speeds of up to about 100 km per second. An articulation mechanism allowed the entire instrument to be rotated or repositioned relative to the body of the Cassini orbiter to investigate

dust particles traveling from specific directions. The PI for CDA was Dr. Ralf Srama of the Max Planck Institute fur Kernphysik, Heidelberg, Germany.

Ion and Neutral Mass Spectrometer (INMS). This spectrometer determined the composition and structure of positive ions and neutral particles in the upper atmosphere of Titan and the magnetosphere of Saturn, and measured the positive ion and neutral environments of Saturn's icy moons and rings. The instrument determined the chemical, elemental, and isotopic composition of the gaseous and volatile components of the neutral particles and the low energy ions in Titan's atmosphere and ionosphere, Saturn's magnetosphere and the ring environment. The PI for INMS was Dr. J. Hunter Waite of SwRI, San Antonio, Texas.

Magnetometer (MAG). Cassini's magnetometer consisted of direct-sensing instruments that detected and measured the strength of magnetic fields in the vicinity of the spacecraft. MAG determined the magnetic fields of the planet and moons and studied dynamic interactions between different magnetic fields in the planetary environment. The instrument included both a flux gate magnetometer and a vector/scalar helium magnetometer. They were used to measure the magnitude and direction of magnetic fields. Since magnetometers are sensitive to electric currents and ferrous metal components, they were placed on an extended boom, as far from the spacecraft as possible. On Cassini, the flux gate magnetometer was located midway out on the 11-meter magnetometer boom, and the vector/scalar helium magnetometer was located at the end of the boom. The boom itself, composed of thin, nonmetallic rods, was folded during launch and deployed about two years after launch. The magnetometer electronics were located in a bay in the Cassini orbiter's spacecraft body. The PIs for MAG were Dr. David J. Southwood and Dr. Michel Dougherty of the Imperial College of Science and Technology, London, England.

Magnetospheric Imaging Instrument (MIMI). This instrument was designed to measure the composition, charge state, and energy distribution of energetic ions and electrons; detect fast neutral particles; and conduct remote imaging of Saturn's magnetosphere. MIMI was the first instrument ever designed to produce an image of a planetary magnetosphere. This information was used to study the overall configuration and dynamics of the magnetosphere and its interactions with the solar wind, Saturn's atmosphere, Titan, rings and the icy moons. The instrument provided images of the ionized gases, called plasma, surrounding Saturn and determined the charge and composition of ions. Like the Cassini plasma spectrometer, this instrument had three sensors that performed various measurements: the low-energy magnetospheric measurement system, the charge-energy-mass spectrometer, and the ion and neutral camera. The low-energy magnetospheric measurement system measured low- and high-energy proton, ion, and electron angular distributions (the number of particles coming from each direction). The charge-energy-mass spectrometer used an electrostatic analyzer, a time-of-flight mass spectrometer, and microchannel plate detectors to measure the charge and composition of ions. The third sensor, the ion and neutral camera, performed two different types of measurements. It obtained three-dimensional distributions, velocities and the rough composition of magnetospheric and interplanetary ions. PIs for MIMI were Dr. Stamatios M. Krimigis and Dr. Mitchel Donald of Johns Hopkins University, Baltimore, Maryland.

Radio and Plasma Wave Science (RPWS). This instrument measured electrical and magnetic fields in the plasma of the interplanetary medium and Saturn's magnetosphere, as well as electron density and temperature. Plasma is essentially a soup of free electrons and positively charged ions, the latter being atoms that have lost one or more electrons. Plasma makes up most of the universe and is created by the heating of gases by stars and other bodies in space. Plasma is distributed by the solar wind; it is also "contained" by magnetic fields (that is, the magnetospheres) of bodies such as Saturn and Titan. The major components of the instrument were an electric field sensor, a magnetic search coil assembly and a Langmuir probe. The electric field sensor was made up of three deployable antenna elements mounted on the upper equipment module of the Cassini spacecraft. Each element was a collapsible beryllium-copper tube that was rolled up during launch and subsequently unrolled to its approximately 10-meter length by a motor drive. The magnetic search coils were mounted on a small platform attached to a support for Cassini's high-gain antenna. The Langmuir probe, which measured electron density and temperature, was a metallic sphere about 50 millimeters in diameter. The probe was attached to the same platform by an approximately 1-meter deployable boom. PIs were Dr. Donald A. Gurnett and Dr. William Kurth of the University of Iowa, Iowa City.

Plasma makes up most of the universe and is created by the heating of gases by stars and other bodies in space.

2.4.4.3 Microwave Sensing Instruments

Cassini carried two microwave sensing instruments: The Titan Radar Mapper (RADAR) and the RSS.

The RADAR instrument investigated the surface of Saturn's largest moon, Titan, whose surface is covered by a thick, cloudy atmosphere that hides the moon's surface in normal optical views, but can be penetrated by radar. The instrument was based on the same imaging radar technology used in missions such as the Magellan mission to Venus and the Earth-orbiting Spaceborne Imaging Radar.

The instrument was composed of the following subsystems: the radio frequency electronics subsystem (RFES), the digital subsystem (DSS), the energy storage subsystem (ESS), and the Antenna Subsystem. The DSS and ESS were located in one of the equipment bays below the high-gain antenna. RFES was in a penthouse-like attachment over the bay. The principal component of the antenna subsystem was the five-beam Ku-band high-gain antenna feed. RADAR shared the high-gain antenna with the RSS for both its active (synthetic aperture radar imaging and altimetry) and passive (radiometry) operations.

The radar was able to take four types of observations: imaging, altimetry, backscatter and radiometry. In imaging mode, the instrument bounced pulses of microwave energy off the surface of Titan from different incidence angles and recorded the time it took the pulses to return to the

spacecraft. These measurements, converted to distances by dividing by the speed of light, allowed construction of visual images of the target surface with a resolution ranging from about 0.3 to 1.7 km.

RADAR altimetry used a similar approach, bouncing microwave pulses off the target body's surface and measuring the time it took the "echo" to return to the spacecraft. In this case, however, the goal was not to create visual images but rather to obtain numerical data on the precise altitude of surface features. The altimeter resolution was about 24 to 27 km horizontally, and 90 to 150 meters vertically.

In backscatter mode, the radar bounced pulses off Titan's surface and measured the intensity of the energy returning. This returning energy, or backscatter, was always less than the original pulse, because surface features reflected the pulse in countless directions, with only a fraction of the original pulse returning to Cassini where the high-gain antenna collected the signal. Scientists drew conclusions about the composition and roughness of the surface from the backscatter measurements.

In radiometry mode, the radar operated as a passive instrument, simply recording the heat energy emanating from the surface of Titan (everything that's not at zero Kelvin emits some radio signal). This information was used to determine the amount of heat absorption by gases and aerosols (such as methane) in Titan's atmosphere, a factor that affected the accuracy of the other measurements taken by the instrument.

The radar was used in different ways at different altitudes. At altitudes between about 22,500 to 9,000 km, the radar switched between scattering measurements and radiometry to obtain low-resolution global maps of Titan's surface roughness, backscatter intensity, and thermal emissions. At altitudes between about 9,000 to 4,000 km, the instrument switched between altimetry and radiometry, collecting surface altitude and thermal emission measurements. Below about 4,000 km, the radar switched between imaging and radiometry. The radar team leader was Dr. Charles Elachi of NASA's Jet Propulsion Laboratory, Pasadena, California.

The RSS "instrument" (experiment) used the spacecraft's radio (telecom) subsystem and the ground antennas of NASA's DSN to study the composition, pressures and temperatures of the atmospheres and ionospheres of Saturn and Titan. RSS also studied the radial structure of and particle size distribution in Saturn's rings, as well as the masses of objects in the Saturn system and the mass of Saturn's ring system as a whole. Radio science also helped search for gravitational waves coming from beyond the solar system. Some of these experiments measured Doppler shifts (frequency shifts) and other changes to radio signals when the spacecraft passed behind planets, moons, atmospheres, or physical features such as planetary rings. From those measurements, scientists derived information about the structures and compositions of the occulting bodies, atmospheres, and rings.

The RSS was composed of elements located in the DSN (part of the ground system) and onboard the spacecraft. The flight RSS instrument consisted of the radio frequency instrument subsystem (RFIS) and elements of the RFS. The main assemblies of the RFIS were the Ka-band

exciter, the Ka-band traveling wave tube amplifier, the Ka-band translator, and the S-band transmitter. In addition, the high-gain antenna was used as part of the RSS instrument to receive the X- and Ka-band signals and to transmit at X-, Ka-, and S-bands. The RSS team leaders were Dr. Arvydas J. Kliore of NASA's Jet Propulsion Laboratory, Pasadena, California, and Dr. Richard French of Wellesley College, Massachusetts.

2.5 Mission Operations System Description (Functional Level)

Two-way communication with the Cassini spacecraft was established through the large dish antennas of the DSN. The spacecraft transmitted and received in the microwave X-band using its parabolic high-gain antenna, which was also used for radio and radar experiments and for receiving signals from the Huygens probe.

Because Cassini's science instruments were fixed to the spacecraft, and the entire spacecraft had to be turned to point them, Cassini was frequently reoriented by using either the reaction wheels or the spacecraft's set of small onboard thrusters. Consequently, most science observations were made without a real-time communications link to Earth. Data were stored on Cassini's two SSRs, each with a capacity of two gigabits.

Each of Cassini's science instruments was run by an instrument microprocessor capable of controlling the instrument and formatting/packetizing science and housekeeping data. Ground engineers controlled the orbiter with a combination of centralized commands to control system-level resources, and some commands issued by the individual science instruments' microprocessors. Packets of data were collected from each instrument on a schedule that varied. Typically, data packets were stored on Cassini's onboard SSRs for later transmission, though once in a while they were transmitted to Earth right away via a real-time transmission. The science instruments had different pointing requirements, which often conflicted with each other and with the need to point the spacecraft toward Earth to transmit data to the ground system. Periods during which the antenna pointed toward Earth were carefully built into the design of the sequence controlling the onboard activities.

Control of the spacecraft was done, for the most part, from autonomous sequences stored onboard the spacecraft. To conduct activities and maintain the health and safety of Cassini, spacecraft sequencing used a combination of centralized commands (for control of the system-level resources) and instrument commands issued by the CDS and the instrument microprocessors. Each instrument's microprocessor formatted that instrument's data (including editing or compression), and the CDS then collected the data on the spacecraft bus on a schedule determined by the active telemetry mode. Packets from the engineering subsystems and instruments were assembled into frames and stored on the SSR or inserted directly into the real-time downlink telemetry stream. Data were normally received by the DSN with one tracking pass by one antenna per day, with occasional extra coverage for special radio science experiments.

Engineering teams and science instrument teams monitored spacecraft telemetry and instruments to ensure a safe and healthy spacecraft. The navigation team processed the tracking data to determine and predict the spacecraft's trajectory.

The spacecraft provided system-level services for each of the 12 science investigations, including instrument command delivery, telemetry collection and transmission, spacecraft pointing and attitude stability, power, and thermal control. The spacecraft was flown with sufficient margins to allow the instruments to operate fairly independently from each other, and with a minimum of real-time ground intervention, but still allowed for collaborative, synergistic collection of data.

Following is a brief description of the teams that formed part of the Mission Operations System, also known as the Ground System.

2.5.1 MANAGEMENT

Project management was responsible for the execution of the Cassini Mission within the resource constraints (cost and schedule). Project management provided technical and programmatic leadership for all aspects of the project, except for science analysis and publications, which were the responsibility of the Cassini project science team. Cassini project management in coordination with the science planning and sequencing team (SPST) manager provided management of the day-to-day operation of the mission (including all flight and ground activities) as well as the planning for future operations.

Cassini project management directed and monitored progress of all MOS activities: mission planning, science planning and analysis, spacecraft planning and analysis, navigation, sequence development, real-time mission operations, data transport and delivery, science data processing, and data archiving. The Cassini Project Manager was the interface between the Cassini flight team and upper JPL management.

2.5.2 PROJECT SCIENCE

The project science team (the Project Scientist and the project science group) was responsible to the Cassini project management and NASA for ensuring that the science objectives of the Cassini mission were being fully met. The project science team was the representative of the Science Team in the day-to-day science activities and decision-making process.

2.5.3 MISSION PLANNING

Prior to launch, the mission planning team was responsible for documenting the Mission Plan. The Mission Plan was the principal reference for high-level descriptions of the Cassini Mission. It documented the interplanetary cruise and Saturn tour trajectories; high-level spacecraft and activity designs; operational strategies and options; and guidelines and constraints for mission operations. The Cassini Mission Plan served to guide the development of detailed event timelines from before

launch through end of mission and it evolved throughout the mission as a living document. The Mission Plan provided the following information:

- An overview of the Cassini Mission, including the spacecraft trajectory during cruise and tour, and a summary of the main events during the flight. It described the science objectives of the mission.
- Descriptions of the spacecraft, probe, instrument, and launch vehicle systems.
- Explanations of the primary operational strategies for the mission.
- Descriptions of the different mission phases.
- Documented mission-level guidelines and constraints, operational modes, and timelines for critical periods.

During operations the mission planning team was responsible for assessing adherence to the mission plan and maintaining and updating the plan. This included responding to unforeseen mission events (e.g., anomalies, idiosyncrasies, and new science requirements), determining the effects of those events on the mission objectives and requirements, and, when required, performing re-planning to accomplish the original objectives or to optimize them.

Specific mission planning activities during operations included:

- Analyzing implications of the actual flight trajectory to achieving the mission goals and objectives.
- Monitoring and evaluating ongoing mission events against mission goals and objectives.
- Monitoring, tracking, and assessing flight system (spacecraft and instruments payload) consumable resources usage against estimates for usage through the end of the mission. Consumable resources included propellant, hydrazine, power, data volume, etc.
- Developing contingency plans necessary to recover from a flight system anomaly or an unforeseen event.
- Developing new mission plans needed in response to new mission objectives.

2.5.4 SCIENCE PLANNING AND SEQUENCING

The SPST was part of the Science and Uplink (SAUL) Office. The SAUL Office was composed of the SPST, the instrument operations team, the Mission Sequencing System (MSS), and science system engineering.

During flight operations, the SPST was responsible for identifying science opportunities by evaluating spacecraft trajectory information, target-body ephemerides, and keep-out periods of time during which spacecraft engineering activities (e.g., spacecraft engineering subsystems

calibrations and orbit trim maneuvers (OTMs)) needed to take place. The science opportunities represented periods of time in the mission where science observations could be performed to achieve the mission's science objectives. The SPST coordinated these observation opportunities with the science teams and the Spacecraft Operations Office to ensure that they were in agreement with performing such observations during the selected times. After several iterations between the SPST, the science teams, and the Spacecraft Operations Office (SCO), an agreement was reached and an integrated science plan was put together by the SPST. Once the integrated science plan was approved by all involved teams, each science/instrument team and the SCO generated their corresponding subsequence files containing the corresponding set of commands for instruments and spacecraft subsystems activities. The SPST accessed these subsequence files and integrated them into a single background sequence. Once generated, the commands were expanded, constraint checked, and compiled by the SPST.

Specific science planning and sequencing activities during operations included:

- Generation of a fully integrated sequence of science events needed to meet the science objectives of the mission.
- Identification of science opportunities based on atmospheric, geological, magnetospheric, ring, and satellite objectives. Opportunities were ranked according to their importance relative to the mission's science objectives.
- Combination of science and instrument engineering inputs into a single, integrated science activity plan.
- Modification of the science activity plan to improve or optimize science return through the use of allocated ground resources (e.g., observation redesign, late updates, "tweaks," etc.) and spacecraft resources (e.g., observation duration, time between activities, etc.).
- Coordination of design observations needed to implement the science activity plan based on spacecraft capabilities and within mission guidelines and flight rules.
- Evaluation of the implementation of the science observation based on initial inputs.
- Ensured that no other activity degraded or inhibited the acquisition of the data.
- Generation and translation of commands (sequence and real-time) needed to implement the activity plan.

2.5.5 MISSION SEQUENCING SUBSYSTEM

The mission sequencing subsystem was part of the SAUL Office.

The MSS team was responsible for defining, creating, maintaining, and delivering the software applications used by the SPST. The MSS team created the requirements and the design for the software applications and then implemented and tested them after the requirements and design had been approved by SPST and the project.

The suite of applications included sequencing and planning software tools that supported the SPST during the execution of the uplink process. Many of the applications were used on previous flight projects and were modified to meet the Cassini requirements. Some of those applications can be traced back more than 25 years. Many of these applications were part of the Advanced Multi-Mission Operations System (AMMOS). These applications were used with minimum modifications because they provided generic capabilities applicable to all missions. Sequence Translator (SEQTRAN) only required the input of Cassini commands to work. This software translated those commands into binary for uplink to the spacecraft. Other applications required some level of Cassini mission-specific adaptation. The required adaptations were designed, implemented and tested by the MSS team. Sequence Generator (SEQ_GEN) was an application that required mission specific adaptation to add Cassini commands and activities. This software checked flight and mission rules. In addition, there were software tools designed and created specifically for Cassini. One of those tools was the Pointing Design Tool (PDT). This software application allowed the teams to create pointing designs that were used to perform science observations. Other software applications were utilities that improved the uplink process. Among the main applications that the MSS was responsible for were: the PDT, SEQ_GEN, and the SEQTRAN, just to mention a few.

2.5.6 SPACECRAFT OPERATIONS

The primary responsibility of SCO was to maintain the health and safety of the Cassini spacecraft, and provide for the return of mission and science data. The spacecraft subsystem engineers prepared telemetry predictions and then analyzed real-time and non-real-time data, identified and resolved anomalies, implemented spacecraft maneuvers, maintained attitude control and flight software, and developed, analyzed, and tested the engineering commands for background sequence uploads and real-time commanding, as required. Spacecraft engineers also utilized the Integrated Test Laboratory (ITL), the hardware testbed, to analyze data, prepare predicts, and simulate commands and sequences. The SCO was also responsible for generating and maintaining various documents (e.g., command and telemetry dictionaries, operations procedures, flight rules and constraints, idiosyncrasies, and plans) and reports (consumables, trends, and subsystem performance) that were necessary to conduct the Cassini Mission.

The primary responsibility of SCO was to maintain the health and safety of the Cassini spacecraft, and provide for the return of mission and science data.

The SCO was responsible for generating all spacecraft subsystem engineering command inputs and for reviewing all system-level commands for uplink to the spacecraft.

Commands were generated (real-time and sequenced) to perform spacecraft subsystem calibrations and to maintain spacecraft health. Spacecraft engineers also reviewed sequenced and real-time command uploads for engineering correctness and completeness. Maneuver designs, using Navigation inputs, were developed by the SCO subsystems and systems engineers, and the appropriate spacecraft commands were determined to carry out the maneuvers.

Spacecraft subsystem engineering data (real-time and non-real-time) were analyzed, and the health, safety, and performance of the spacecraft were determined by the spacecraft subsystem and system engineers. To carry out this responsibility, spacecraft performance models were developed. These models were software programs and/or hardware models that generated predictions of spacecraft performance and analyzed spacecraft data. The spacecraft system engineers analyzed all spacecraft system data (real-time and non-real-time) to assess spacecraft performance. Investigations were conducted of any spacecraft anomalies, and resolutions were developed to correct them.

Spacecraft attitude/pointing determination and planning was the responsibility of the AACS engineer, who prepared attitude predictions, and analyzed/compared pointing data to the predictions, and provided inputs to science, mission planning, and sequencing/commanding, as required. The SCO developed a suite of analysis tools, which included tools that support calibration, contingency planning, downlink analysis, flight software maintenance, maneuvers, modeling, and the uplink process.

The SCO developed and maintained the ITL, a flight system simulator (testbed, simulator, test lab, etc.) that was used to perform testing (validation) of command sequences prior to transmission to the spacecraft. Spacecraft ITL engineers maintained the flight system simulator and operated it for the mission.

Maintenance of the onboard flight software was required in order to assure proper operation of the spacecraft. The CDS and the AACS engineers were responsible for this activity. This activity involved managing spacecraft flight software maintenance, the generation of flight software memory loads, and the control of all changes to flight programs, including databases.

2.5.7 NAVIGATION

The navigation team was responsible for determining the position and predicted flight path of the spacecraft and correcting that flight path to achieve mission objectives. The navigation process involved a sequence of actions:

1. The acquisition of radiometric tracking and/or optical measurements.

2. The determination of the statistically best estimate of the trajectory based on the tracking and/or optical measurements.

3. The computation of trajectory correction maneuvers (TCMs) to achieve the desired targeting objectives.

In addition, the navigation team performed ongoing planning and analysis activities to ensure that the navigation performance was consistent with the mission and science objectives.

Specific navigation team activities during operations included:

- **Orbit Determination:** The navigation team determined the trajectory and location of the Cassini spacecraft by performing precise measurements of line-of-sight coherent Doppler and range acquired at S- or X-band frequency by using the DSN equipment.
- **Maneuver Design and Analysis:** Many propulsive maneuvers were required to navigate the Cassini spacecraft during the cruise phase (TCMs) and to modify the orbit during the tour phase (orbit trajectory maneuvers). The navigation team designed and verified propulsive maneuvers to modify the spacecraft trajectory and to correct navigation errors in order to achieve the Cassini mission targeting objectives, taking into account the mission and spacecraft constraints. The team monitored and evaluated the maneuver performance in real-time. As part of this process, the team also assessed propellant margin through the end of the mission.
- **Trajectory Analysis:** The navigation team generated the spacecraft trajectory that satisfied mission requirements, based on orbit determination estimates and planned maneuvers. The team updated the trajectory design as needed in response to mission events and science objectives.
- **Optical Navigation:** By using the ISS, the navigation team incorporated optical target-relative navigation measurements into the orbit determination process. The team used these measurements in conjunction with tracking data to support approach navigation and/or orbit maintenance.
- **Navigation Operations Software Maintenance:** The navigation team, in conjunction with the multi-mission navigation team, maintained the navigation software and databases in accordance with flight project requirements. The team responded to software failure reports and change requests.

2.5.8 FACILITY AND PI INSTRUMENTS OPERATIONS

The responsibility for operating the Cassini instruments depended on whether the instrument was a facility instrument or a PI instrument. The facility- and PI-developed instruments are listed in Section 2.4.4. Basically, facility instruments were operated at JPL while PI-developed instruments were operated from the PI's home organization.

Operations responsibilities for the Cassini instrument payload are listed in Table 2.5-1. Figure 2.5-1 depicts the geographical locations for all of the teams responsible for instrument operations. More details of the instrument operations roles and responsibilities are described in Sections 2.5.8.1 and 2.5.8.2.

Table 2.5-1. Distributed operations responsibilities for instruments.

Instrument/Experiment	Responsible Team/	Instrument/Experiment
Optical Remote Sensing Instruments		
Composite Infrared Spectrometer (CIRS)	CIRS Ops Team/ Goddard Space Flight Center (GSFC)	Greenbelt, MD, USA
Imaging Science Subsystem (ISS)	Instrument Ops (IO) Team/ Jet Propulsion Laboratory and Space Science Institute	Pasadena, CA, USA Denver, Colorado, USA
Ultraviolet Imaging Spectrograph (UVIS)	UVIS Ops Team/University of Colorado Boulder	Denver, Colorado, USA
Visible and Infrared Mapping Spectrometer (VIMS)	Instrument Ops (IO) Team/ Jet Propulsion Laboratory and University of Arizona	Pasadena, CA, USA Tucson, AZ, USA
Fields Particles and Waves Instruments		
Cassini Plasma Spectrometer (CAPS)	CAPS Ops Team / Southwest Research Institute (SwRI)	San Antonio, TX, USA
Cassini Dust Analyzer (CDA)	CDA Ops Team/Max Planck Institute	Heidelberg and Stuttgart, Germany
Ion and Neutral Mass Spectrometer (INMS)	INMS Ops Team / Southwest Research Institute (SwRI)	San Antonio, TX, USA
Magnetometer (MAG)	MAG Ops Team/Imperial College	London, England
Magnetosphere Imaging Instrument (MIMI)	MIMI Ops Team / Johns Hopkins University, Applied Physics Laboratory (APL)	Laurel, MD, USA
Radio and Plasma Wave Science Instrument (RPWS)	RPWS Ops Team/ University of Iowa	Iowa City, IO, USA
Microwave Remote Sensing		
Titan Radar Mapper (RADAR)	Instrument Ops (IO) Team/ Jet Propulsion Laboratory	Pasadena, CA, USA
Radio Science Subsystem (RSS)	Instrument Ops (IO) Team/ Jet Propulsion Laboratory	Pasadena, CA, USA

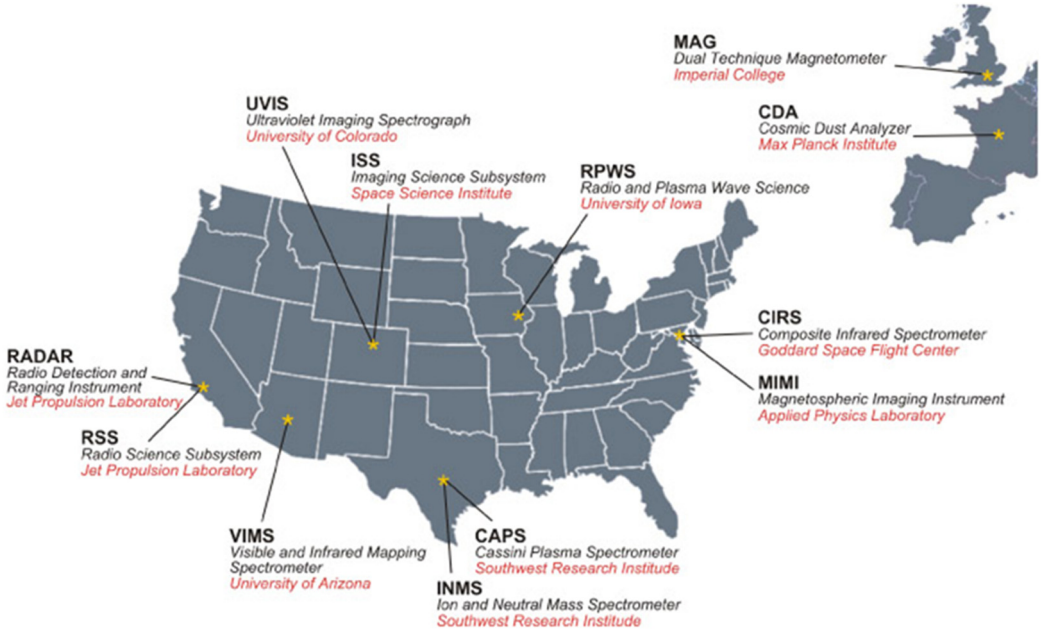

Figure 2.5-1. Geographical location for operations instrument teams.

2.5.8.1 Facility Instrument Operations by the Instrument Operations Team

The operations responsibilities for the three facility instruments (ISS, RADAR, and VIMS) and the RSS investigation were performed by the instrument operations (IO) team at JPL. These operations responsibilities were similar for all instrument, including the PI instrument (see Section 2.5.8.2). These common operations responsibilities are summarized below.

2.5.8.1.1 Facility Instrument (ISS, RADAR, and VIMS) Operations by the IO Team

- Analyzed and assessed the health and safety of the instrument
- Analyzed, predicted, and assessed the performance of the instrument
- Analyzed and predicted instrument resource usage
- Maintained instrument telemetry alarms
- Assessed and resolved instrument anomalies
- Maintained team operations procedures and contingency plans

2.5.8.1.2 Instrument/Science Activity Planning and Command Generation Support by the IO Team

- Participated in the planning of the instrument activities through the SPST
- Generated, verified (constrained check), and validated instrument commands and sequences
  - Generated, verified (constrained check), and validated instrument expanded blocks (IEBs) and instrument non-interactive (or instrument internal) commands
- Generated, verified (constrained check), and validated instrument flight software uploads
- Validated the final instrument command and sequence products via manual review, if required

2.5.8.1.3 Science Data Processing by the IO Team

- Processed instrument raw science data (the processing and generation of facility instrument high-level products were the responsibility of the facility instrument science teams at their home institution)

2.5.8.1.4 Science Data Products Delivery

The delivery of the facility instruments' high-level science data products to the Planetary Data System (PDS) was the responsibility of the facility instruments science teams directed by a corresponding Team Leader. The Team Leaders prepared the high-level science data products at

their home institutions and delivered these products directly to the PDS for permanent archive, except for the RSS. The RSS high-level science data products were generated by the RSS PI science team at its home institution; however, the IO team at JPL prepared and delivered the RSS science data volumes to the PDS for permanent archive.

All of the above roles and responsibilities for the operation of the facility instruments are described in greater detail in Volume 5, under the Uplink Operations Processes and Downlink Operations Processes sections.

2.5.8.2 Principal Investigator Instrument Operations Teams

The PI instrument operations teams were staffed by their corresponding instrument institution and were remotely located at their corresponding institutions. Figure 2.5-1 shows the geographic locations of the instrument institutions. Each PI instrument operations team was responsible for the overall health and safety of their particular instrument. A summary of the common functions performed by the PI instrument operations team during operations is as follows:

2.5.8.2.1 PI Instrument Operations

- Analyzed and assessed the health and safety of the instrument
- Analyzed, predicted, and assessed the performance of the instrument
- Analyzed and predicted instrument resource usage
- Maintained instrument telemetry alarms
- Assessed and resolved instrument anomalies
- Maintained team operations procedures and contingency plans

2.5.8.2.2 Instrument/Science Activity Planning and Command Generation

- Participated in the planning of the instrument activities through the SPST
- Generated, verified (constrained check), and validated instrument commands and sequences
  - Generated, verified (constrained check), and validated IEBs and instrument non-interactive (or instrument internal) commands
- Generated, verified (constrained check), and validated instrument flight software uploads
- Validated the final sequence products via manual review if required

2.5.8.2.3 Science Data Processing

- Processed instrument/science data
- Generated higher-level science data products
- Generated PDS volumes and corresponding labels for all science data products

2.5.8.2.4 Science Data Products Delivery

- Delivered science data products to the PDS for permanent archive

2.5.9 REAL-TIME OPERATIONS TEAM

The real-time operations (RTO) team worked in two functional areas: flight operations and data management. In flight operations, also called mission control, the on-duty Ace† interacted with the DSN, with the multi-mission data services operations team (DSOT), and with other ground-system functions during tracking passes. This constituted the real-time interface between Flight System and Ground System.

The second RTO area was data management. This involved operation of the Telemetry Delivery System (TDS) repositories and cognizance of their content, and creating and maintaining fully documented stores of TLM, MON, and QQC data. (DSN radiometric TRK data acquired under RTO's control was managed and stored separately by the navigation team; RS data was acquired by RSS with RTO's assistance, and stored separately.)

2.5.9.1 RTO Flight Operations Functional Area

Under the flight operations function, the RTO Ops Lead nominally worked dayshifts to provide interface between Aces and the rest of the flight team. Aces worked any time of any day to staff DSN passes (and later, ESA Deep Space Antenna passes), ensuring that there was always a Cassini representative on console when the spacecraft was scheduled to be tracked. Through cross-training, every Ace was also capable of performing the team interface tasks, and the Operations Lead was certified for console work. The Operations Lead developed Ace certification requirements and checklists, and conducted training and certification.

RTO served at the endpoint of the Cassini uplink system, and at the starting point of the Cassini downlink system. At the start of each DSN track, the Ace would verbally brief the station on the latest operational requirements for upcoming activities, and then would monitor both the DSN and the spacecraft while the track progressed, validating the predicted space-link

† "Ace" is the voice-net call sign for the engineer serving as Mission Controller, also called the Flight Controller. The word is not an acronym, but it originated as a reference to a single expert point of contact on the flight project for all real-time interactions, such as for commanding, for decisions about DSN and other ground system configuration activities, problem reporting, and general communications among the project's various science and engineering teams.

performance. On average a track occurred about once a day, and the duration of each track was in the neighborhood of 9 hours plus pre-cal setup time.

Uplink: The Ace radiated CMD data to the spacecraft via the DSN, as authorized per the Command Request Forms, and confirmed spacecraft receipt of the CMD data via TLM. This CMD function came at the end of the long-term processes, largely external to RTO, of sequence development, plus the shorter-term work on subsequences. The Ace also routinely transmitted commands in real-time to reset the spacecraft's fault-protection command-loss timer, and sent other real-time commands as needed. RTO and the SIP lead engineer together exercised great caution to minimize the risks inherent to commanding. RTO coordinated with DSN in real-time to ensure proper reconfiguration when necessary to respond to commanded state changes on the spacecraft, such as for TCMs, OTMs, and other commanded events that caused pointing or telecom configuration changes. RTO also ensured proper radiometric uplink and downlink in service of navigation and radio science requirements.

Downlink and Anomaly Response: RTO managed timely deployment of ancillary files, produced by other teams, which were needed for ground system operation. These included TLM-packet decommutation maps, light-time files, channel parameter table (CPT) files, channel conversion language (CCL) files, spacecraft clock time–spacecraft event time (SCLK-SCET) coefficient files, and Automated Alarm Notification pager files. An important task for the Ace was to keep the TLM red-alarm limit CPT files up-to-date, editing them per user requests, testing and then distributing them throughout the flight team's workstations in coordination with SCO and the science teams.

Naturally, the Ace was often the first flight team member to recognize anomalies in the ground system and the flight system.

Naturally, the Ace was often the first flight team member to recognize anomalies in the ground system and the flight system. The Ace's task was to discriminate between ground or flight system origin, and to take appropriate action under the Anomaly Response Operations Plan (a document which RTO led efforts to keep accurate, usable, and pertinent).

Anomalous conditions may have become evident in many places including the uplink transmitter power, the downlink carrier signal strength, the telemetry-capture performance, TLM and MON channel values, and TLM alarm limit violations. Cassini telemetered thousands of engineering measurements that were limit-checked in the Ground System via the data monitor and display (DMD), and carrying out Cassini's strict policy of maintaining current and meaningful red-alarm limit settings (via CPT edits) ensured the ability to identify and respond to valid flight system anomalies in a timely manner. The Ace documented each anomaly, and resolved it or initiated its resolution within the flight team, and ensured that data continued being loaded to TDSs as soon as possible for access by users. Other parts of the flight team were involved when anomaly resolution required commanding, or for wider procedure or policy changes.

2.5.9.2 RTO Data Management Functional Area

Under the data management function, in coordination with DSOT and the Cassini DGS team, the RTO DMT loaded data to the TDSs, maintained online and off-site data backups and archives, researched and produced reports and explanations of gaps in the data, and interfaced with science teams and DSOT to locate data that various instrument and engineering teams may have had trouble finding. RTO DMT also loaded data to the TDS from archives and backups as required to service some requests, and managed in cases of TDS anomalies, some of which would require extensive rebuilding of the TDS catalogs.

2.5.10 DOWNLINK GROUND SYSTEM TEAM

The Downlink Ground Data System (DGDS) team was responsible for the development and maintenance of the Cassini downlink and data tools. Following is a list of their specific responsibilities:

- Interfaced with the Multi-Mission Ground Data System and Services (MGSS) mission control, data management and accountability, and spacecraft analysis subsystem (MDAS) to develop requirements, resolve problems, and determine integration schedule of core tools
- Interfaced with telemetry, tracking and command (TT&C) subsystem to develop requirements, resolve problems, and determine integration schedule of core tools
- Interfaced with Cassini offices and teams to develop requirements, establish priorities, and determine delivery schedule to the project
- Established and maintained team staffing to meet project commitments
- Oversaw and approved documentation in conjunction with software cognizant engineers
- Provided the tools, training, and resources required for accomplishing development tasks
- Coordinated Cassini use of and compatibility with DSOT
- Maintained ground system compatibility with the telemetry dictionary used for operations
- Maintained Cassini adaptation of multi-mission downlink tools and environment
  - cascat environment
  - Cassini Distributed Object Manager (DOM)
  - DMD customizations
  - CMD customizations
  - ITL telemetry support
  - Administered the Cassini DOM

- Maintained the Cassini downlink, RTO, web tools
  - Rampage
  - Acelog
  - PSG Automation Tool (PAT)
- Managed and performed systems administration of the flight operations, ITL, webnet, Science Operations and Planning Computer (SOPC), and Science Operations (SCIOP) workstations, servers, and networks. Responsible for the oversight of workstation, servers, and network operations, repairs. Responsible for initiation of changes to architectures and design as required, and coordinating implementation with Cassini teams and Office of the Chief Information Officer (OCIO). Maintained spare equipment and logistics support. Managed all maintenance and service contracts, software licenses, and spares.
- Maintained interfaces with external information and technology (IT) entities (MGSS and OCIO).
- Maintained Cassini project compliance with applicable IT security requirements. This included maintaining the Information Technology Security Database (ITSDB) and responding to SPLs (security problem logs). Developed and maintained IT security plans and perimeter access requests (PARs) for the appropriate Cassini systems.

2.5.11 System Engineering and Configuration Management

System engineering (MOS engineering and GDS engineering) ensured that the end-to-end mission operations system was working properly. This included, but it was not limited to, operations documentation, processes, procedures, interfaces, and GDS (ground software and hardware). System engineering was in charge for the following specific responsibilities:

- Ensured that Level-3 (system level, L3) processes were working properly
- Updated L3 processes as needed to factor in lessons learned and experience from the flight team
- Ensured that Level-4 (team level, L4) operations procedures were being followed
- Ensured that L4 teams were maintaining operations procedures and contingency plans properly
- Updated/maintained Flight Operations Plan (FOP), as needed
- Updated/maintained Operational Interface Agreements (OIAs), as needed
- Supported the planning, generation, and execution of verification and validation (V&V) exercises

- Identified and proposed modifications to the GDS (tools and capabilities) needed to successfully support the operations processes and procedures
- Monitored all aspects of the GDS
- Led investigation and resolution of GDS anomalies (incident/surprise/anomaly, ISA)
- Maintained and managed ground software, hardware, and networks consistent with the GDS Software Management Plan
- Coordinated development, testing, integration, and release of GDS upgrades
- Led and managed GDS deliveries
- Assessed GDS change requests
- Ensured proper system and database administration
- Identified improvements to GDS processes and tools
- Ensured that the Software Interface Specifications (SISs) were correct and coordinated any required changes or updates
- Led the update of the VIMS and CIRS thermal models for FRPO

Configuration management (CM) consisted of JPL personnel with MGSS partnership. The CM Engineer was responsible for ensuring that configuration management tasks were properly performed in accordance with the NASA and JPL policies. The CM Engineer had the following specific responsibilities:

- Track, route, close, archive, and report status of change requests
- Run Change Control Board
- Control GDS software baseline
- Audit software installed on project workstations

2.5.12 MISSION OPERATIONS ASSURANCE

Mission operations assurance (MOA) was the responsibility of the Mission Operations Assurance Manager (MOAM). The MOAM was responsible for ensuring that MOA tasks were properly performed in accordance with NASA and JPL policies. The MOAM was responsible for the following specific tasks:

- Anomaly (ISA) management, including criticality rating and team assignment
- Concurrence on ISA closures
- Facilitating anomaly review meetings
- Reviewing operations processes

- Management of project's risk items
- Ensure the existence of adequate and appropriate operations assurance processes that contributed to the success of the project
- Support project staff in recommending/developing solutions to operational problems based on project needs and requirements
- Provide mission assurance interfaces with flight team and remote instrument teams for matters related to mission assurance

2.5.13 DSN Mission Interface

The DSN Mission Interface Manager (MIM) provided the interface between the Cassini mission system and the DSN organization. Also, the DSN MIM was responsible for maintaining and updating the DSN operational interfaces between the Cassini Project and the DSN organization.

2.6 Mission Phases

The Cassini Mission is divided into five major phases, each phase containing several sub-phases. Following are the phases and corresponding sub-phases.

2.6.1 Launch Phase

The Launch Phase spanned the time period between launch (L) and L + 30 days. During this time interval, the spacecraft went through a relatively rapid series of transitions which took it from the launch pad on Earth (see Figures 2.6-1 and 2.6-2) to a Venus-targeted trajectory, then eventually took it to Saturn. Because of the launch environment and the operation of the spacecraft for the first time, the events in the launch phase are geared primarily towards characterizing the spacecraft's behavior in the space environment, performing essential engineering checkouts and calibrations, and preparing the spacecraft for its first main engine maneuver, which occurred at L + 25 days.

The first 30 days of the mission were divided into two sub-phases: the launch sequence sub-phase and the sub-phase containing the first TCM, called the TCM-1 sub-phase. The launch sequence sub-phase was autonomous, lasting two days, and covered the interaction between the spacecraft and launch vehicle through separation, the powering-on of select heaters, and the acquisition of the spacecraft's signal by the DSN. The TCM-1 sub-phase began at L + 2 days and addressed the events that led up to and surrounded the first TCM and included spacecraft system health checks and a limited number of maintenance activities.

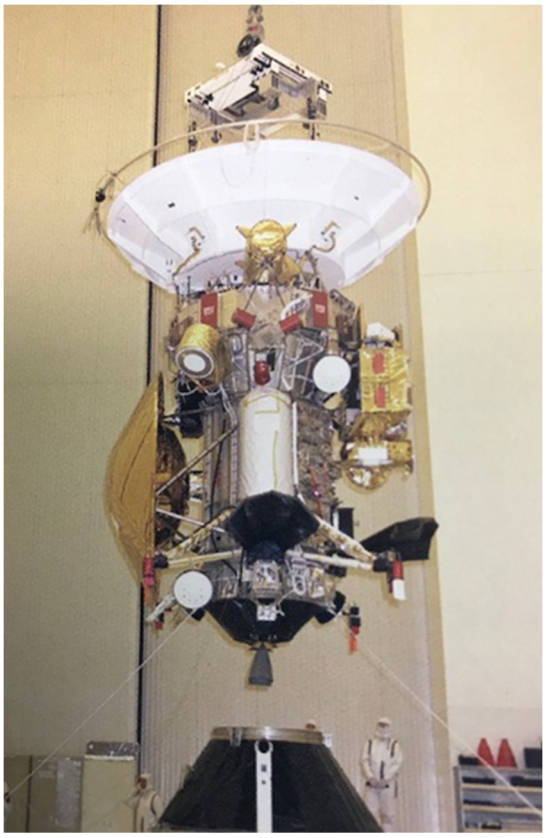

Figure 2.6-1. The Cassini-Huygens installed on the launch adapter.

Figure 2.6-2. Cassini's launch via a Titan IVB vehicle.

2.6.1.1 Launch Sequence Sub-phase

Cassini had a 30-day nominal launch window, extending between October 6 and November 4, 1997, that provided for an arrival date at Saturn of July 1, 2004. If the spacecraft had launched after November 4, Cassini would have missed its ideal arrival date at Saturn. The spacecraft could still have launched into its primary trajectory as late as November 13, but in that case, its arrival date at Saturn would have been pushed back as late as June 25, 2005—practically a year later than planned.

After a first attempt was postponed on October 13, Cassini successfully lifted off from the Cape Canaveral Air Station complex 40 on October 15, 1997 at 08:55 UTC. The solid rocket motors burned from liftoff to separation at 2 minutes, 23 seconds at an altitude of 68,000 meters. Stage 1 ignition began at 2 minutes, 11 seconds at an altitude of 59,000 meters, and Stage 2 ignition (and Stage 1 separation) occurred at 5 minutes, 23 seconds after liftoff at 167,000 meters. During the first 3 minutes and 27 seconds of flight, the payload fairing shrouded the spacecraft protecting it from direct solar illumination.

The Centaur upper stage separated from the launch vehicle at 9 minutes, 13 seconds at 200,000 meters. The first Centaur burn began at 9 minutes, 13 seconds and lasted approximately 2 minutes. This burn placed the Cassini spacecraft into an elliptical, 170-kilometer by 445-kilometer parking orbit with an inclination of about 30°. Cassini's orbit around Earth was designed to provide an orbital lifetime of about 20 days in case the Centaur failed to have a successful second burn and injection. After 17 minutes in parking orbit, the Centaur fired again and launched Cassini toward Venus en route to Saturn. The injection launch energy, or C3, was 16.6 km^2 per $second^2$.

Cassini initiated and completed its first critical on-board subsequence (called TEMP) during parking orbit coast, and actually started the onboard launch sequence in addition to turning on spacecraft heaters.

Cassini's second critical subsequence (called PREP), 30 seconds after the second Centaur burn, prepared the spacecraft for separation from the Centaur. PREP opened the prime thruster branch latch valve, turned on the pyro switching units, and turned on the spacecraft's X-band exciter and amplifiers for the low-gain antenna for acquisition by the DSN's Canberra station.

The third critical subsequence (called SEP) was initiated following the worst-case completion time of PREP (6 minutes after the second Centaur burn). At this point, the spacecraft was separated from the Centaur.

Immediately after separation, the spacecraft's AACS took control and pointed the high-gain antenna toward the Sun to achieve a thermally safe attitude. X-band uplink and downlink was established, the RPWS Langmuir probe was deployed via pyro, instrument replacement heaters and main engine oxidizer valve heaters were turned on, and the SRU, ISS, and VIMS decontaminations were started.

The Centaur, after separation from the spacecraft, executed a collision and contamination avoidance maneuver (C/CAM) that prevented it from impacting either Venus or the spacecraft. This burn occurred approximately 20 minutes after separation to allow the spacecraft and the Centaur to drift apart such that the plume from the Centaur RCS firing would not impact the spacecraft. Approximately 8 minutes after C/CAM, the Centaur executed a blowdown maneuver to expel unused propellant and to further reduce the probability of impact with the spacecraft or Venus. About an hour after separation, the Centaur depleted its hydrazine from the RCS. The Centaur mission ended approximately 87 minutes after separation.

Figure 2.6-3 illustrates the main events executed during the launch sequence.

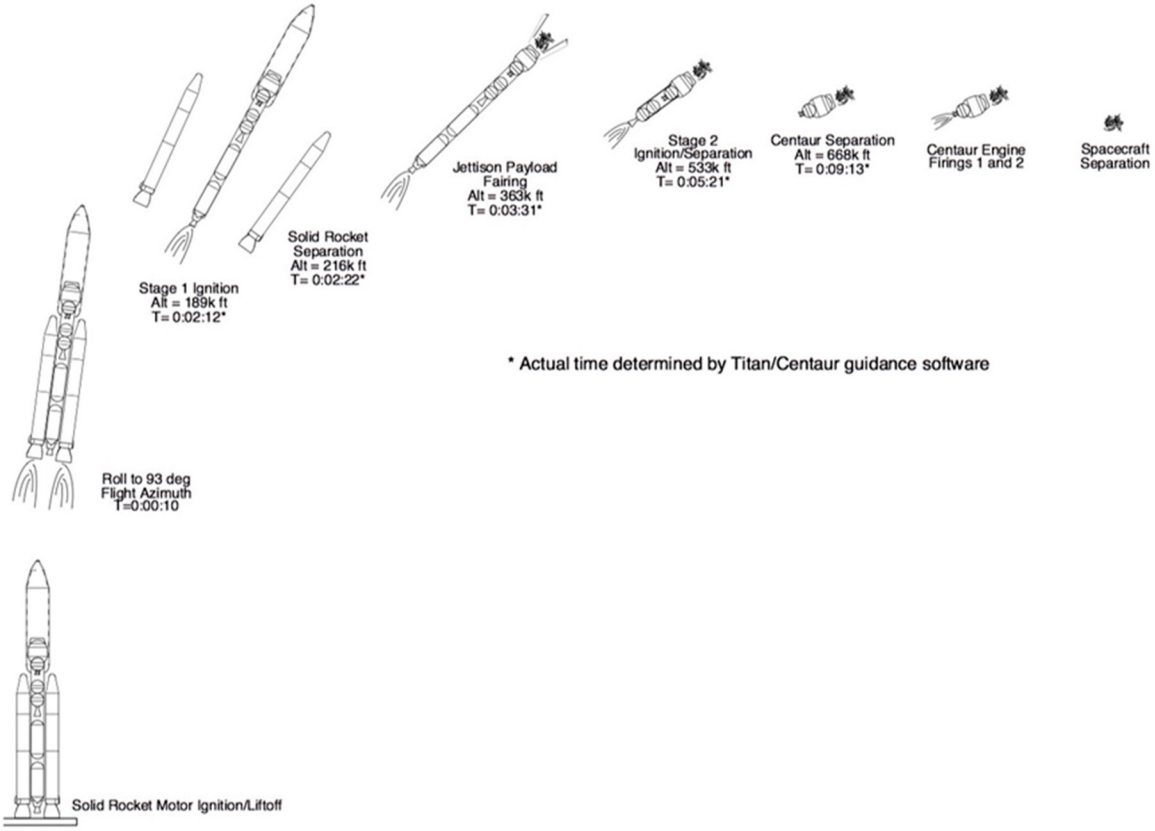

Figure 2.6-3. The Cassini-Huygens launch events.

2.6.1.2 TCM-1 Sub-phase

The TCM-1 sub-phase began on day 291 (October 18) of the mission and was comprised of four 1-week sequences. During the beginning of the TCM-1 sub-phase, the spacecraft was in a relatively inactive state. Ground controllers used telemetry downlinked from the spacecraft to make an initial characterization of the spacecraft and to assess whether its various subsystems survived the launch environment. Controllers also began deployment, decontamination, tank heating, and AACS checkout activities.

During most of the TCM-1 sub-phase, the spacecraft remained Sun-pointed (i.e., with its high-gain antenna aimed at the Sun). The only event requiring the spacecraft to go off Sun-point was the TCM itself, when Cassini's main engine had to be pointed in a specific orientation that prevented Sun-point (CK).

PMS Activities: Before the first trajectory correction maneuver only, the fuel and oxidizer tanks were heated in order to avoid an irreversible overpressure in the propellant lines. If the tanks fully pressurized before the spacecraft passed through the peak temperature regime, when entering the maximum thermal environment, the tank pressure could climb without a way to bring it back down, possibly causing an overpressure.

Each tank had one heater and one redundant backup heater. The oxidizer tank heater was turned on at approximately L + 8 hours. Since the fuel tank requires less heating time, the fuel tank heater was turned on a few days later. The tank heating was interrupted for probe checkout and periodic instrument maintenance due to power constraints. Both heaters were turned off approximately 2 days before TCM-1.

After opening the main engine cover, the spacecraft vented, primed, and pressurized the bipropellant lines (REA-A only) between one and two days before TCM-1. Venting removes the gas between the latch valves and the engines, creating a vacuum in the propellant lines. Priming fills these lines with propellant. The tanks then pressurized at a temperature higher than the peak temperature expected en route to Venus. Each step takes only seconds to complete, but a real-time "Go" command was needed from controllers on Earth (CK) before moving on to the next step, to ensure that the previous step was successful. After pressurizing, the valves were left open until approximately 2 days after TCM-1.

AACS Activities: There was a window to update AACS parameters in real-time at L + 2 days. An IRU characterization, engine gimbal assembly (EGA) exercise, and accelerometer calibration were scheduled during the TCM-1 sub-phase in order to ensure functionality before TCM-1.

TCM-1 and Thermal Characterization: TCM-1 was an Earth injection clean-up maneuver at L + 25 days. The spacecraft executed TCM-1 with its main engine for a ΔV magnitude of 2.8 meters per second. The burn sequence included holding the spacecraft off-Sun after burn completion to allow the spacecraft heating to be characterized in a relatively benign environment. The main engine cover was opened 48 hours before the start of the burn, and closed during the TCM-1 minisequence several hours after burn completion. Because of the high data-rate capability at the beginning of the trajectory, it took less than one DSN pass to downlink the data from TCM-1 using the playback (PB) and real-time engineering (RTE) 948 data mode.

Regulator Leak Problem: As the initial pressurization was being performed just prior to TCM-1, the primary regulator showed an unexpectedly high leak rate of 1,700 standard cubic centimeters per minute (sccm). The specified rate for leakage from this regulator was supposed to be 0.6 sccm or less. In response, ground controllers closed high-pressure latch valve (LV) 10. The incident was addressed in ISA Z44505.

While regulator leakage is a well-known phenomenon, the magnitude of this leak was surprising, especially given the leakage characteristics demonstrated by pressure regulator (PR) 1 during ground testing. Analysis demonstrated that particulate contamination could very easily explain the observed regulator leakage, since the requisite particle size that causes a 1,700 sccm leak is two orders of magnitude smaller than the filter capacity between pyro valve (PV) 1 and PR-1. That is, a particle that just fits and passes through the filter upstream of PR-1 could cause a leak a hundred times larger than the leak observed at initial pressurization. Regardless, analysts recommended that the Cassini Mission continue to use PR-1 unless the leakage had reached 20,000 sccm.

… , a particle that just fits and passes through the filter upstream of PR-1 could cause a leak a hundred times larger than the leak observed at initial pressurization.

Solid-State Recorder: There were SSR pointer resets scheduled for L + 18 and L + 25 days. The primary SSR was switched from SSR-A to SSR-B at L + 18 days, just before the scheduled pointer reset. At L + 29 days, the redundant SSR was turned off.

ISS and VIMS Decontaminations: The spacecraft powered on decontamination heaters for these instruments in order to "boil off" any contaminants deposited on their optics or radiators as a result of the launch environment. VIMS and ISS Level-1 decontaminations began during the launch sequence sub-phase. ISS decontamination was increased to Level-2 at the beginning of C1 (L + 3 days). The VIMS high-power decontamination lasted 150 days. ISS decontamination was reduced to Level-1 and the VIMS infrared (IR) optics heaters were paused for periodic instrument maintenance, probe checkout, and TCM-1. The VIMS visible optics heater were also paused for the periodic instrument maintenance. Level-2 ISS decontamination concluded after the end of the TCM-1 sub-phase, when the decontamination had reached a cumulative 30 days.

The spacecraft executed several instrument cover deployments, antenna deployments, and latch releases during the first 30 days after launch. These included MIMI launch latch release, CAPS launch latch release, CIRS launch latch release, CDA cover jettison, MIMI cover releases, and UVIS membrane puncture. There was also a periodic instrument maintenance scheduled for L + 12 days. However, the Ka-band traveling wave tube amplifier's helix current maintenance could not occur before L + 4 months and was excluded from this first maintenance activity.

The Huygens probe team also requested an early checkout shortly after launch to take advantage of the high downlink data rates. The first probe checkout was scheduled for L + 8 days. This was the earliest time allowable considering post-launch cool-down inside the probe, while also allowing room for subsequent contingency actions that may have been necessary while the downlink rate was still up at 24.885 kilobits per second (until approximately L + 12 days). The checkout provided post-launch verification for all subsystems and experiments, and was of particular importance for the GCMS by pumping out any contaminants introduced during launch.

2.6.2 CRUISE OPERATIONS PHASE

2.6.2.1 Inner Cruise Phase

The inner cruise phase consisted of three sub-phases: Venus-1, instrument checkout, and Venus-2–Earth. Activities accomplished in each sub-phase are described in following subsections.

The inner cruise phase spanned the time period from November 14, 1997 through November 7, 1999. During most of this phase, the spacecraft remained Sun-pointed because it was so close to the Sun, and therefore telecommunications used the low data-rate low-gain antennas. The downlink capability of the low-gain antennas at large spacecraft–Earth ranges was very limited.

Figure 2.6-4 shows the timeline of events for the inner cruise phase. Between L + 30 days and L + 150 days the downlink data rate varied between 20 and 948 bits per second. During this 4-month period, the spacecraft performed routine maintenance activities and engineering calibrations, which enabled the Mission and Science Operations Office to progressively improve their understanding of the spacecraft's health and capabilities.

Routine maintenance was limited to engineering subsystems and instrument maintenance. On some days during inner cruise, the downlink data-rate capability dropped below 40 bps for a

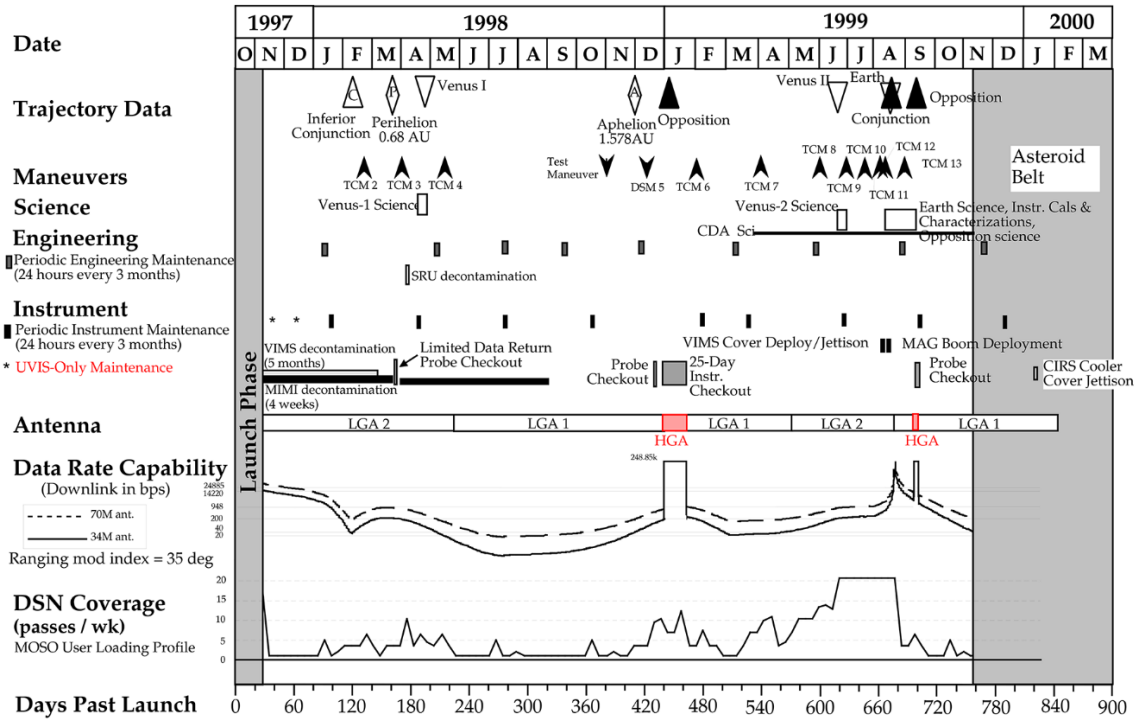

Figure 2.6-4. Cassini Inner Cruise Phase.

short period of time, even with ranging turned off. So during those periods, controllers on the ground avoided spacecraft activities generating large amounts of data.

Beginning on December 28, 1998, the spacecraft approached opposition and pointed its high-gain antenna towards Earth for 25 days and kept the probe equipment temperature within the required range. This provided a high data-rate window in which checkout activities were accomplished. Off-Sun pointing greater than 2.5° was permitted for this 25-day period.

The DSN coverage shown in Figure 2.6-4 reflects the DSN tracking during the inner cruise phase. A detailed description of the project's request to the DSN can be found in the Program Service Level Agreement (PSLA). The number of passes requested per week satisfied navigation radiometric data requirements and provided telemetry visibility during periods of spacecraft activities requiring ground intervention, such as maneuvers or planetary flybys. During the inner cruise phase, Cassini utilized 34-meter DSN coverage. (The 70-meter DSN stations were not available to uplink X-band until the year 2000. X-band uplink is required for 2-way navigation tracking data.)

The transitions from LGA-1 to LGA-2 are based on which antenna has the highest gain for a particular geometry. These transitions occurred at Sun–Spacecraft–Earth (SPE) angles of approximately 44°; when this angle was less than 44°, LGA-1 had the higher gain, and when the angle was at least 44°, LGA-2 provided the higher downlink capability.

During most of the inner cruise phase, the spacecraft remained Sun-pointed and downlinked telemetry via the low-gain antennas. The engineering activities onboard the spacecraft were geared towards maintenance and calibration of the various engineering subsystems, as well as providing support for the trajectory course maneuvers and the deep space maneuver executed during the phase.

Probe checkouts (PCOs) were required about every six months to exercise the probe's internal systems to maintain their health. PCOs are usually accomplished with a 70-meter antenna for downlink to use their high-rate probe checkout telemetry mode, or when circumstances permit, the high-gain antenna.

PCO-1 was done on October 23, 1997, when the spacecraft was still relatively close to Earth and was able to support the high-data-rate downlink on a 34-meter antenna. PCO-2 had no conveniently close high-data-rate period to allow for real-time downlink. ESA agreed to a compromise required downlink of about 40 percent of the data from this checkout. Fortunately, before the Venus-1 flyby, some 70-meter coverage was available, permitting the orbiter to transmit data using PB&RTE-948 data mode for periods at high elevation. PCO-2 was carried on March 27, 1998.

The mission used the January 1999 opposition period for the high downlink of PCO-3. Cassini was able to be Earth-pointed near opposition, so it could use the spacecraft's high-gain antenna. PCO-3 was carried out on December 22, 1998. However, since the spacecraft was Earth-pointed, and the probe was receiving some sunlight, the checkout occurred six days prior to the start of Earth-point to allow time for probe equipment to cool down after the checkout. Therefore, PCO-3

did not return the checkout data in real-time. High data rates during the ICO period allowed rapid playback of the probe data, so the full data set was returned during the first day of the ICO period.

The mission executed PCO-4 just after the Earth flyby, nine months after PCO-3, when the high-gain antenna was available for a limited period near opposition. This checkout occurred on September 15, 1999. Extensive activities before and during the flyby related to the MAG boom deployment and calibration (see the Earth flyby description later in this section) made PCO-4 impractical to be done until the flyby was completed.

2.6.2.2 Venus-1 Flyby Sub-phase

The Venus-1 sub-phase started lasted from November 14, 1997 through September 13, 1998, and encompassed sequences C5 through C9. During this period, the Cassini spacecraft performed two TCMs (one other TCM was cancelled), one planetary swing-by, and three switches between LGA-2 and LGA-1. Most of the period was dedicated to engineering and instrument maintenance activities.

Cassini's encountered Venus for the first time on April 26, 1998 (see Figure 2.6-5). The spacecraft approached Venus from a sunward direction, and made closest approach just after entering Venus's shadow for a period of about 15 minutes. At closest approach, the spacecraft was 284 km from Venus, with a velocity relative to the planet of about 11.8 km per second. The spacecraft was occulted from the Earth for about 2 hours during the flyby. The Earth occultation zone started about 15 minutes after the spacecraft left the Sun occultation zone. The navigation team managed trajectory accuracy for the Venus flyby by using two trajectory correction maneuvers, 60 and 20 days before closest approach, along with a cleanup maneuver 20 days after the flyby.

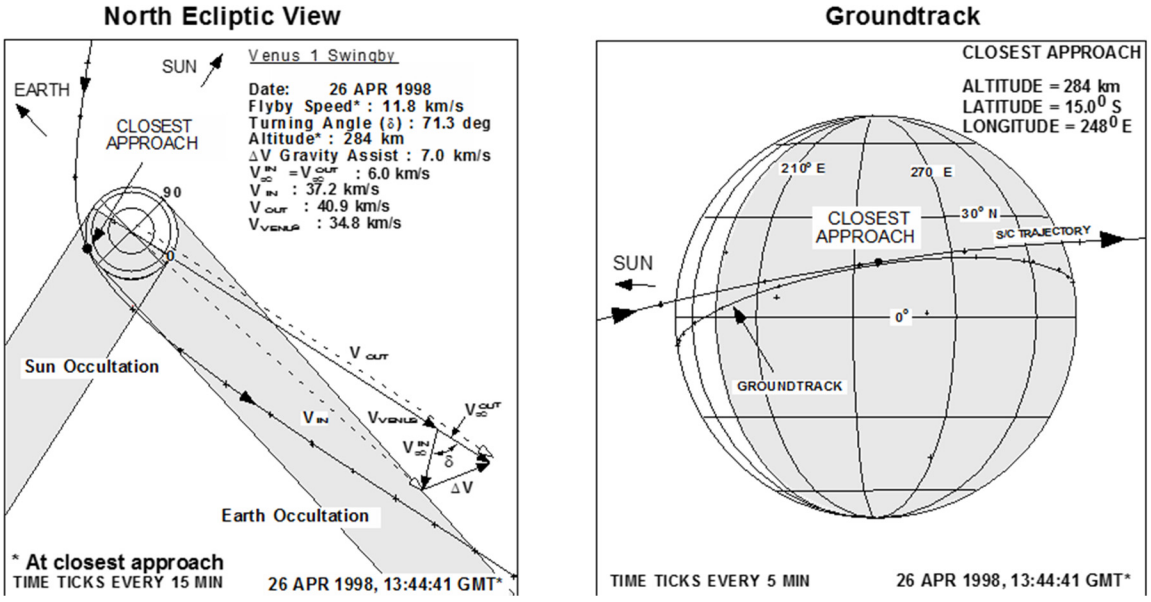

Figure 2.6-5. Venus-1 flyby.

DSN requirements for the Venus-1 flyby consisted of one pass per day on approach, beginning 90 days before the Venus-1 flyby, followed by continuous coverage during the five days around the flyby. Continuous coverage was defined as no gaps greater than 8 hours (Earth Swing-by (ESB) requirement 418-1D(k)in Project Policies document). Coverage was reduced to one pass per day for the five days following the flyby.

Instrument Checkout Sub-phase

The instrument checkout sub-phase lasted from September 14, 1998 through March 14, 1999. The sub-phase consisted of sequences C10–C13 and is characterized by the January 9, 1999 opposition. Because opposition nearly aligned the Earth and Sun (from Cassini's point of view), the spacecraft used the high-gain antenna as both a sunshade and as its downlink antenna, which provided a high data rate for checkout activities. The spacecraft began Earth-point on December 28, 1998, as the spacecraft approached opposition. Cassini kept its high-gain antenna towards Earth for a period of 25 days and kept the probe equipment temperature within the required range. Off-Sun pointing greater than 2.5° was permitted.

All instrument teams scheduled checkout activities for their instruments within that 25-day period centered on opposition. It was the first opportunity since launch to exercise most of the instruments and check their status beyond routine instrument maintenance. One of the tests repeated the "quiet test" performed during assembly test and launch operations, which allowed instruments to monitor other instruments as they turned on and off. This provided valuable insight into how to integrate science observations during the Saturn tour.

During the instrument checkout activities, the spacecraft autonomously went into a safe state due to a slow z-axis turn to keep the Sun in the X-axis direction during opposition, which caused star position errors. These errors caused AACS fault protection to call spacecraft safing. Most of the instrument checkout activities were able to be rescheduled after a 10-day safing period. Those not completed were rescheduled for the ICO-2 sub-phase.

2.6.2.3 Venus-2–Earth Sub-phase

The Venus-2–Earth sub-phase started on March 15, 1999, 45 days prior to the second Venus flyby, and continued through November 7, 1999, or Earth + 82 days. The sub-phase encompassed sequences C13–C16. The period included seven scheduled TCMs, two planetary swing-bys, and 25 science activities in addition to normal engineering activities. Figure 2.6-6 shows the Venus-2–Earth timeline.

At the beginning of the Venus-2–Earth sub-phase, the spacecraft was Sun-pointed and communicating through LGA-2. On approach to the Venus-2 flyby, the mission was allocated one DSN pass per day. The spacecraft executed TCMs 37 days before the flyby (TCM-7) and 14 days before the flyby (TCM-8). In support of the flyby, the DSN coverage increased to three passes per day.

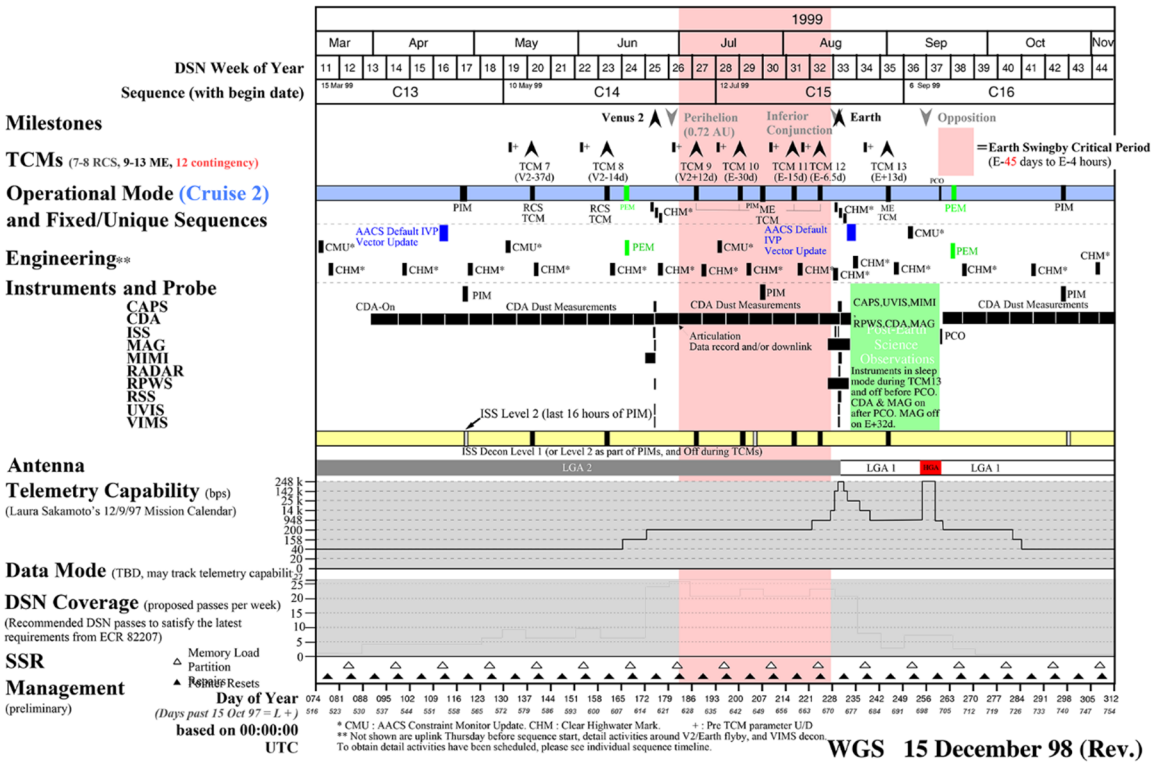

Figure 2.6-6. Cassini Venus-2–Earth Sub-phase Timeline: C13 through C16 sequences.

After perihelion, and 12 days after the Venus flyby, the spacecraft executed the first Earth-targeting maneuver (TCM-9), and then three more pre-Earth maneuvers to ensure a successful Earth flyby. Cassini also performed a post-Earth cleanup maneuver 13 days after the Earth flyby. The DSN coverage-demands then decreased until the spacecraft was switched to the high-gain antenna in February 2000.

Opposition occurred 26 days after the Earth flyby, again presenting an opportunity to use the high-gain antenna for both a sunshade and communication with Earth. For four days the spacecraft was pointed to Earth and stayed within 2.5° of the Sun. Five instruments planned observations as Cassini passed through Earth's magnetotail.

During this sub-phase, about two-dozen activities involving maintenance, calibration, checkout, and science observations were carried out, using all of the Cassini instruments except INMS and CIRS. These activities are summarized in Table 2.6-1.

The first flyby of this sub-phase was the second flyby of Venus (see Figure 2.6-7). This flyby was an energy-increasing (with respect to the Sun) gravity-assist that changed the trajectory to meet Earth about 55 days later. The encounter, along with the Earth flyby, provided the spacecraft with the heliocentric energy to reach Jupiter in late 2000. A timeline for Venus-2 science activities is shown in Figure 2.6-9.

Closest approach occurred by the time the spacecraft left the Earth occultation zone. This occultation lasted approximately 15 minutes. At closest approach, the spacecraft was 603 km from Venus, with a Venus-relative velocity of 13.6 km per second. The spacecraft performed targeting maneuvers at 140, 37, and 14 days before closest approach, and a cleanup maneuver 12 days after the flyby. For the Venus-2 flyby, the spacecraft required one pass with the DSN every two days beginning 90 days before the flyby, plus one pass per day from 50 days before the flyby until three days before the flyby. Then the DSN provided continuous coverage from two days preceding the Venus flyby until two days following the flyby.

Table 2.6-1. Earth spacecraft activities.

Activity	Instr.	Description	Observation Timing (duration usu. less than instrument-on time)
Near Venus-2			
CAPS Observations	CAPS	Characterize interaction of Venus with Solar Wind	2 hrs near C/A
ISS Venus-2 Observations	ISS	Flat-field calib. for ISS WAC and NAC	10 minutes near C/A
Venus-2 MAG Field	MAG	Measure magnetic field	4 hrs centered on C/A
MIMI Venus-2	MIMI	Science obs.; UV sensitivity calib.	4 hrs centered on C/A
RPWS Venus-2 Science	RPWS	Measure plasma waves and search for lightning	At least 2 hrs, beginning 1 hr + 15 min. before C/A
UVIS Venus-2 Activity	UVIS	Measure Venus airglow; determine thermosphere time variation	30 min. near Venus 2
VIMS Observations	VIMS	Map tropospheric motion and night side of Venus	23 min., starting 20 min. prior to boresight viewing the Venus terminator
Venus 2 – ESB			
CDA Activity	CDA	Continuous interplanetary dust measurements	Continuously after Venus 2 to ESB
Near ESB			
CAPS Calibration	CAPS	Calibrate spectra and take data	> = 13 hrs between 3–10 Earth radii
MAG Boom Deployment	MAG	Deploy MAG boom	After Sun range > 0.97 AU (about 5 days before ESB) and before ESB
MAG Calibration	MAG	Calibrate MAG's alignment	From MAG activation for boom deployment until 14.22 kps downlink no longer possible
MIMI Earth Swing-by	MIMI	Calibrate sensors and take data	10 hrs centered on C/A
Radar Operation	RADAR	Transmit and receive pulses for closed-loop test of radar	~30 min of data acquisition, centered around Earth occultation of Sun, following C/A, maximized for ranges < = 40,000 km
RPWS Validation and Testing	RPWS	Validate capability to determine propagation characteristics of plasma waves; test direction-finding capability	> = 13 days + 2 hrs, beginning 2 hrs before C/A
Earth Flyby Trajectory Determination	RSS	Search for anomalous trajectory perturbation by determining pre- and post-flyby trajectory	DSN tracking as continuously as possible from encounter − 10 hrs to encounter + 10 hrs
VIMS Covers Jettison and Deployment	VIMS	Jettison of VIMS IR channel radiator cover; deployment of VIMS IR channel optics cover	After final TCM prior to ESB, prior to MAG boom deploy, and at > 2 days prior to last outbound Earth orbit crossing

Table 2.6-1. Earth spacecraft activities.

Activity	Instr.	Description	Observation Timing (duration usu. less than instrument-on time)
Near ESB; using Moon			
ISS Lunar Calibration	ISS	Image the Moon for several calibrations; study regional compositional differences on Moon	40 min near C/A to Moon, dictated by pointing restrictions
UVIS Characterization	UVIS	Characterize scattered light w/ EUV and FUV; characterize HDAC sensitivity	30 min, beginning when Moon enters the UVIS slit
VIMS Calibration	VIMS	Calibrations and science data using the Moon	1.5 hrs beginning ~2 hrs before C/A, and 2.0 hrs beginning ~1 hrs after C/A
After ESB			
CAPS Earth Observation	CAPS	Observe geomagnetic tail and interstellar particles	~5-day high-gain antenna-to-Earth period centered on opposition
CDA Dust Measurements	CDA	Continuous science dust measurements	29 days, from ESB to high-gain antenna-to-Earth period*
MAG Earth-Extended-Tail Operations	MAG	Measurements of the magnetic field in Earth's magnetotail	29 days, from ESB to high-gain antenna-to-Earth period*
MIMI Earth Magnetotail	MIMI	Calibrate LEMMS, CHEMS, and INCA; magnetotail measurements	29 days, from ESB to high-gain antenna-to-Earth period*
RPWS Magnetotail Observations	RPWS	Look for signatures of the distant geomagnetic tail	29 days, from ESB to high-gain antenna-to-Earth period*
UVIS Observations	UVIS	UV measurements of the geocoronal H tail; measurements of Lyman β, α, and He 584	29 days, from ESB to high-gain antenna-to-Earth period*

* in sleep mode for TCM-13

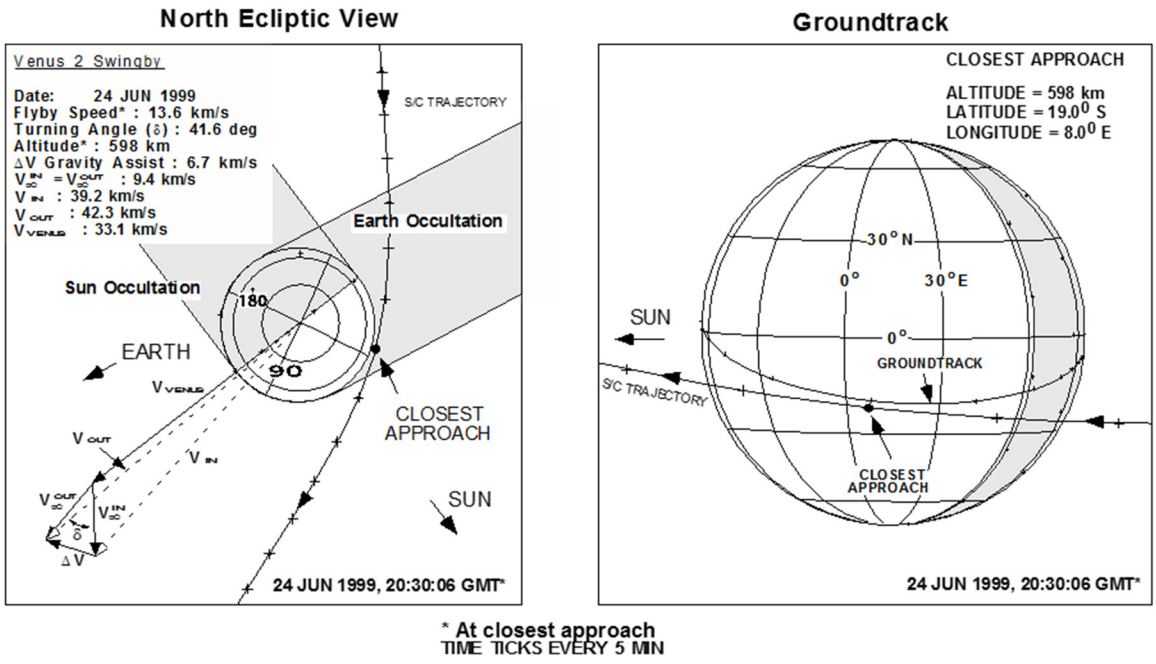

Figure 2.6-7. Venus 2 flyby.

Cassini performed its Earth flyby on August 18, 1999, 55 days after the Venus-2 flyby (see Figure 2.6-8). The spacecraft approached the Earth approximately from the direction of the Sun, and closest approach occurred immediately after the spacecraft entered the Sun occultation zone. The occultation lasted approximately 30 minutes. Cassini's altitude at closest approach to Earth was 1,175 km, with an Earth-relative velocity of 19.0 km per second.

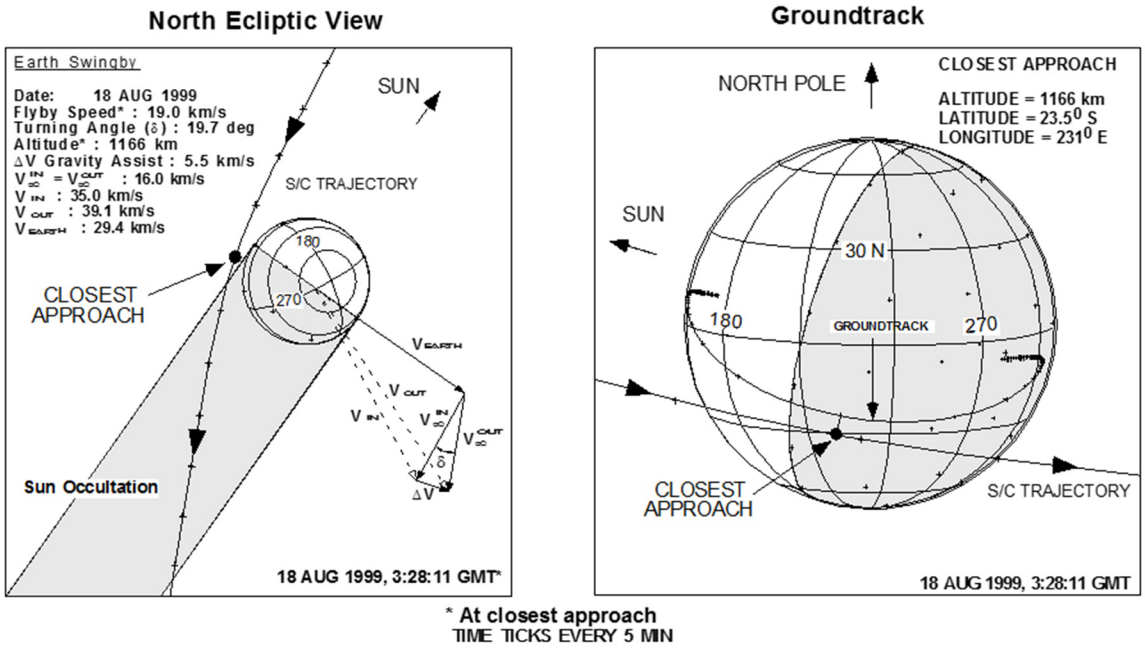

Figure 2.6-8. Earth flyby.

Preceding the Earth flyby, the spacecraft performed four TCMs at 43, 30, 15, and 6.5 days before closest approach. Cassini also had a cleanup maneuver 13 days after the Earth flyby. The DSN provided continuous coverage from the Venus 2 flyby through the Earth flyby. One week after the Earth flyby, that coverage dropped to one pass every two days. A timeline for Earth science activities between Venus and Earth is shown in Figure 2.6-9. The post-Earth science activities through opposition are shown in Figure 2.6-10.

2.6.2.3.1 Earth Swing-by Considerations

The Cassini Project was required to assure that an inadvertent reentry of the spacecraft at Earth be next to impossible (mean probability less than one in a million). As a result, constraints were placed on all project elements, including the mission.

The mission constraints fell mostly in the Venus-2–Earth leg. First, the trajectory design over the launch period was constrained to Earth swing-by altitudes no lower than about 800 km.

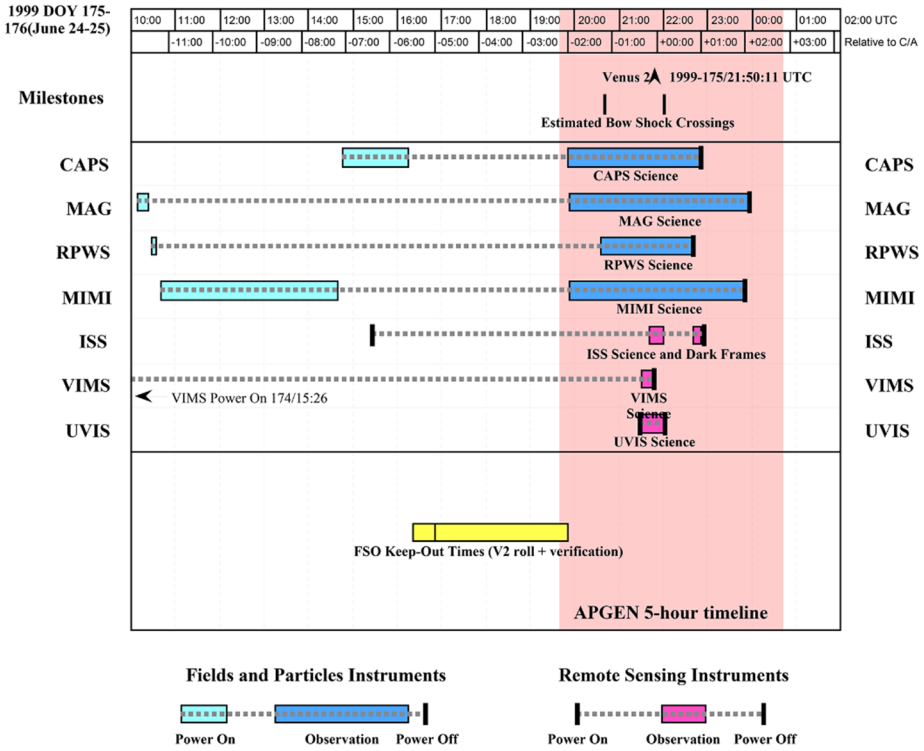

Figure 2.6-9. Cassini Venus-2 Science Timeline (C14 Sequence), Time Frame = 16 hours.

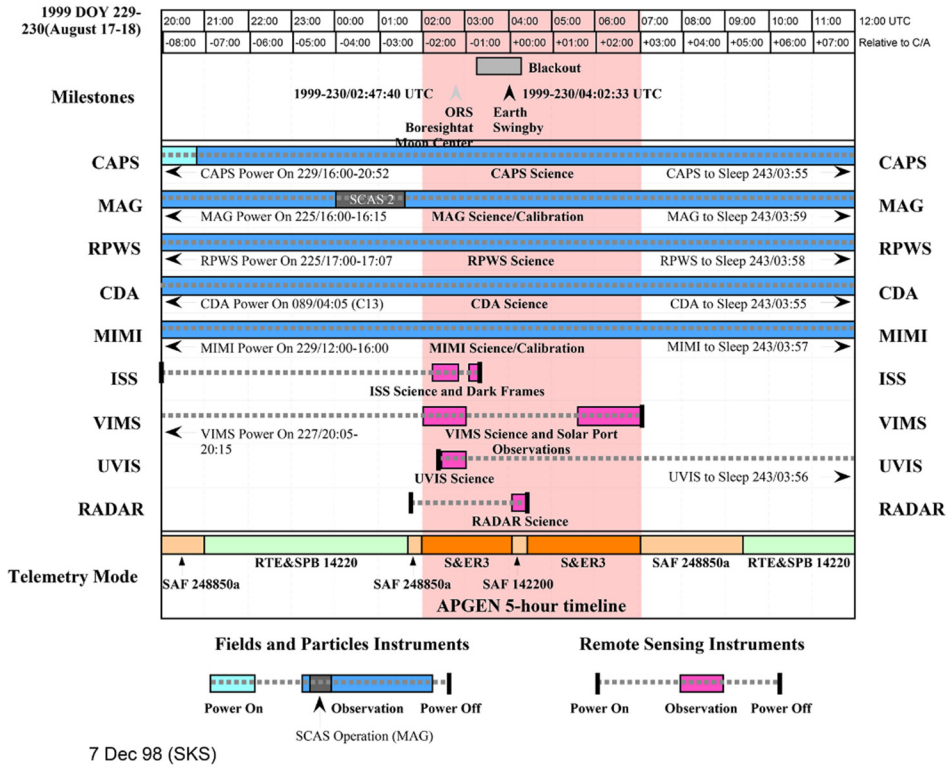

Figure 2.6-10. Cassini Earth Swing-by Science Timeline (C15 Sequence), Time Frame = 16 hours.

Second, the bipropellant system needed to be in blowdown mode for the leg, with no pyro events or any other propulsion activities not needed for TCMs or maintenance of a Sun-pointed attitude between maneuvers.

Third, the orientation of the spacecraft was constrained during the leg to roll the Huygens probe to the ecliptic in the leading direction of the heliocentric trajectory (the high-gain antenna remained Sun-pointed). That attitude was intended to shield some parts of the spacecraft from micrometeoroids, and was compatible with maintaining communications with the spacecraft through LGA-2, which points in the same roll direction as the probe.

Fourth, the spacecraft was required to be tracked continuously to rapidly detect any deviation from the desired course so that corrective actions could be taken if needed.

Fifth, for the final maneuver before the Earth swing-by, ground controllers had to uplink Cassini's magnitude and direction information (parameters) about 24 hours before the maneuver. And then Cassini had to zero out that information from the sequence immediately after the maneuver to protect against inadvertently repeating the maneuver.

The trajectory of this leg was biased away from the Earth aim point until the last 6.5 days. The most important effect of the biasing was to keep the ΔV magnitude required to impact the Earth greater than 1.6 meters per second over the entire leg, which nullified the effect of several small ΔV failure modes. The biasing strategy is detailed in the Earth Swing-by Plan and the Navigation Plan, and was crucial to meeting the Earth swing-by requirement.

The Venus-2–Earth portion of cruise contained not only demanding navigation coverage, but some of the worst conditions for telemetry as well. Continuous DSN coverage was required throughout the Venus-2–Earth leg. From the beginning of the sub-phase through Earth closest approach, the spacecraft used LGA-2. After the Earth flyby, the SPE angle dropped to low values again and the spacecraft used LGA-1 until the thermal constraints allowed the high-gain antenna to be used in February 2000. During the low-gain antenna coverage, ground controllers maintained an uplink/commanding bit-rate of at least 31.25 bps.

The spacecraft downlinked telemetry from each trajectory correction maneuver and flyby. Telemetry coverage for the Earth magnetotail passage, leading up to opposition, required several additional passes since the 14.22 kilobits per second capability was no longer available.

2.6.2.3.2 Mag Boom Deployment and Earth Flyby Calibrations

In the 24-hour period surrounding Earth flyby, the spacecraft passed in and out of the Earth's magnetosphere. This time was the most crucial for magnetometer alignment calibration to ensure that measurements at Saturn are accurate. Without the measurement of Earth's well-defined magnetic field, the measurement threshold of the instrument would be degraded enough to prevent the achievement of at least one major science goal (the measurement of Saturn's magnetic field orientation, or tilt, to an accuracy of 0.1°).

The Cassini Project also accepted activities for CAPS, MIMI, RPWS, Radio Science, and VIMS during the approach to Earth as well as ISS, UVIS, and VIMS observations using the Earth's moon. RADAR observed the Earth just after Earth closest approach.

Figure 2.6-11 shows the MAG boom deployment activities. Thermal restrictions limited the boom deployment to sometime after the last outbound passage of 0.97 AU (which was five days prior to Earth). The MAG boom deployment was scheduled for 44 hours prior to Earth. This timing avoided the scheduled pre-Earth maneuver periods and gave the navigation team enough time to determine whether or not an Earth avoidance contingency maneuver (TCM-12A) was necessary. If the contingency maneuver would have been necessary, the MAG boom deployment and science calibrations would have been dropped from the sequence.

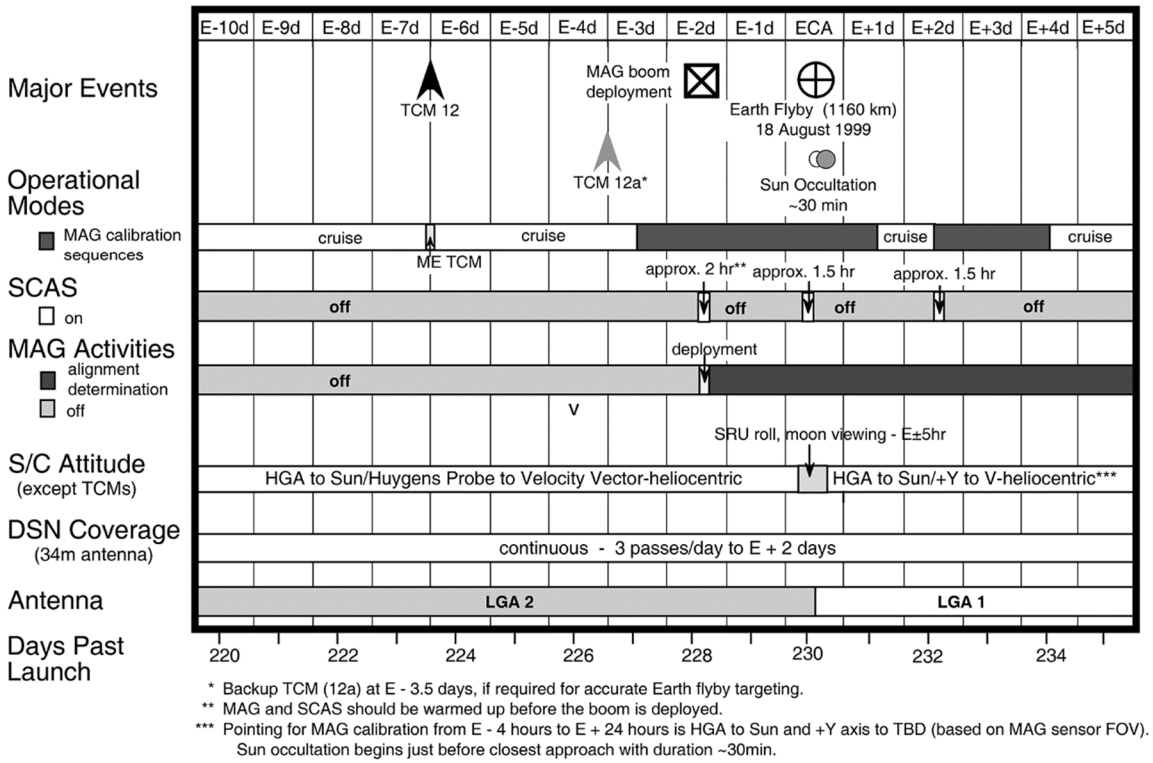

Figure 2.6-11. MAG Boom Deployment and Alignment Determination Activities.

The MAG calibration sequence was planned for a cumulative period of six days, broken up into two blocks. The MAG team used science calibration subsystem (SCAS) for about five hours during near-Earth MAG operation: two hours while the MAG boom was being deployed, about one and one-half hours before entering the Earth's magnetosphere, and one and one-half hours after exiting the Earth's magnetosphere. The purpose of SCAS is to create a known magnetic field for the magnetometer to measure. The high-gain antenna was constantly Sun-pointed throughout this time period, and Earth's magnetic field lay within the magnetometer's 45° field of view, which is along the spacecraft's X-axis.

2.6.2.3.3 Post-Earth Activities

After Earth closest approach, there were several other activities planned. The radar observation performed an end-to-end test of the radar system using Earth as a target. Several instruments finished up their Earth calibrations and science measurements and then remained on, except during TCM-13 (13 days after the Earth flyby) when they were in sleep mode. The instruments came on again after the trajectory correction maneuver and stayed on until just prior to the probe checkout 27 days after the Earth flyby, when they were turned off. The spacecraft turned the high-gain antenna toward Earth 24 days after the flyby, which allowed high data return on the high-gain antenna. The PCO-4 occurred just prior to the end of the high-gain antenna period. After four days on high-gain antenna, the spacecraft was turned back to Sun point, switched to LGA-1, and turned MAG and CDA on. MAG was turned off four days later. CDA remained on throughout the rest of the sequence.

2.6.2.4 Outer Cruise Phase

The outer cruise phase consists of sub-phases for high-gain antenna transition, ICO-2, Jupiter, and quiet cruise. This subsection provides an overview of the activities and plans in the outer cruise phase, which extends from November 8, 1999 (when the spacecraft reached a Sun range of 2.7 AU) to July 7, 2002 (about 2 years prior to SOI). At 2.7 AU, the high-gain antenna began continuous Earth-pointing, with the restriction that the Huygens probe was used as a Sun shield for the rest of the spacecraft, without violating probe thermal restrictions. A timeline for the outer cruise phase and the science cruise phase is shown in Figure 2.6-12.

The outer cruise navigation activities shown on the timeline include the seven trajectory correction maneuvers between the Earth flyby until just after the Jupiter flyby.

A second instrument checkout activity (ICO-2) was added for the summer of 2000, which required additional DSN passes to support science activities and reaction wheel unloading. The one planetary encounter in this phase was the flyby of Jupiter in December 2000. Extensive Jupiter science was accomplished which required additional DSN support. Science at Jupiter was an opportunity to test Saturn observation techniques. Data rates during this phase were much less tightly constrained than during most of the previous mission phases, because of the final transition to exclusive use of the high-gain antenna, which was made on February 1, 2000. This fact made it much easier to perform cruise science and instrument checkout activities.

The outer cruise navigation activities shown on the timeline include the seven trajectory correction maneuvers between the Earth flyby until just after the Jupiter flyby. DSN tracking coverage is also shown, and is driven in large measure by the navigation requirements for radiometric data to determine the spacecraft trajectory and plan the trajectory correction maneuvers. Five of these maneuvers (TCM-14 to TCM-18) occur in the outer cruise phase. The

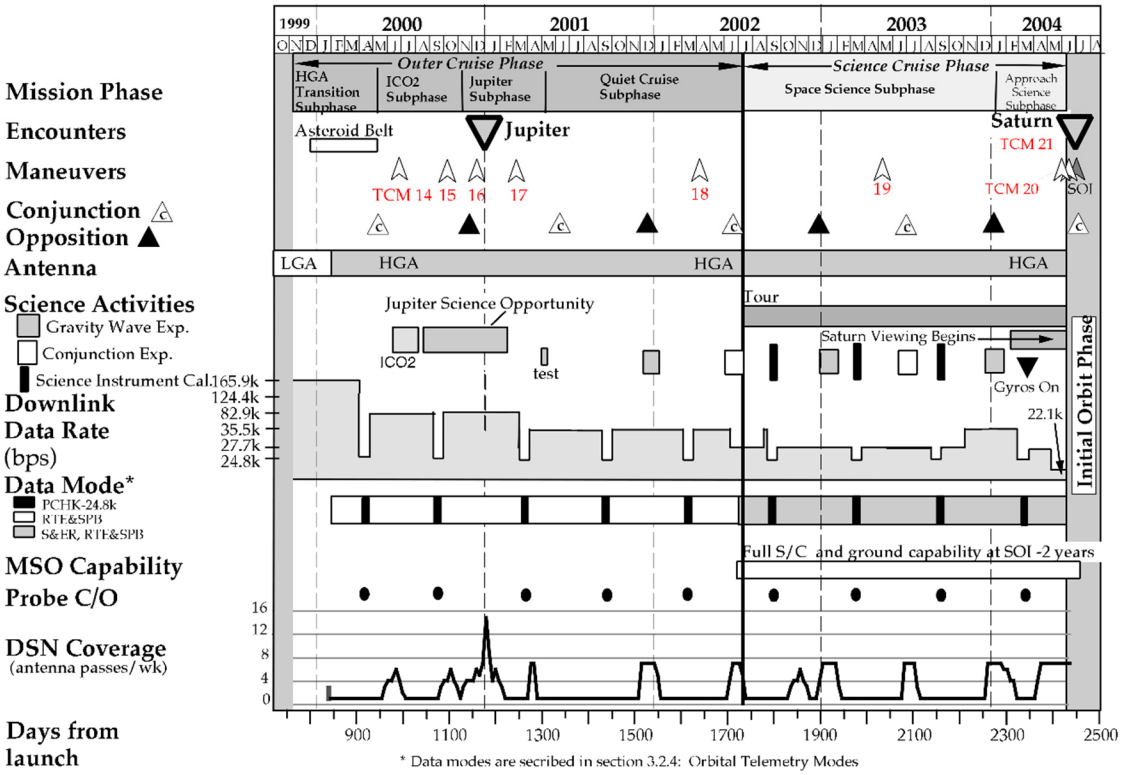

Figure 2.6-12. Cassini Outer Cruise/Science Cruise Phases.

DSN tracking for navigation data was typically one pass per week, with increased tracking around the maneuvers (TCM-21 to TCM-14) and the Jupiter flyby science observation period (October 1, 2000–April 29, 2001).

The engineering maintenance activities continued from the inner cruise phase including EGA exercise, RWA exercise, backup assisted load format injection loader (BAIL) maintenance, SRU calibration, and PMS flushing maneuver.

There were five scheduled probe checkouts in outer cruise. PCO-5 was performed February 2, 2000, one day after the spacecraft switched to the high-gain antenna. This PCO was the first time a probe checkout was performed with the Sun outside the high-gain antenna's main beam. This provided unique circumstances to investigate DWE performance in a noise-free environment.

PCO 6 was performed July 28, 2000. This was moved earlier in time to allow science to use templates during the September timeframe.

PCO 7 was performed on March 22, at the end of the majority of Jupiter observations.

PCO 8 was scheduled in September 2001, in C28.

PCO 9 occurred approximately 6 months after PCO-8.

2.6.2.5 Spacecraft High-Gain Antenna Checkout Sub-phase

The sub-phase followed the Venus-2–Earth sub-phase and preceded the ICO-2 sub-phase, and incorporated sequences C17 to C19. During this sub-phase, the ISS and VIMS instruments' decontamination heaters were on, CDA executed dust calibrations, and MAPS performed some observations after pointing the high-gain antenna to Earth.

During the initial part of the sub-phase (C17 and part of C18), the spacecraft communicated with Earth via LGA-1, but the spacecraft was the farthest it had ever been from Earth and would soon transition to the high-gain antenna for regular use. As a result, data rates before the transition were relatively low and spacecraft activities were kept to a minimum. Sequence C17 included standard maintenance activities and one PEM. Sequence C17 also included the Y2K turnover, which did not cause any problems. To be safe, however, all uplinks and critical activities were avoided for three days around the century change date. Activities during the LGA-1 portion of C18 included a PIM, ORS observations (by ISS, VIMS, and UVIS) of the asteroid Masursky near closest approach (at 1,634,000 km), and ISS dark frame calibration images directly following the ORS observations.

The high-gain antenna was turned toward Earth for regular use on February 1, 2000, during C18. With the greater telemetry capabilities of the high-gain antenna, the spacecraft performed several activities during the rest of C18: playback of the Masursky data and ISS dark frames, a probe checkout, a probe S-band relay test, a telemetry-ranging interference test, MAG calibrations, and a PEM. The spacecraft also began MAPS observations (by CAPS, CDA, MAG, MIMI, and RPWS) within a few days after transitioning to the high-gain antenna.

The first six weeks of C19 were used for a checkout of new flight software. The AACS version A7 software was uploaded near the beginning of this period, and the first two weeks were devoted to AACS tests. The next four weeks were originally scheduled for CDS tests of version 7.0. However, these tests were delayed to late July and August of 2000 to allow time for additional regression testing. During the AACS checkout period, MAPS activity ceased, although ISS and VIMS decontamination heaters remained on. Several activities took place during the last three weeks of C19: the MAPS observations resumed and continued throughout the sequence, three RSS activities (high-gain antenna pattern calibration, high-gain antenna boresight calibration, and USO characterization), the CIRS cooler cover release, and a PIMAll activities were successful.

A few days before the end of sequence C19, the command loss timer setting was increased slightly, to account for the 10-day period at the beginning of sequence C20 during which the geometry of superior conjunction made commanding problematic.

2.6.2.6 Instrument Checkout-2 Sub-phase

The second instrument checkout sub-phase was scheduled from May 6, 2000 to November 5, 2000, after the spacecraft had begun using the high-gain antenna and the spacecraft office

completed their engineering checkout activities. During ICO-2, the flight team performed instrument checkouts that required reaction wheel capability and any instrument checkouts that were not successfully completed during ICO-1. In addition, pre-Jupiter science was requested during this sub-phase. The CDS flight software V7 uplink and checkout, which was delayed from March, was rescheduled to late July through early September 2000, causing many of the ICO-2 activities to be rescheduled into a shorter and denser period. Some activities were postponed until after the Jupiter observations were completed in 2001.

The ICO-2 sub-phase began with a superior conjunction, which precluded early science or engineering activities. MAPS instruments remained on to prevent cycling the instruments but data return was not assumed during conjunction. Two trajectory correction maneuvers were scheduled for Jupiter targeting, in June and September. The latter of the two was moved out of October to allow for Jupiter science to begin using a repeatable template.

Engineering activities included the continuous use of reaction wheels and, beginning October 1, 2000, Cassini's dual SSRs. There were no scheduled instrument PIMs done during ICO-2 since all instruments had other activities that accomplished this function. Other engineering activities included two RWA friction tests, two PEMs, and an SRU calibration.

Science activities began with the MAPS instruments, continuing from sequence C19. New flight software was loaded for eight instruments in late May, and a CDA FSW update was done in September. New quiet tests while operating on reaction wheels, for most instruments were done in July, although the RSS quiet tests were done in September and radar-related tests were done in late June. A probe checkout occurred in late July.

Spacecraft turns were done for radar observations of the Sun and Jupiter in June and again in September. The star Alpha Piscis Austrinus (Fomalhaut) was also observed in September by VIMS with ISS and UVIS doing ride-along science. No other science turns were scheduled until October. On October 1, Jupiter science began using a repeating five-day template with 11 turns per five-day period, including two downlinks. The turns in the five-day template involved four orientations:

- ORS boresights to Jupiter, Z-axis parallel to ecliptic
- High-gain antenna to Sun, rolling about Z-axis
- Probe to Sun, rotating about X-axis
- High-gain antenna to Earth, probe offset from Sun for CDA, not rotating, downlink orientation

Additional instrument activities for calibration, checkout, and science were also scheduled.

2.6.2.7 Jupiter Sub-phase

The Jupiter flyby occurred on December 30, 2000, at an altitude of about 9.7 million kilometers with a velocity relative to Jupiter of about 0.4 km per second. This gravity assist rotated the trajectory 12° and increased the heliocentric velocity by 2 km per second. The Jupiter relative speed at closest approach was about 11.6 km per second. At this distance, Jupiter filled the NAC field of view. The spacecraft performed extensive Jupiter science, which required additional support from the DSN: templates using up to two passes every five days, and a maximum of one pass every 30 hours in the 10 days on either side of closest approach. The mission studied Jupiter with Cassini's science instruments to test how to build and execute viable Saturn sequences. The Jupiter sub-phase was from November 6, 2000 to April 29, 2001, and incorporated sequences C23 to C25. However, Jupiter remote sensing observations actually begin on October 1, 2000, in sequence C22.

Figure 2.6-13 illustrates the flyby geometry for Cassini and for the previous Voyager missions. Although Cassini was not assumed to pass through Jupiter's magnetopause, it actually recorded six crossings as well as 44 bowshock crossings during the Jupiter sub-phase.

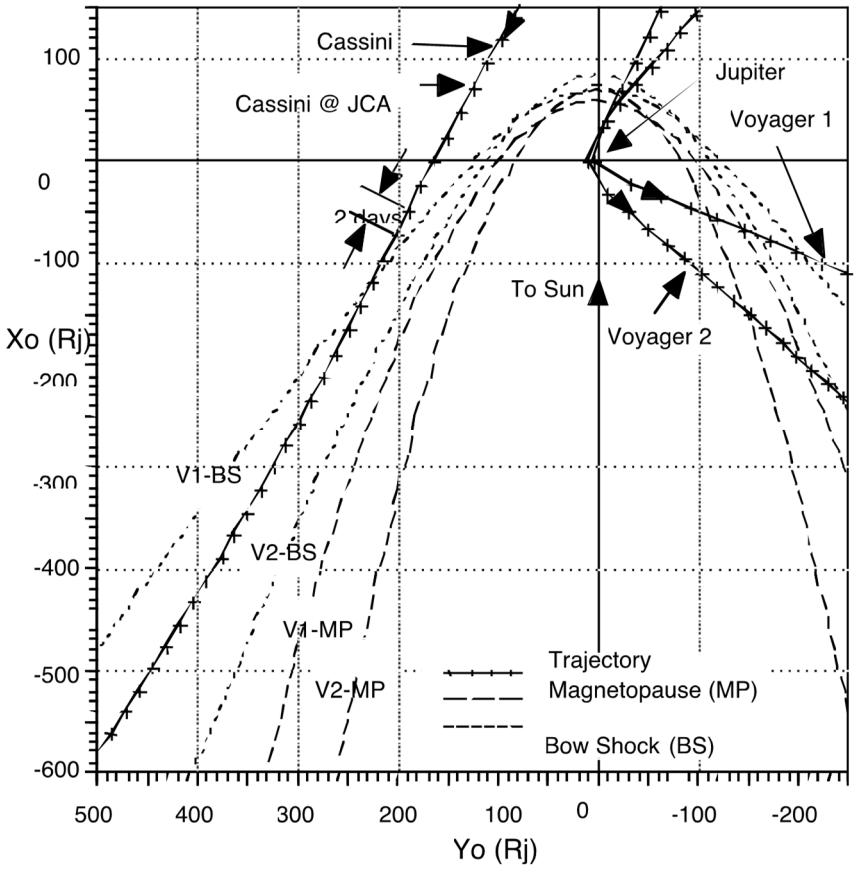

Figure 2.6-13. Cassini-Jupiter magnetotail passages.

The spacecraft performed TCM-17 in sequence C24 and was executed on February 28, 2001, to correct for Jupiter perturbation errors. During Jupiter science operations, the RPWS instrument was calibrated in small blocks, each lasting 10 hours (five blocks before the Jupiter flyby and four after the flyby).

During passage through Jupiter's magnetotail, the spacecraft's reaction wheels and dual solid-state recorders were in continuous use. The Cassini team scheduled no instrument PIMs during the Jupiter sub-phase since all instruments had other activities that accomplished that function. Other engineering activities included: two PEMs, star ID extended bodies test, and RWA unloads. The team performed a Huygens probe checkout on March 22, 2001, following a 5-day probe relay test in early February (in place of a 5-day science template). The spacecraft executed a radar radiometer calibration 89 days after the Jupiter flyby. Beginning 48 days before Jupiter flyby, the spacecraft Ka-band was turned on for the rest of Jupiter sub-phase to perform the Ka-band upgrade task with DSS-25. Most of the RSS activities scheduled between mid-March and the end of April 2001 were in preparation for the gravitational wave experiment (GWE) test #1 performed at the beginning of May 2001. The preparation work for the GWE test included USO characterization, repeat of ICO test E, 3-link test, high-gain antenna boresight calibration, Operational Interface Test (OIT) and its follow-up test, and high-gain antenna pattern calibration. The spacecraft also performed a successful in-flight test for the RTE and science playback (SPB) 35.5 telemetry mode in sequence C25 in preparation for using the new mode extensively in sequence C26.

Jupiter science observations were scheduled between Jupiter flyby − 90 days and Jupiter flyby + 82 days. This period of Jupiter science observations was divided into A, B, C, D, E, F, and G Jupiter science phases. Each of these science phases contained specific Jupiter science objectives and observations. Phase A occurred during the ICO-2 sub-phase.

The Jupiter sub-phase science activities began with science phase B; the first 10 days (Jupiter flyby − 55 days to Jupiter flyby − 45 days) contained two more instances of the late ICO-2 (Phase A) five-day science template. Sequence C23 incorporated phases B, C, D, and E, and covered from Jupiter flyby − 55 days to Jupiter flyby + 15 days. The major science activities during these science phases, except for the science observations continued from the late ICO-2 five-day template, included 2 × 2 mosaics of Jupiter, ring movies, atmospheric and Europa opposition surge observations, north–south maps of Jupiter, Io eclipse observations, dust stream detection, coordinated Hubble Space Telescope and Cassini observations, and the observations of Callisto opposition surge and Himalia closest approach. When the spacecraft neared closest approach, resolution improved and the phase angle changed significantly, satellite and ring observations became more important. During this time frame the spacecraft performed more atmospheric, ring, and satellite observations, such as: the ORS boresights slewed slowly from north to south then stepped in a 1 × 3 mosaic from south to north; 3 × 2 mosaic was executed with full filter set and a 3 × 3 mosaic designed to obtain the best Jupiter picture; Io thermal studies and Io torus monitoring; and satellite eclipse observations. The coordinated Galileo and Cassini observations for Io dust stream and Io eclipses were performed during this closest approach time frame. The solar wind monitoring, which began in Jupiter science phase A, continued in C23. From Jupiter flyby to the

end of C23, the most important science objectives include the coordinated Hubble and Cassini observations of Jupiter's aurora and solar wind, phase angle coverage of Jupiter's atmosphere and ring, coordinated Galileo ring and satellite observations, and the radar observation of Jupiter's synchrotron emission.

The spacecraft experienced a problem with the RWAs on December 16, 2000. Increased friction on one of the wheels caused the spacecraft to autonomously switch to the RCS for attitude control. With the switch to RCS, the spacecraft used more hydrazine. Two of the four joint CAPS-Hubble observations, a Jupiter north–south map, the Himalia "flyby," and a UVIS torus observation were all executed on RCS before the sequence was terminated on December 19, 2000. MAPS data continued to be recorded at a reduced rate. All other planned science activities were cancelled until December 29, when they were resumed.

The reaction wheels began being used again for attitude control on December 22, with constraints imposed to avoid low RPM regions. This was accomplished by biasing the wheels. Continued testing by AACS personnel suggested the anomaly was a transient event so the sequence was restarted on December 29. Subsequent tests and studies eventually led to a project directive to use the RCS system as primary control beginning with sequence C27.

Observations lost due to the anomaly include four Jupiter north–south maps, two CAPS solar wind measurements, numerous Galilean satellite observations at various longitude and phase angles, Europa eclipse, numerous ring and Io torus measurements, and Jupiter feature tracks.

During this time frame, magnetospheric science was one of the most important science objectives since Cassini was in and out of Jupiter's magnetosheath while Galileo was in the solar wind.

The science phases F and G were executed from Jupiter flyby + 15 days to Jupiter flyby + 82 days. Phase F lasted the entire C24 sequence, and Phase G filled the first 2 weeks of the C25 sequence. During this time frame, magnetospheric science was one of the most important science objectives since Cassini was in and out of Jupiter's magnetosheath while Galileo was in the solar wind. This enabled the same type of science as inbound when Cassini was in the solar wind while Galileo was in the magnetosphere. Major science observations for science Phases F and G included coordinated Cassini/Hubble for joint observations of Jupiter's aurora, the outbound crescent movie, a search for lightning, and continuous monitoring of Io's torus emissions and dust streams.

A slightly modified version of the tour ORS operational mode was used for all of the Jupiter science phases (A–G). RADAR activities were performed in SAF-142a and SAF-248 telemetry modes, and all non-radar observation periods were performed in the S&ER-3 telemetry mode.

2.6.2.8 Quiet Cruise Sub-phase

The quiet cruise sub-phase is a 14-month period that started at the end of the Jupiter sub-phase and ended two years before SOI. During this sub-phase, routine maintenance, engineering, and navigation functions were carried out. One GWE was planned for December 2001 and one conjunction experiment for June 2002. The GWE preparation included two 1-week test periods starting in early May 2001 and August 2001.

Many activities that were deferred from ICO-2 and were not accomplished during Jupiter activities were scheduled for quiet cruise. In addition, newly proposed activities for both science and engineering activities were considered for quiet cruise activities. The mission integrated science and engineering activities during the science planning virtual team activity, which began in January 2001. Templates were again used to efficiently plan science and engineering activities for quiet cruise. One change from the Jupiter sub-phase was that data was recorded on only one SSR.

A new telemetry mode of 35.5 kbps was implemented just prior to the start of quiet cruise sub-phase to allow more efficient use of the downlink capability, which was diminishing due to geometry. The Program Manager authorized increasing the requested DSN passes to a minimum of two passes per week to accommodate the increased science activity. Additional passes were also requested for GWEs, GWE tests, conjunction experiment, and TCM-18. Other increases in DSN passes were expected for radio science activities, AACS activities, CDS new FSW, and probe tests. All new requests were documented in the PSLA.

All cruise activities beginning in May 2000 assumed RWA for attitude control. Since the anomalous behavior in December 2000, tests and studies led to a Program decision to use RCS as the primary attitude control system. RWA was allowed for certain activities that required increased stability or pointing accuracy, e.g., GWE and RSS tests. This restriction was in force beginning with sequence C27. Other requests for turns on thrusters required approval by the Program Manager.

2.6.2.8.1 Gravitational Wave Experiments

The project requirements called for support of GWEs while en route to Saturn near at least three oppositions, for periods of at least 40 days each, and with Ka-band tracking coverage from Goldstone of one pass per day. Additional tracking was requested using X-band links with DSN stations at Madrid and Canberra. These experiments were scheduled for the three oppositions after the Jupiter flyby in December 2001, December 2002, and January 2004. However, the 2004 GWE was rescheduled to begin October 20, 2003, to relieve some of the DSN resource contention in January 2004 due to Mars missions and other projects.

During GWEs, the spacecraft was configured into an operational mode with X-band and Ka-band uplinks, and X-band and Ka-band downlinks. The X-band downlink was required for engineering telemetry, including high-gain antenna inertial pointing. Attitude control was on reaction wheels for these 40-day periods. The spacecraft was rolled 180° about the Earth line when needed in order to unload the reaction wheels momentum without having to use thrusters. Since the RTG

thermal torque and the magnetometer-boom solar torque are body fixed, the reaction wheel momentum change due to the X- and Y-axis torque reverses direction under the effect of the 180° roll. The Z-axis momentum continued to accumulate, but the rate was acceptably low. Keeping the turn rate below 180° per four hours assured that the Doppler stability was not compromised. The turns were expected to be performed a few times during each GWE.

Within a month before each GWE, GWE test, and conjunction experiment, there was a high-gain antenna electrical boresight peak calibration. This calibration lasted two hours and included X- and Ka-bands for the GWEs and S-, X-, and Ka-bands for the conjunction experiments. These calibrations required telemetry modulation be turned off. Note that GWEs and conjunction experiments extended into the science cruise phase.

2.6.2.8.2 Conjunction Experiments

The project requirements call for support of conjunction experiments whose purpose is to perform tests of general relativity and to study the solar corona. These experiments were conducted while en route to Saturn, near at least two solar conjunctions, for periods of at least 30 days each, and with Ka-band tracking coverage from Goldstone of one pass per day. Additional tracking was requested at S-band for the study of the solar corona. These experiments were scheduled during the two conjunctions preceding SOI, from June 6, 2002 to July 6, 2002, and from June 16, 2003 to July 16, 2003. The spacecraft was configured in the RSS2/RWA operational mode. For complete calibration of the plasma noise during the general relativity test, X-band and Ka-band uplinks and X-band and Ka-band downlinks were used. The solar corona study required X-band uplink and simultaneous X-band and S-band downlink (for SEP > 2°) and X-band uplink and simultaneous X-band and Ka-band downlink (for SEP ≤ 2°). The team acquired Doppler and range (at X-band) data throughout the conjunction experiment, and the spacecraft-maintained attitude control using reaction wheels during these 30-day periods.

2.6.2.9 Science Cruise Phase

Cruise science and instrument calibrations continued during the science cruise phase, which began on July 8, 2002 and continued through May 15, 2004. Sub-phase activities included instrument calibrations, late cruise science, and preparation for Phoebe flyby science and Saturn approach science. Two sub-phases comprised this phase: space science and approach science. In spring of 2003, new flight software allowed engineering data to be sent to a separate partition on the SSR so that not all engineering data needed to be downlinked on every pass. The impact of this was to increase the SSR data volume available for science data. Mission and science operations software for science pointing, timeline analysis, opportunity analysis (geometric observation models), resource allocation, science data records, etc., were all to be completed by January 2004 to support the approach science sub-phase. The Cassini Mission maintained a complete list of mission and science operations and science deliverables throughout the mission.

2.6.2.9.1 Space Science Sub-phase

The space science sub-phase began on July 8, 2002 and ran through January 10, 2004. TCM-18 and TCM-19 occurred during the space science sub-phase. Activities during this period were requested in the post-Jupiter final scoping package and the space science scoping package. These activities included:

- Two GWEs scheduled during the space science sub-phase for December 2002 and October 2003.
- The second conjunction experiment occurred during the space science sub-phase and was scheduled for June 2003 to July 2003.
- An SOI readiness test to simulate the activities associated with SOI. This took place about one year prior to SOI (June 30, 2004).
- A probe relay operational readiness test in November 2003. This included orienting the orbiter to point the high-gain antenna to a simulation of the probe touchdown point on the rotating surface of Titan.

2.6.2.9.2 Approach Science Sub-phase

The approach science sub-phase covered the period from January 12 through May 15, 2004. At that point in the trajectory, the spacecraft had long since left the Jovian system and was approaching Saturn at a rate of 5 km per second. Most of the activities during that 4-month period were Saturn science observations and preparation for the Phoebe flyby, SOI, and tour operations.

The reaction wheels were turned on for continuous use about six months prior to SOI to provide a more stable viewing platform. Around the same time, the imaging instruments began atmospheric imaging, and making long-term atmospheric movies. CIRS began long integrations of Saturn's disk.

About four months prior to SOI, Saturn filled one third of the NAC field of view and one half of the CIRS far-infrared (FIR) field of view. The Saturn approach was made toward the morning terminator at a phase angle of about 75°, and VIMS gathered data on the temperature difference across Saturn's terminator. UVIS scans of the Saturn system began about three months prior to SOI. Fields, particles, and waves instruments also collected solar wind information and recorded Saturn emissions as the spacecraft neared the planet. Science data gathered during this period was stored on the SSR and transmitted back to Earth. Tracking coverage at the start of the sub-phase was increased to three passes per week even though the first two months were heavily contested with other projects for DSN resources. Daily tracking coverage began 90 days prior to SOI.

2.6.3 ORBITAL OPERATIONS PHASE

2.6.3.1 Saturn Approach and Phoebe

The first event of the tour (though it occurs before SOI) was a targeted encounter with Phoebe 20 days prior to the SOI burn. Among planetary satellites, Saturn's outermost satellite is unusual. Phoebe has a rotation period of about 9.4 hours, an orbital period of 550 days, and a diameter of about 220 km. Its inclined, retrograde, chaotic orbit is strong evidence that the moon is a captured object. Evidence from albedo measurements suggested Phoebe would have craters on its surface. Determining whether or not Phoebe is asteroidal in character was an important scientific goal. Determining the density of Phoebe was important in meeting this goal. As this was the only possible encounter with Phoebe, the data acquisition opportunity was unique. The science operating modes used for this flyby were 1) the ORS mode to allow ISS, CIRS, UVIS, and VIMS observations as well as a more accurate determination of the Phoebe rotation period and 2) the RSS2/RWA mode to allow mass determination. The flyby of Phoebe occurred on June 11, 2004, 19 days before SOI. The Phoebe closest approach was at 2,000 km altitude at 19:32 UTC, at a phase angle of 155°.

The imaging characteristics are shown in Figure 2.6-14. Beginning about 10 hours from Phoebe, the NAC FOV was rapidly filled. At closest approach, the resolution of Phoebe was about

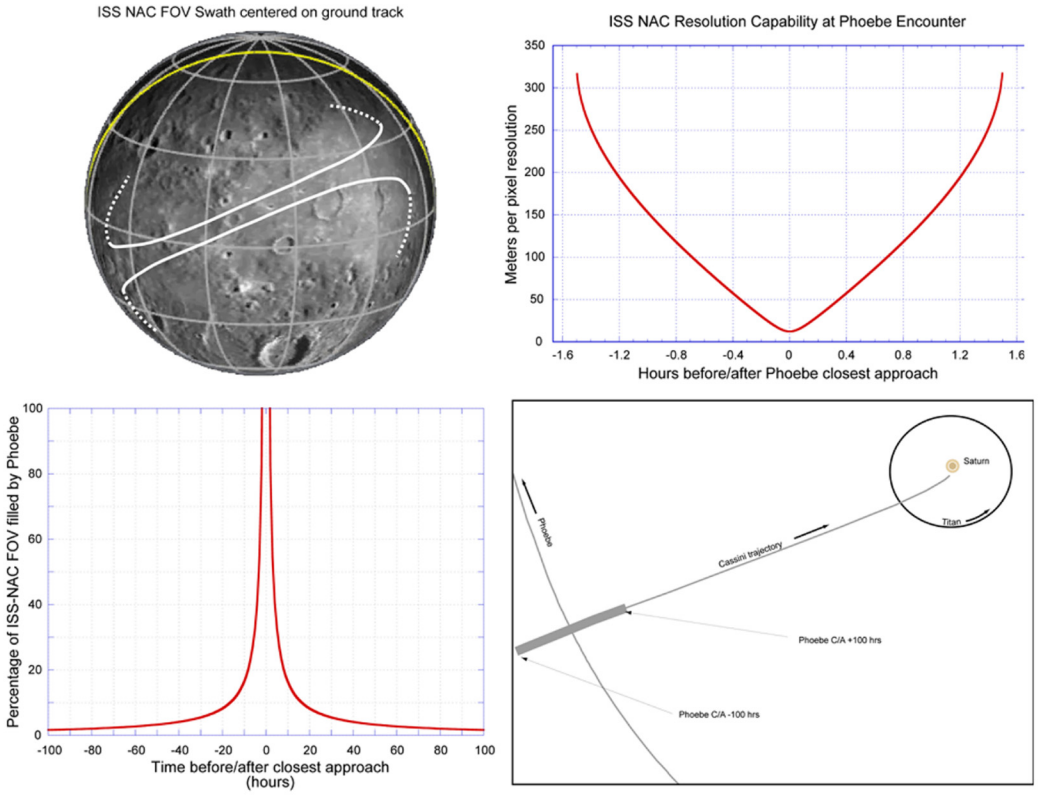

Figure 2.6-14. Characteristics of Phoebe flyby.

12 meters per pixel, a resolution 1,500 times better than Voyager and excellent for morphologic mapping and for studying the geologic character of Phoebe, including surface mapping. A complete map of Phoebe was desired with the range less than 160,000 km.

During the approach to Saturn, the spacecraft performed three approach trajectory correction maneuvers. TCM-20 is the final Phoebe targeting maneuver and was done with pressurized tanks by firing pyro valve 25 and opening latch valve 10. After TCM-20 was complete, LV-10 was closed until 70 seconds before the SOI burn begins. TCM-21 ensured that the B-plane delivery error at the orbit insertion point was less than 130 km (one sigma). The maneuver needed to be done at least 14 days before SOI because the fault protection recovery period (based on Magellan and Voyager experience) can be as long as two weeks if the fault is difficult to diagnose and/or new software uplinks are required. There was another trajectory course maneuver opportunity at S − 10 days, which was available if needed. Two SSRs were used for recording science data beginning June 1, 2004.

2.6.3.2 Saturn Orbit Insertion

As Cassini approached Saturn, it executed the first targeted flyby of the tour of Phoebe on June 11, 2004, 19 days before SOI. The arrival date and trajectory were specifically selected to accommodate this flyby and was the only opportunity during the mission (prime and extended) to study Phoebe at close range. The altitude at closest approach was 2,000 km, offering resolution up to about 10 meters per pixel, many times better than Voyager. The flyby was highly successful.

Saturn Orbit Insertion occurred on June 30, 2004 (Pacific Time, July 1 UTC), where the spacecraft made its closest approach to Saturn's surface during the Prime Mission at an altitude of only 0.3 Saturn radii (18,000 km). Due to this unique opportunity, the 97-minute 626 m/s SOI burn required to place Cassini in orbit around Saturn executed earlier than its optimal point centered on periapsis, and instead ended at periapsis, allowing unique science observations of Saturn's magnetosphere and the main rings immediately after closest approach, and before the descending ring-plane crossing. Due to concerns about ring particle impacts, a protective attitude of HGA to dust ram was assumed for both the ascending (before the SOI burn) and descending ring-plane crossings, and the main engine cover was closed after the burn. Furthermore, an eight-day quiet period was observed prior to SOI, where turns, instrument articulations, and power state changes directly unrelated to orbit insertion were not permitted. SOI science and engineering data were played back twice to ensure ground receipt and make room for post-SOI observations during a distant Titan encounter (named "T0"). Figure 2.6-15 below depicts the major events performed during the approach to Saturn.

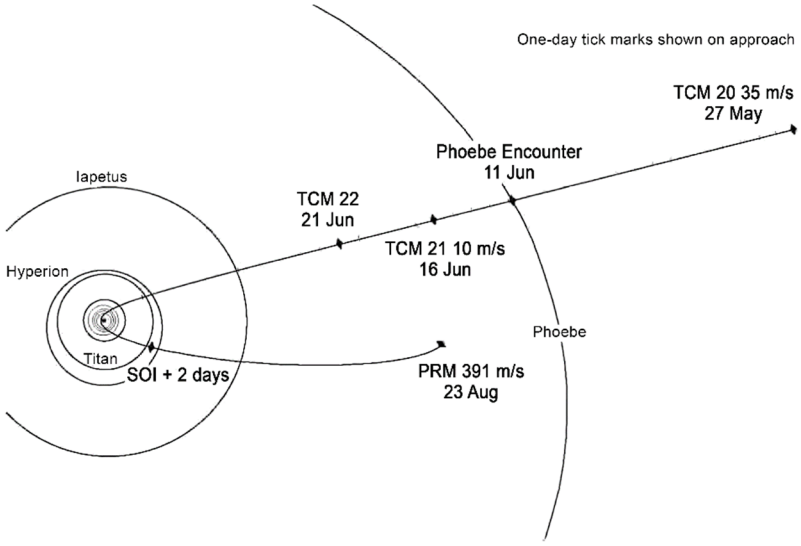

Figure 2.6-15. Cassini-Huygens Saturn Approach and Insertion.

2.6.3.2.1 SOI Overview

Figure 2.6-16 shows the SOI events timeline. After the Phoebe flyby and clean-up trajectory course maneuvers, there was a quiet period that began eight days before the SOI burn. DSN coverage during approach was one pass per day, with continuous coverage on trajectory course maneuver days. Continuous coverage began two days prior to SOI and continued through one day following SOI. The mission considered extending the continuous coverage on both sides of the burn.

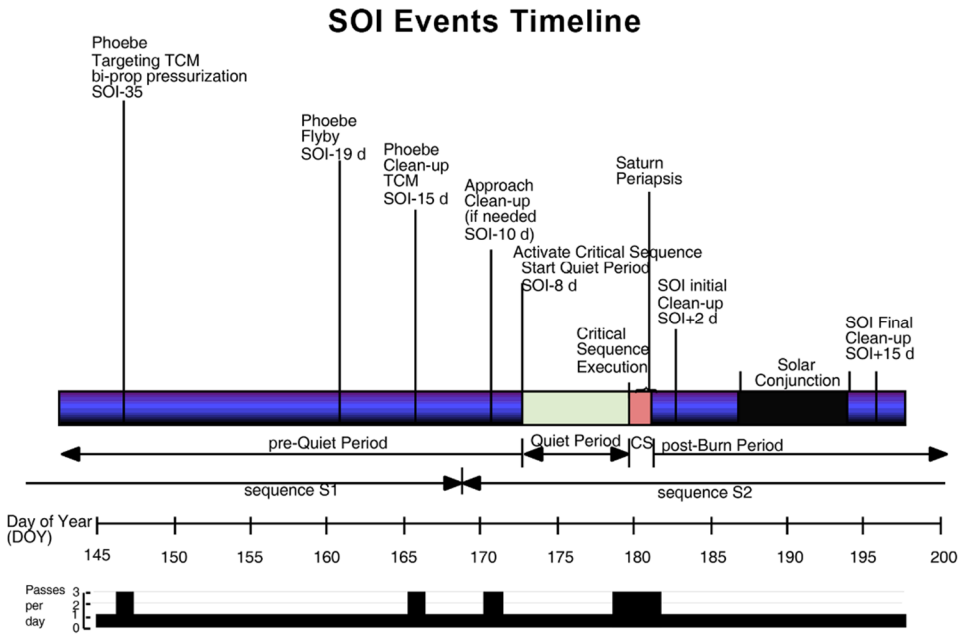

Figure 2.6-16. SOI Events Timeline.

Before the critical sequence began, the spacecraft turned off reaction wheel control and went to thruster attitude control. This allowed turns for safing, SOI burn orientation, and science viewing to be done faster than if on wheels. During the quiet period and burn itself, only FPP instruments were on. Other instruments were either in sleep or off to provide power margins for the critical burn event. Spacecraft vibrations during the main engine firing were likely to degrade remote sensing in any case.

2.6.3.2.2 Initial Orbit

After SOI, the spacecraft performed a pair of cleanup maneuvers to correct for errors in the SOI burn. The first manuever was immediately before the superior conjunction, two days after SOI, and the second was after conjunction, 16 days after SOI. The initial cleanup was based on only one day of tracking after the SOI burn was complete. The trajectory course maneuver could not be delayed much further due to solar noise, which degraded Doppler tracking around the conjunction period (July 5–12, 2004).

Beginning with the periapsis raise maneuver 53 days after SOI, the spacecraft executed a sequence of nine maneuvers to target the Huygens probe and orbiter trajectories for the proper entry and flyby conditions to ensure that Huygens could successfully make its science observations and relay those data to the Cassini orbiter via radio.

Three new Titan encounters, Ta, Tb, and Tc, were designed with a distant flyby during probe delivery on Tc. These three initial Titan encounters replace the first two Titan encounters of the T18-5 tour. If the Huygens probe couldn't be delivered at the Tc flyby, a contingency trajectory existed that allowed a second chance to deliver the probe. This contingency retargeted Tc to a lower altitude and introduced a new distant flyby, Td, for probe delivery. However, this contingency would cause Cassini to fall off of the tour and unable to return to the T18-5 tour until the 13TI (T6) flyby.

The periapsis trajectory course maneuver required 392 m/s and the orbiter deflection maneuver (ODM) required 26 m/s. In addition to the trajectory course maneuvers, the initial orbit also contained three probe checkouts. The data from the last pre-separation checkout, along with orbiter status, determined whether or not to target to the Titan impact point at the Titan-1 flyby. DSN coverage after SOI was generally one pass per day. Additional coverage was required for unique events including maneuvers. Continuous coverage was required on maneuver days. Additional details on the probe mission are given in Section 2.6.4.

The tour consisted of 75 orbits of Saturn with various orientations, orbital periods ranging from 7 to 118 days, and Saturn-centered periapsis radii ranging from about 2.7 to 15.6 R_S (Saturn radii). Orbital inclination with respect to Saturn's equator ranged from 0–75.6°, providing opportunities for ring imaging, magnetospheric coverage, and radio (Earth), solar, and stellar occultations of Saturn, Titan, and the ring system. A total of 45 targeted Titan flybys occurred during the tour. Of these, 41 had flyby altitudes less than 2,800 km and two had flyby altitudes greater than 10,000 km. Titan flybys were used to control the spacecraft's orbit about Saturn as well as for Titan science

acquisition. The tour also contained 13 close flybys of icy satellites and 30 additional distant flybys of icy satellites within 100,000 km.

After SOI, Saturn tour science gathering began in earnest. However, much of the focus was on preparations for successful release and descent of the Huygens probe to the surface of Titan.

2.6.4 HUYGENS PROBE MISSION

The final checkout of the Huygens probe was made 31 days before its separation from the orbiter, and this supports a go/no-go decision to proceed with the probe mission at the Titan-C encounter. Twenty-eight days before separation and 48 days before entry, a depassivation activity was scheduled for the probe batteries to ensure that they were fully functional for entry and descent. The probe targeting maneuver was then executed on December 18, 2004, two days before separation, placing the Huygens spacecraft on an impacting trajectory with Titan. Final commands to the probe were sent three days later to complete preparations for release, and this included setting the probe coast timer.

The spin-stabilized probe was targeted for a southern latitude landing site on the day side of Titan.

Separation of the Huygens probe then occurred on December 24, 2004, which was 20 days before entry to Titan on January 14, 2005. The probe spin/eject device (SED) separated the probe with a relative speed of 0.3–0.4 m/s and spun it up to a rate of >5 rpm. At separation, the probe axis was pointed to achieve a zero-angle-of-attack entry and such that the velocity increment by the SED springs provided the final targeting to the entry aim-point. The last two maneuvers of the orbiter before probe entry provided its final targeting to the required aim-point to achieve the radio relay link geometry and to obtain the required gravity assist from Titan for subsequent encounters in the orbital tour. The first of these maneuvers was the ODM, which was executed four days after separation, or E-17 days. This maneuver of about 26 m/s targeted the orbiter for the planned flyby of Titan at an altitude of 60,000 km and delayed the orbiter's closest approach to occur just over two hours after probe entry. The relative position of the orbiter with respect to Titan during probe entry and descent provided a view toward the probe for approximately four and a half hours after entry. The orbiter high-gain antenna was pointed toward the predicted probe landing site to capture the probe telemetry during descent (maximum duration 150 minutes) and for approximately two hours after probe touchdown.

The spin-stabilized probe was targeted for a southern latitude landing site on the day side of Titan. To minimize trajectory dispersion and thus enhance data relay link performance, and to avoid probe skip-out, the probe entry angle into the atmosphere was relatively steep at 64°. The term "entry" generally refers to the arrival of the probe at the interface altitude of 1,270 km, which defines the interface point for probe targeting requirements. The probe did not experience significant atmospheric drag until a much lower altitude. The B-plane angle of the probe aim point was −190°. This resulted in a landing site at about 10.7° (±7°) N and 160° (±13°) E. The large east–west uncertainty in the landing site was driven by uncertainties in the Titan-relative ephemeris and in the

magnitude and direction of zonal winds on Titan. No Earth or Sun occultations by Titan (as seen from either the probe or orbiter) occurred during the probe-relay flyby.

2.6.4.1 Probe Separation

Successful separation of the Huygens probe from the Cassini orbiter was defined as a separation that did not jeopardize the functional or structural integrity of the probe or orbiter and gave the probe the required post-separation trajectory and attitude within allowable uncertainties. To accomplish this, the pre-separation state vector (position and velocity) and attitude had to be such that, after the dynamics of separation were applied, the probe was left with the proper velocity to reach the aim point, and the proper attitude for atmospheric entry. The pre-separation attitude was achieved by rotating the combined spacecraft under AACS control to an attitude, which left the probe at the desired post-separation attitude.

The Cassini attitude determination system provided an estimate of the spacecraft attitude and turning rates with respect to the J2000 coordinate system. The high accuracy celestial-inertial mode was used for attitude determination in the period prior to the separation event. In this mode, the SRU and an on-board star catalog determined the spacecraft attitude in the J2000 reference frame. Attitude estimates were propagated by the IRU between SRU measurement updates.

The RCS was used to control the combined spacecraft attitude immediately prior to the separation event. RCS control algorithms maintained the spacecraft attitude and rate about all three spacecraft axes within a limit cycle whose angular size was commandable. The control was achieved using four Z-facing thrusters and another four Y-facing thrusters. It was assumed that, following the turn to the probe separation orientation, sufficient time was allowed for the spacecraft to attain a quiescent state with rates below 0.01° per sec on all axes. However, the firing of the RCS thrusters were inhibited 10 seconds prior to probe separation, and re-enabled 60 seconds following probe separation.

After the probe was positioned to its separation orientation, the AACS continually monitored the spacecraft attitude. If the AACS determined that the probe pointing direction had varied beyond a settable threshold, the orbiter/probe separation event would have been aborted.

All of the activity between the time of the separation command and the time at which the orbiter and probe were no longer in physical contact took place in approximately 0.15 seconds.

Once the separation command was initiated, a sequence of dynamic events occurred that resulted in separation of the probe. These events included the firing of pyro bolts, engagement of the separation push-off springs, ramps and rollers, and the separation of the electrical connectors, as well as motion of the orbiter under the separation-induced loads. All of the activity between the

time of the separation command and the time at which the orbiter and probe were no longer in physical contact took place in approximately 0.15 seconds.

The results obtained for the probe separation analysis are shown in Table 2.6-2 for the expected propellant loading case. The probe axial velocity (spacecraft −X-axis direction) of 0.3367 m/s was within the requirement of 0.3 to 0.4 m/s. The probe lateral velocity, the vector sum of the y and z components, was 0.0039 m/s, well within the ICD requirement of <0.032 m/s. The probe axial spin rate was 7.29 rpm, satisfying the requirement of >5 rpm. The maximum orbiter angular rate (the maximum of x, y, or z) is 0.974° per second (0.1624 rpm), satisfying the requirement of <7° per second.

Table 2.6-2. Probe/orbiter post-separation velocity state.

	Δvx (m/s)	Δvy (m/s)	Δvz (m/s)	wx (rpm)	wy (rpm)	wz (rpm)
Probe	−0.3367	0.0014	0.0036	7.2900	−0.0049	−0.0700
Orbiter	0.0471	−0.0011	−0.0006	−0.1624	0.1045	0.018

The dynamics of the probe and the orbiter during the five minutes between the time of separation and the time the two bodies were ~15 meters apart has been studied. The analysis results indicate that the overall minimum clearance obtained was found to occur between the Langmuir probe and the Huygens probe. The minimum clearance of 0.153 m occurred for the low propellant mass scenario. This value of minimum clearance is considered to be satisfactory. To assure that no unmodeled spacecraft motion occurred until the probe cleared the vicinity of the orbiter, the AACS inhibited the firing of the RCS thrusters until 60 seconds following the probe separation event.

The AACS switched from the celestial-inertial mode to the coast mode 10 seconds before probe separation. In the coast mode, the RCS thrusters were inhibited from firing and the spacecraft attitude and rates were continuously sensed by the IRU. Sixty seconds after the separation event, the AACS switched to the detumble mode. In this mode, the RCS thrusters were re-enabled and the spacecraft rates were reduced to low, commandable threshold values. When the orbiter rates were within the prescribed threshold limits, the AACS was switched to the celestial-inertial mode and a turn was commenced to return the orbiter to the attitude that it had just prior to the probe release event.

Post-separation imaging of the probe was considered to improve the knowledge of its ephemeris and entry conditions at Titan. The development team conducted a preliminary feasibility study but important issues remained on the ability to point the WAC and NAC accurately enough given uncertainties in the probe and orbiter velocities after separation. If the pointing was sufficiently accurate, images could be obtained shortly after separation with the WAC and up to six days after separation with the NAC. While studies indicate that all probe mission requirements could be met without post-separation imaging, this option could have enhanced the probe relay pointing margins and provided diagnosis of certain probe separation anomalies.

2.6.4.2 Probe Relay

The probe flew directly into Titan's atmosphere, where it relayed data to the orbiter for about 2.5 hours during its descent to the surface. The probe continued to broadcast data from the surface until the spacecraft passed over the horizon, about 4.5 hours after the probe began broadcasting, which included 2 hours of data while the probe was on the surface. This was the first (and so far only) landing to take place in the outer solar system. Refer to the Titan-C (Huygens) mission description for more information about the Huygens probe mission. Figure 2.6-17 provides a summary of the Huygens probe descent events.

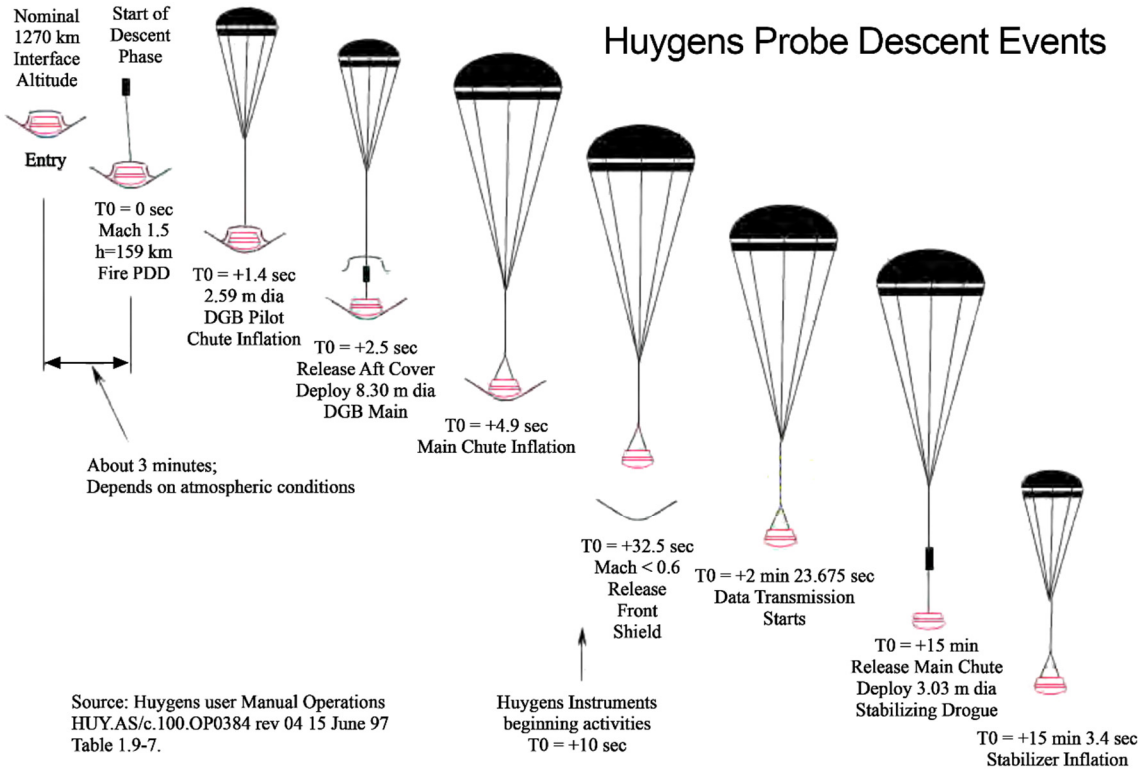

Figure 2.6-17. Huygens probe descent timeline.

The probe entry event occurred over the Goldstone tracking complex at about 0858 UTC (spacecraft event time, with a 67.7-minute one-way light time). Because the orbiter was looking at Titan through most of the Goldstone tracking pass, DSN support on this day was primarily through the 70-meter antennas at the Canberra and Madrid tracking complexes. On approach to Titan, the last downlink before probe relay was to the Madrid station (DSS 63). Following the playback of all data remaining on the solid state recorders, the orbiter was turned nearly 180° to point the high-gain antenna at the predicted probe impact point. The probe support avionics (PSA) were configured to receive data from the probe. Some orbiter instruments were put in a low power state to allow power for the PSA. The data from the probe were transmitted at S-band in two separate data streams, and both were recorded on each SSR.

SSR partitions 4, 5, and 6 were resized as part of the probe-relay critical sequence. Following completion of the predicted descent, the orbiter continued to listen to the probe for 30 minutes, in case the probe transmissions continued after landing. The orbiter was required to stay pointed at the predicted probe landing site for three hours, based on an earlier prediction of the longest descent time being 150 minutes, plus at least 60 minutes after landing. (Current ESA analysis gives an expected descent time of 141 ± 15 minutes, with the principal uncertainties being the Titan atmospheric density, Titan topography, and uncertainties in the probe parachute area and drag coefficients, including wind-induced oscillations.)

To prevent any interference with reception of the probe data, no transmissions from the orbiter were allowed during probe relay (FR80A4) at any frequency. Transmissions from the orbiter high-gain antenna at X-band were turned off by the probe mission sequence shortly after the orbiter turned away from the Earth to point the high-gain antenna at the predicted probe landing site. Additional protection was included in the probe mission sequence and in the configuration of the orbiter fault protection algorithms to ensure no violation of this flight rule; this protection included periodic or cyclic commands to ensure that transmissions were kept off at S, X, Ka, and Ku frequencies.

When the probe data collection was complete, that data were write-protected on each SSR. The spacecraft then turned to view Titan with the optical remote sensing instruments, until about one hour after closest approach. A specific science profile was not defined, but the best combination of remote sensing with fields, particles, and waves, and INMS observations were defined for the first close Titan flyby (Titan-1) within orbiter operating constraints. Instrument data could not overwrite the probe data on the SSRs.

Soon after closest approach, the orbiter turned the high-gain antenna towards Earth and began transmitting the recorded probe data. The complete, four-fold redundant set of probe data was transmitted twice, and its receipt verified, before the write protection on that portion of the SSR was lifted by ground command, marking probe mission completion. The first playback after Titan closest approach was to the Canberra 70-meter antenna and included all of the probe data. The second playback including all of the probe data and the orbiter instrument observations was returned over the subsequent Madrid 70-meter tracking pass, which was at higher tracking elevations.

2.6.5 SATURN ORBITAL OPERATIONS

2.6.5.1 Prime Mission

After the probe data receipt was verified, the orbiter continued on the 75-orbit tour of the Saturnian system, which included 45 close Titan flybys for gravity assist and science acquisition. The Titan flybys and Saturn orbits were designed to maximize science coverage while meeting resource and operations limitations. Figure 2.6-18 shows a view from above Saturn's north pole of all tour orbits in a rotating coordinate system in which the Sun direction is fixed. The broad range of orbit orientations allowed detailed survey of the magnetosphere and atmosphere of Saturn. Figure 2.6-19 shows a side view, from a direction perpendicular to the plane formed by the Saturn–Sun

line and Saturn's North Pole, in which the inclination of the orbits is apparent. The characteristics of the orbits are summarized in Table 2.6-3.

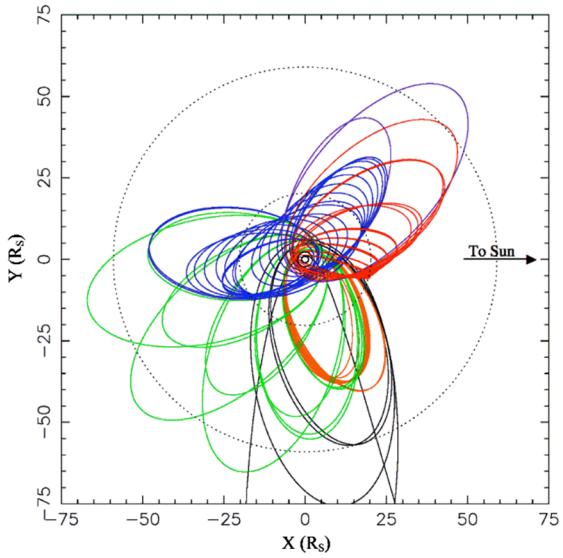

Figure 2.6-18 Tour Petal Plot – North Pole View.

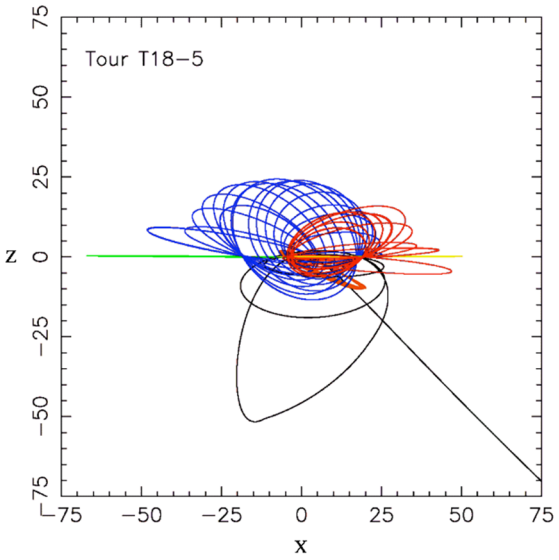

Figure 2.6-19. Tour Petal Plot – Side View.

Table 2.6-3 Characteristics of the orbits.

EM	78	78TI (t)	Titan	2008 - 213T02 : 20	Jul31	Thu	T45; outbound 3, 980 km flyby, v=6.1 km/s, phase=7 deg

Thirteen close flybys and dozens of more distant flybys of selected icy satellites were also completed to determine icy satellite surface compositions and geologic histories. Cassini's orbital inclination varied widely to investigate the field, particle, and wave environment at high latitudes, including the hypothesized source of the unique Saturn kilometric radiation. High inclinations also permitted high-latitude Saturn radio occultations, viewing of Saturn's polar regions, traversal through unknown regions of the magnetosphere, and more vertical viewing of Saturn's rings.

On a typical day in the tour, science data was collected continuously for 15 hours by the spacecraft reorienting itself at a variety of targets. One instrument at a time controlled the pointing of the spacecraft, and other instruments would "ride along" and collect data at the same time.

The remaining 9 hours were spent on Earth-point, downlinking (or playing back) the data. During downlink, since the Z-axis of the spacecraft must be fixed to Earth, the spacecraft could only rotate about the high-gain antenna to collect fields, particles, and waves data. This sweeping during playback allowed three-dimensional and temporal measurements of the fields and particles environment.

The Prime Mission ended on June 30, 2008, for a total mission duration of 10.7 years. The spacecraft and all instruments remained healthy at the end of the tour. The tour was very successful and made many new scientific discoveries about the Saturn system. Several of the mission's achievements are highlighted in the following paragraphs.

- During the 45 targeted flybys of Titan, many important observations were made about Saturn's largest moon. The atmosphere of Titan is composed of 98% nitrogen with the remainder mostly methane. Other observations have revealed sand dunes, ethane and methane lakes in both the northern and southern polar regions, and large ethane clouds. Scientists also theorized that an underground ocean may exist on Titan separating the crust from the core.
- Enceladus is the most geologically active moon in the Saturnian system. Flybys of this moon have revealed varying surface features such as craters in the northern hemisphere and recent resurfacing activity and "tiger stripes" in the southern hemisphere, near the south pole. The "tiger stripes" are the source of jets that spew water vapor away from the surface of Enceladus. The ejected particles are the primary source of Saturn's E-ring.
- When Cassini launched in 1997, Saturn only had 18 known moons. As of 2019, there are 82 known moons in orbit around the planet, of which 53 have received official names. The new moons discovered by Cassini include Methone, Pallene, Polydeuces, Anthe, and Daphnis. Moonlets have also been discovered in the rings, which may have arisen from the shattering of a larger moon.
- Iapetus is one of Saturn's most interesting moons. Observations have revealed that one-half of the moon (the leading hemisphere) is very dark, while the light side is almost five times brighter. Scientists theorize that the dark side of the moon is coated in particles that it has swept up during its orbit. Flybys have also revealed a

13 km ridge around the 1,500 km diameter equator of the moon with mountains larger than the Olympus Mons on Mars.

2.6.5.2 Extended Missions

2.6.5.2.1 Equinox Mission

At the conclusion of the Prime Mission tour phase on June 30, 2008, Cassini initiated a 2-year 3-month extended mission named the Equinox Mission (EM). This extended mission began on July 1, 2008, and was funded through September 30, 2010. The EM continued to explore the Saturn system's rings, magnetosphere, and icy satellites, especially Enceladus. The extension also allowed scientists to make observations during Saturn's northern vernal equinox. The Equinox Mission trajectory consisted of 64 more orbits of Saturn, 28 more Titan flybys, and 11 more close icy moon flybys, seven of which were Enceladus flybys.

2.6.5.2.2 Solstice Mission

At the conclusion of the Equinox Mission, the Cassini team initiated a 7-year mission extension named the Solstice Mission, stretching the tour to September 15, 2017. The overarching goal of the Solstice Mission was to observe the complex and dynamic Saturn system over a wider range of geometries and conditions, including Saturn's May 2017 northern summer solstice. By end of mission, Cassini observed most of the northern winter season and all of the northern spring season.

On November 30, 2016, Cassini began the penultimate phase of the mission, the ring-grazing orbits. This 20-week phase consisted of 20 high-inclination orbits with apoapses near Titan's orbit and periapses just outside the main ring system. The final targeted Titan flyby on April 22, 2017, set Cassini on the Grand Finale—a series of 22 orbits with periapses that passed between Saturn and its rings; a region no spacecraft had explored before.

On September 11, 2017, Titan gave Cassini a "goodbye kiss," a distant non-targeted flyby that put Cassini on its impact trajectory with Saturn. End-of-mission occurred at 11:56 UTC on September 15, 2017, when Cassini plunged into Saturn's atmosphere and Earth lost the spacecraft's signal forever.

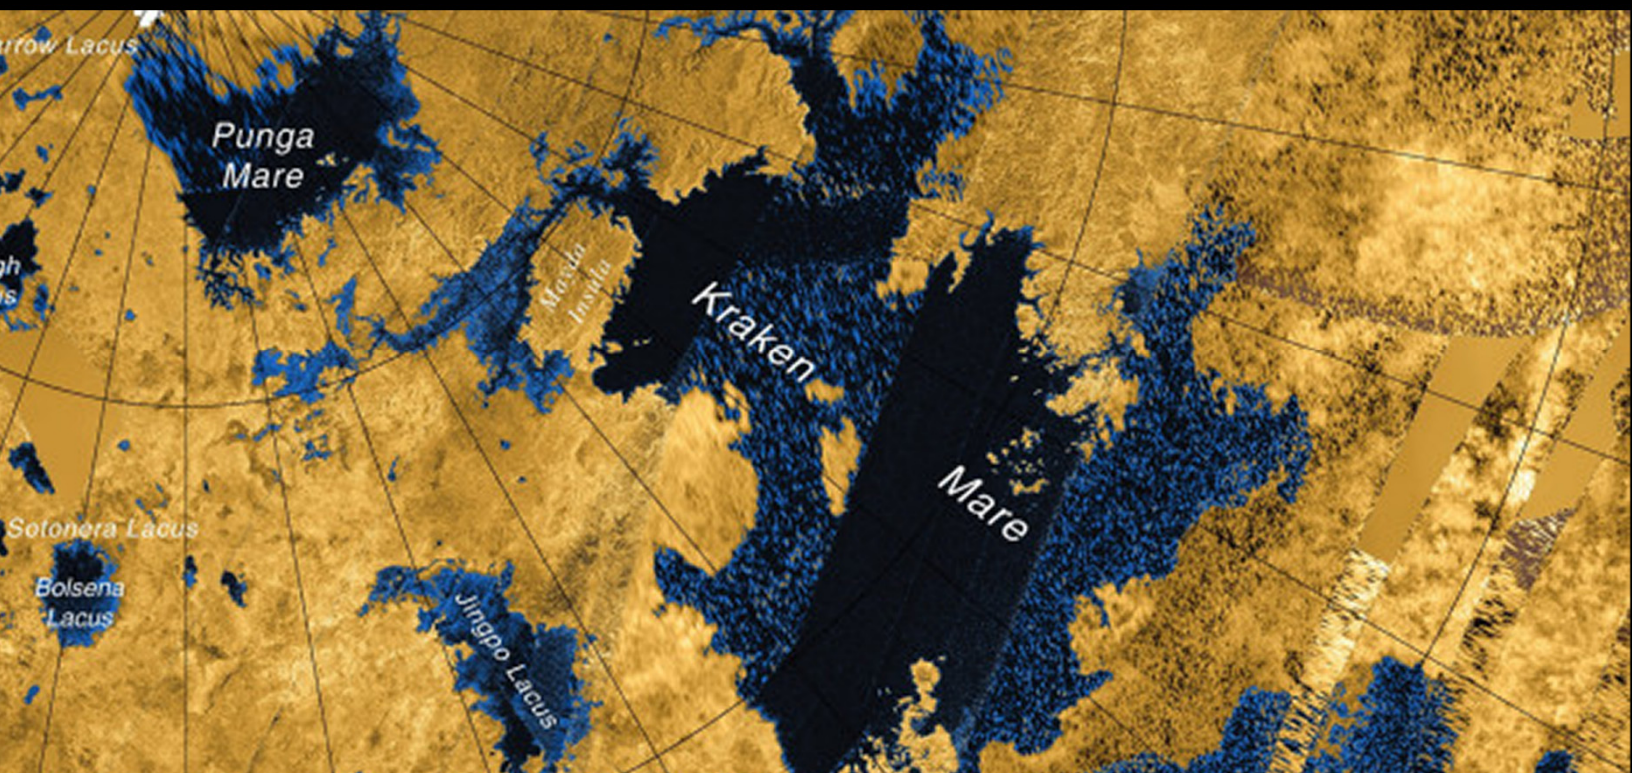
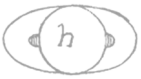
Science Mission Results





3 SCIENCE MISSION RESULTS

For ease of researchability, Volume 1 Section 3 Science Mission Results is separated into three main categories: 3.0 Mission Science Highlights and Science Objectives Assessment; 3.1 Discipline Science Results; and 3.2 Instrument Science Results. All categories are also available as stand-alone documents.

The 3.1 Discipline Science Results category is separated further into six disciplines:

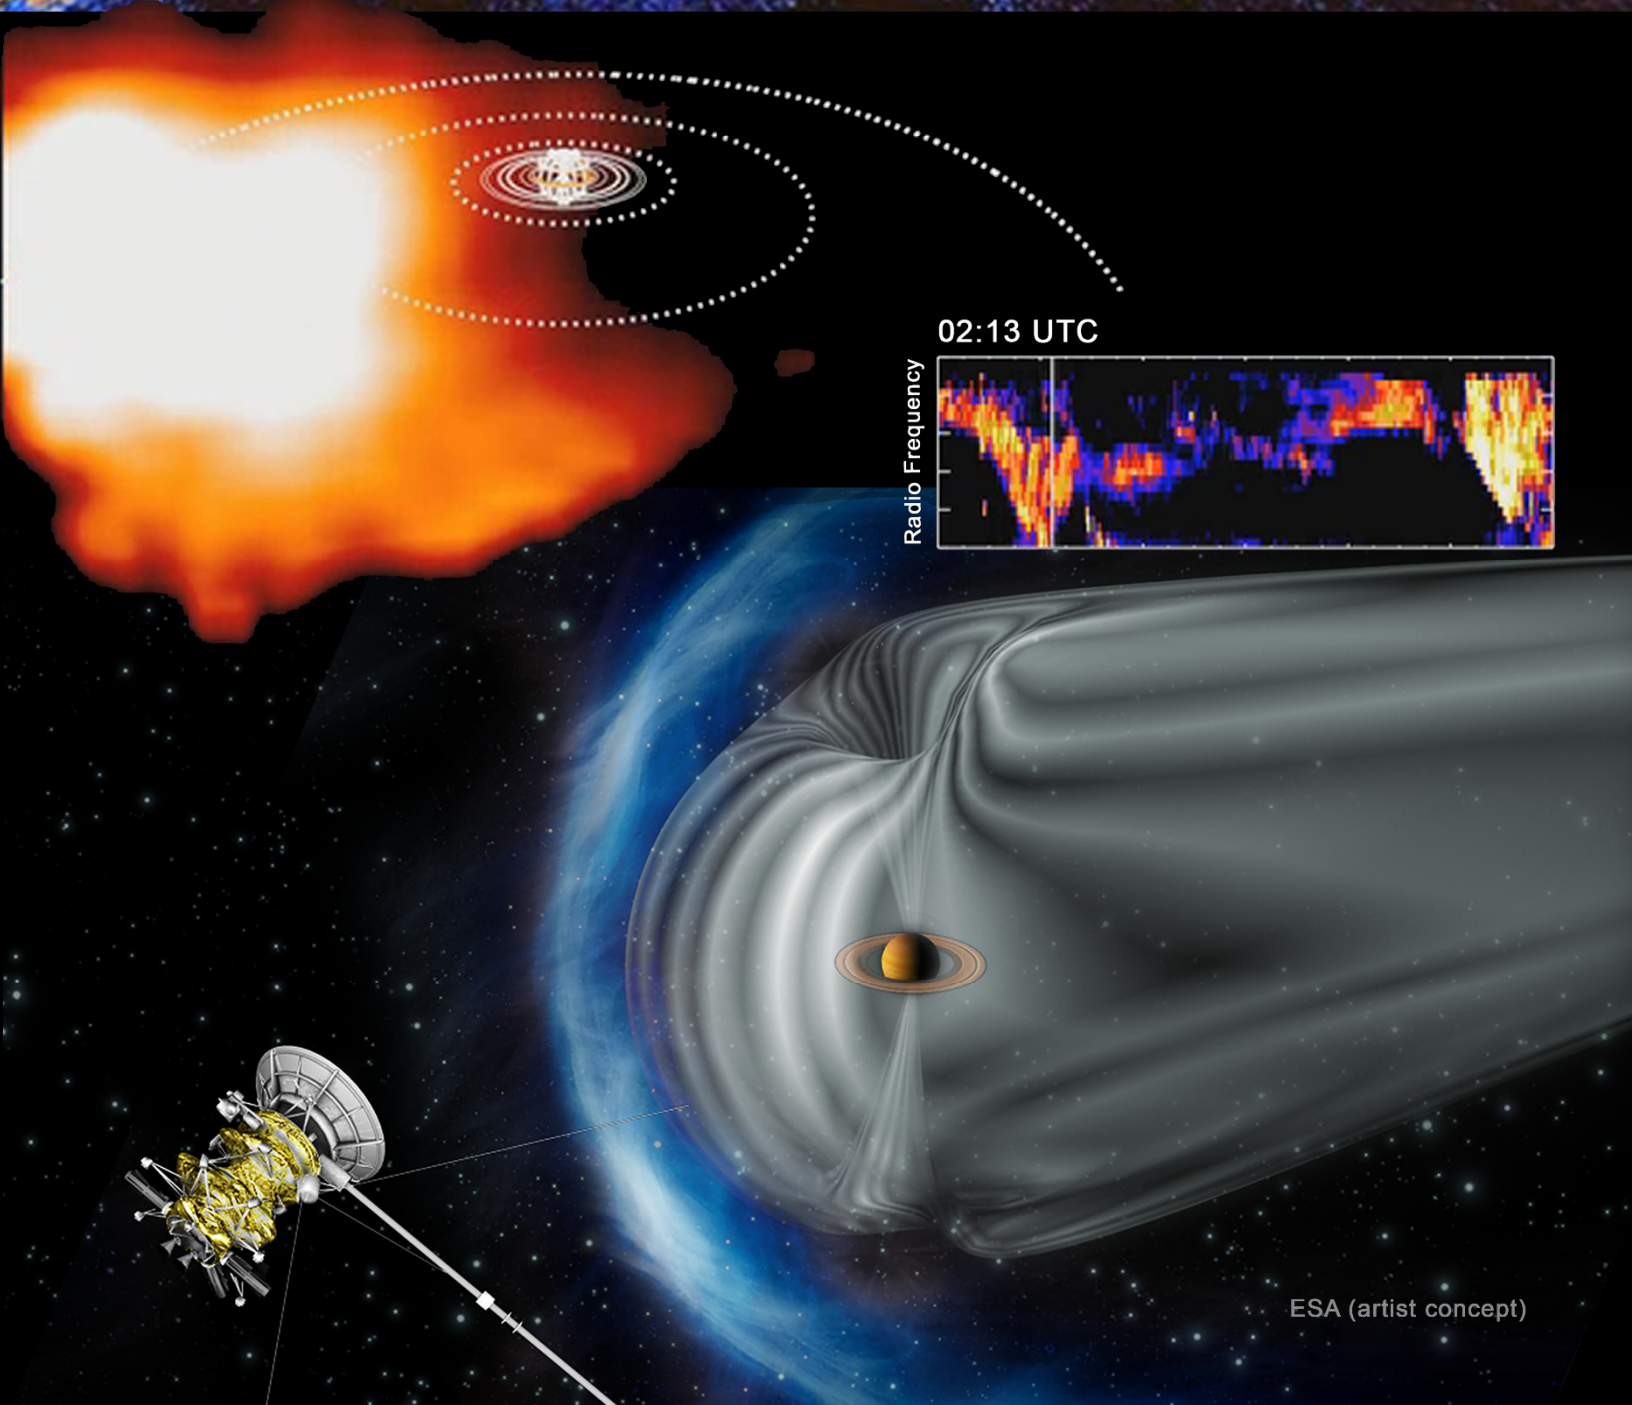
- Huygens
- Icy Satellites
- MAPS
- Rings
- Saturn
- Titan

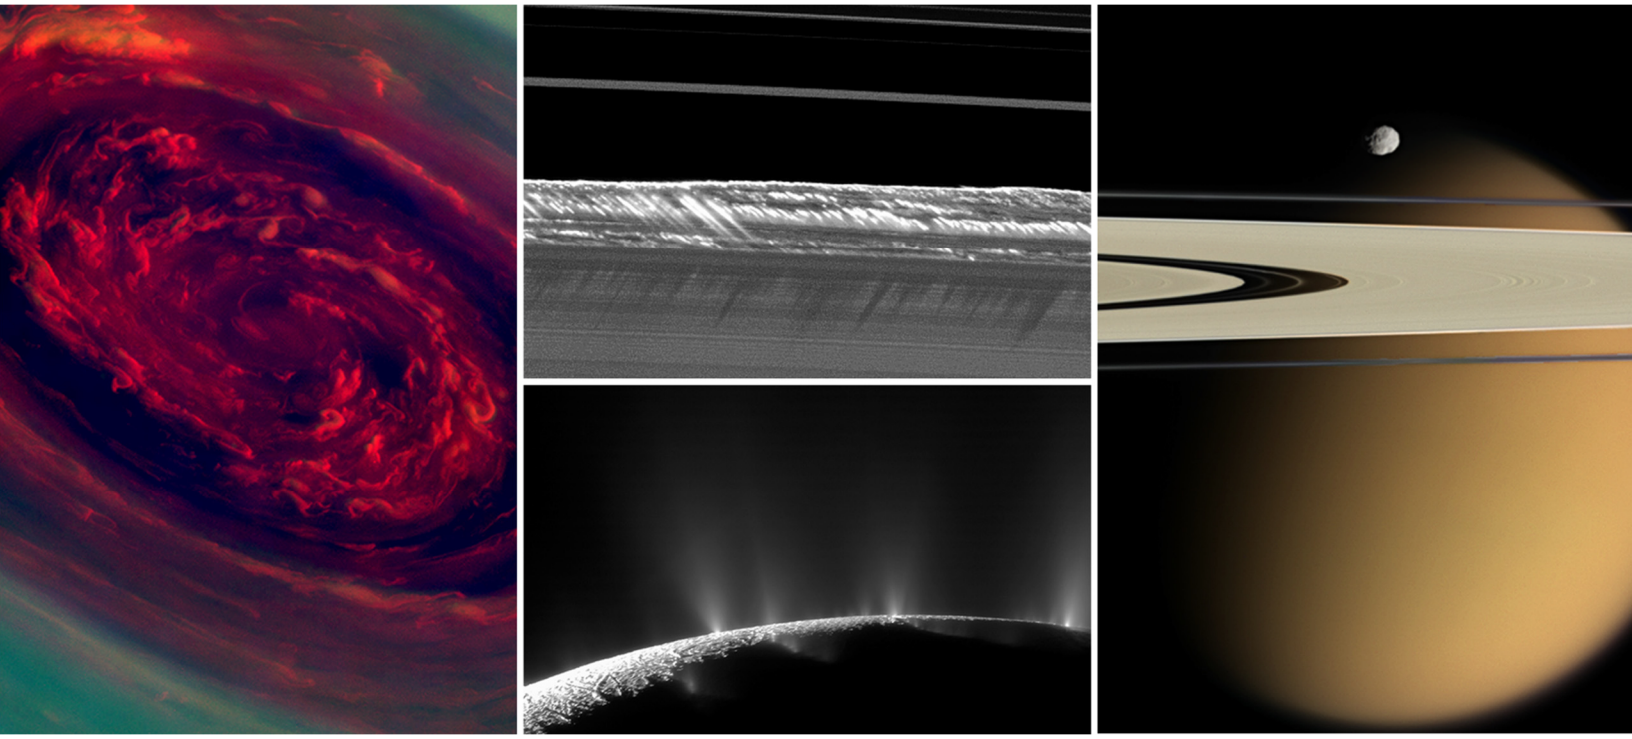
The 3.2 Instrument Science Results category is separated into three sub-categories followed by the respective instrument: (totaling 12 instruments)

- Optical Remote Sensing Instruments
  - Composite Infrared Spectrometer (CIRS)
  - Imaging Science Subsystem (ISS)
  - Ultraviolet Imaging Spectrograph (UVIS)
  - Visual and Infrared Mapping Spectrometer (VIMS)
- Fields, Particles, and Waves Sensing Instruments
  - Cassini Plasma Spectrometer (CAPS)
  - Cosmic Dust Analyzer (CDA)
  - Ion and Neutral Mass Spectrometer (INMS)
  - Magnetometer (MAG)
  - Magnetospheric Imaging Instrument (MIMI)
  - Radio and Plasma Wave Science (RPWS)
- Microwave Remote Sensing Instruments
  - Titan Radar Mapper (RADAR)
  - Radio Science Subsystem (RSS)

3.0 Mission Science Highlights and Science Objectives Assessment

NASA/JPL-CALTECH/ASI/USGS





Mission Science Highlights and Science Objectives Assessment

Cassini-Huygens, humanity's most distant planetary orbiter and probe to date, provided the first in-depth, close up study of Saturn, its magnificent rings and unique moons, including Titan and Enceladus, and its giant magnetosphere. Discoveries from the Cassini-Huygens mission revolutionized our understanding of the Saturn system and fundamentally altered many of our concepts of where life might be found in our solar system and beyond. Cassini-Huygens arrived at Saturn in 2004, dropped the parachuted probe named Huygens to study the atmosphere and surface of Saturn's planet-sized moon Titan, and orbited Saturn for the next 13 years making remarkable discoveries. When it was running low on fuel, the Cassini orbiter was programmed to vaporize in Saturn's atmosphere in 2017 to protect the ocean worlds, Enceladus and Titan, where it discovered potential habitats for life.

EXECUTIVE SUMMARY

The scientific findings and discoveries of the Cassini-Huygens mission revolutionized our understanding of the Saturn system. This international mission consisted of the Cassini Saturn orbiter and the Huygens Titan probe. With 19 participating countries, the project was an archetype for effective international collaboration.

> The primary goal of Cassini-Huygens is to conduct an in-depth exploration of the Saturn system [NASA 1989].

Overall, the Cassini-Huygens mission was a tremendous success, meeting or exceeding essentially all of its science goals listed in the 1989 Cassini and Huygens Announcements of Opportunity (AOs) and in the Cassini Traceability Matrices first defined in 2007 near the end of the Prime Mission (PM). A complete assessment of these objectives is given in a set of color-coded tables in the Project Science Assessment section.

Due to the very broad scope of the Cassini-Huygens mission, this short overview just scratches the surface of the breadth and depth of Cassini-Huygens' scientific findings. The details of the scientific findings of the mission, including discipline and team science assessments, can be found in the following reports in Section 3. They provide in-depth information on the many investigations that constitute the Cassini-Huygens mission. A concise overview of the scientific findings of Cassini's 13-year mission can be found in Spilker [2019].

A vast amount of unique scientific data was returned over Cassini's 13-year mission and a large volume of that data has yet to be thoroughly analyzed and interpreted. Planetary scientists continue to analyze these data, and will do so for decades to come. All of the Cassini data and supporting information are stored in the Planetary Data System (PDS), available for analysis by future generations of planetary scientists.

The following sections present a brief history of the mission, ties to the previous Decadal Survey, and a short mission overview. The chapter includes the mission science objectives and a project assessment of those objectives, as well as the mission's top science highlights and major open questions. The Cassini-Huygens mission successfully answered a large number of scientific questions and posed many new ones, setting the stage for future missions to Saturn and the outer planets.

Origin of the Cassini Mission

Three trailblazing spacecraft, Pioneer 11 in 1979, Voyager 1 in 1980, and Voyager 2 in 1981, flew past Saturn and provided short, fleeting glimpses of this unique system, including the giant moon, Titan. Beginning in 2004, NASA's Cassini spacecraft became the first robotic craft to orbit Saturn and perform detailed seasonal and temporal studies. In 2005, the European Space Agency's (ESA) Huygens probe, carried by the Cassini orbiter, was the first human-made object to land on an outer planet moon, Titan.

The Cassini orbiter was named after the Italian/French astronomer Giovanni Domenico Cassini, who discovered several Saturnian satellites and ring features, including the Cassini division, between 1671–1685. The Titan probe was named after the Dutch astronomer Christiaan Huygens who discovered Titan in 1655.

Cassini-Huygens was an international flagship mission, a cooperative undertaking by NASA, ESA, and the Italian space agency (Agenzia Spaziale Italiana (ASI)). Initial conversations about this mission began not long after the Voyager flybys in the early 1980s. The Voyager instruments were unable to penetrate Titan's thick photochemical haze and many new questions were raised by these flybys. Discussions and planning for a return mission to Saturn, including an in-depth study of the system and a probe into Titan's atmosphere, spanned many years. Some of the discussion that follows can also be found in the Space Science Reviews chapter by Matson et al. [2002].

Formal discussions began in June 1982 when a Joint Working Group was formed by the Space Science Committee of the European Science Foundation and the Space Science Board of the National Academy of Science in the United States. The charter of this Joint Working Group was to study possible modes of cooperation between the United States and Europe in the field of planetary science. Seven years later, after much discussion and many meetings between these international partners, the Cassini and Huygens AOs were released in 1989.

The scientific objectives for the mission and the implementation approach were developed further by the work of the Joint NASA/ESA Assessment Study that was carried out in mid-1984 through 1985, and in 1988. These study groups defined the scientific objectives for the Cassini-Huygens mission and published them in the group's final reports [ESA 1985, 1988]. These objectives then became formally established when they were incorporated into both the NASA and ESA Announcements of Opportunity [ESA 1989; NASA 1989, 1991]. Early summaries of the mission can be found in Lebreton [1991], a book edited by Spilker [1997], and in Matson et al. [2002].

Instrument Teams and Interdisciplinary Investigations

Prior to issuing the Announcements of Opportunity, NASA, ESA, and ASI carried out informal discussions regarding organization and management of the Cassini-Huygens mission. These agreements were formalized in a Memoranda of Understanding (MOUs) between NASA and ESA, signed in 1990, and between NASA and ASI, signed in 1993. The scientific organization of the mission evolved from these memoranda.

The selections of scientific instruments and facility teams were coordinated between NASA and ESA. Investigations for the Huygens probe were announced by ESA in September 1990, and NASA announced Saturn orbiter selections in November 1990. Both agencies also selected interdisciplinary investigations. The ESA Huygens selection was comprised of six Principal Investigator (PI) instruments and three interdisciplinary science (IDS) investigations. The initial NASA Cassini selection was comprised of seven PI-led instruments, four facility instruments, and seven IDS investigations. Facility instruments were scientific instruments already selected and defined by NASA

to be part of the Cassini payload (e.g., the imaging cameras). Scientists proposed to be Team Members (TMs) or Team Leaders (TLs) for these predefined instruments. PI-led instruments included a full instrument proposal, along with a proposed list of Co-Investigators (Co-Is). IDSs proposed scientific investigations relevant to the mission. With the death of NASA-selected IDS James Pollock in 1994, the number of NASA-selected IDS investigations was reduced to six. Absent from the proposed Cassini instruments was one capable of measuring the properties of Titan's upper atmosphere. Such an instrument was regarded as critical to the mission, so in May 1991 NASA issued a second AO, for the Ion and Neutral Mass Spectrometer (INMS) TL and TMs. The results of that selection were announced in February 1992. For facility instruments, NASA selected a TL and TMs, while for PI-led instruments, NASA selected the PI along with his/her proposed team of Co-Is.

Cassini and Huygens accommodated 27 major scientific investigations that were supported by 18 specially designed instruments, 12 on the Cassini orbiter and 6 on the Huygens probe. Lists of the instrument and IDS investigations for Cassini and Huygens can be found in Tables 3-1 and 3-2.

The flight operations of the Cassini mission were carried out at the Jet Propulsion Laboratory (JPL) in Pasadena, California. The data were collected at NASA's Deep Space Network (DSN) stations, with support at times from ESA stations, and sent to the instrument teams. The operations of the Cassini instruments were distributed to their home institutions. Cassini's distributed operations represented a paradigm shift from previous flagship missions, such as Voyager and Galileo, where operations were conducted primarily at JPL. The instrument teams analyzed their respective instrumental data and prepared instrumental operation sequences at their home institution and transmitted them to JPL for uplink. The flight operations of the Huygens probe were carried out from ESA's European Space Operations Center (ESOC) in Darmstadt, Germany, where the Huygens Operations Center (HPOC) was also established.

Table 3-1. Cassini orbiter investigations. If two scientists are listed, the first individual was the PI or TL at the time of AO selection in 1990. The second name is the individual who was leading the instrument team at the end of the mission, with a transition at some point during the mission.

Investigation/Acronym	Scientist/Affiliation	Brief Objectives
Cassini Plasma Spectrometer (CAPS)	D. Young (PI), Southwest Research Institute J.H. Waite (PI), Southwest Research Institute	In situ study of plasma within and near Saturn's magnetic field
Cosmic Dust Analyzer (CDA)	E. Grün (PI), Max Planck Institut für Kernphysik R. Srama (PI), Universität Stuttgart	In situ study of ice and dust grains in the Saturn system
Composite Infrared Spectrometer (CIRS)	V. Kunde (PI), NASA Goddard Space Flight Center F.M. Flasar (PI), Goddard Space Flight Center	Temperature and composition of surfaces, atmospheres, and rings within the Saturn system
IDS – Magnetosphere and Plasma	M. Blanc (IDS), Research Institute of Astrophysics and Planetology, Toulouse	Interdisciplinary study of plasma circulation and magnetosphere-ionosphere coupling
IDS – Rings and Dust	J. Cuzzi (IDS), NASA Ames Research Center	Interdisciplinary study of rings and dust within the Saturn system
IDS – Magnetosphere and Plasma	T. Gombosi (IDS), University of Michigan	Interdisciplinary study of the plasma environment in Saturn's magnetosphere
IDS – Atmospheres	T. Owen (IDS), University of Hawaii	Interdisciplinary study of the atmospheres of Titan and Saturn
IDS – Satellites	L. Soderblom (IDS), U.S. Geological Survey	Interdisciplinary study of the satellites of Saturn

Table 3-1. Cassini orbiter investigations. If two scientists are listed, the first individual was the PI or TL at the time of AO selection in 1990. The second name is the individual who was leading the instrument team at the end of the mission, with a transition at some point during the mission.

Investigation/Acronym	Scientist/Affiliation	Brief Objectives
IDS – Aeronomy and Solar Wind Interaction	D. Strobel (IDS), Johns Hopkins University	Interdisciplinary study of aeronomy in the Titan and Saturn atmospheres
IDS – Origins	J. Pollock (IDS), NASA Ames Research Center (deceased 1994)	Interdisciplinary study of the origin and evolution of the Saturn system
Ion and Neutral Mass Spectrometer (INMS)	J.H. Waite (TL), Southwest Research Institute	In-situ compositions of neutral and charged particles within the Saturn magnetosphere
Imaging Science Subsystem (ISS)	C. Porco (TL), Space Science Institute	Multispectral imaging of Saturn, Titan, rings, and the icy satellites to observe their properties
Dual Technique Magnetometer (MAG)	D. Southwood (PI), Imperial College M. Dougherty (PI), Imperial College	Study of Saturn's magnetic field and interactions with the solar wind
Magnetospheric Imaging Instrument (MIMI)	S. Krimigis (PI), Applied Physics Laboratory D. Mitchell (PI), Applied Physics Laboratory	Global magnetospheric imaging and in-situ measurements of Saturn's magnetosphere and solar wind interactions
Titan Radar Mapper (RADAR)	C. Elachi (TL), NASA Jet Propulsion Laboratory	Radar imaging, altimetry, and passive radiometry of Titan's surface
Radio and Plasma Wave Science (RPWS)	D. Gurnett (PI), University of Iowa W. Kurth (PI), University of Iowa	Measure the electric and magnetic fields and electron density and temperature in the interplanetary medium and within the Saturn magnetosphere
Radio Science Subsystem (RSS)	A. Kliore (TL), NASA Jet Propulsion Laboratory D. French (TL), Wellesley College	Study of atmospheric and ring structure, gravity fields, and gravitational waves
Ultraviolet Imaging Spectrograph (UVIS)	L. Esposito (PI), University of Colorado	Spectra and low-resolution imaging of atmospheres and rings for structure, chemistry, and composition
Visible and Infrared Mapping Spectrometer (VIMS)	R. Brown (TL), NASA Jet Propulsion Laboratory	Spectral mapping to study composition and structure of surfaces, atmospheres, and rings

Table 3-2. Huygens probe investigations. The table below lists the Huygens instrument and IDS investigations as selected in response to the Huygens 1989 AO. (Table after Matson et al. [2002])

Investigation/Acronym	Scientist/Affiliation	Brief Objectives
Aerosol Collector Pyrolyser (ACP)	G. Israel (PI), CNRS, Service d'Aéronomie	In situ study of clouds and aerosols in the Titan atmosphere
Descent Imager and Spectral Radiometer (DISR)	M. Tomasko (PI), University of Arizona	Temperatures and images of Titan's atmospheric aerosols and surface
Doppler Wind Experiment (DWE)	M. Bird (PI), Universität Bonn	Study of winds from their effect on the *Probe* during the Titan descent
Gas Chromatograph and Mass Spectrometer (GCMS)	H. Niemann (PI), NASA Goddard Space Flight Center	In situ measurement of chemical composition of gases and aerosols in Titan's atmosphere
Huygens Atmospheric Structure Instrument (HASI)	M. Fulchignoni (PI), Observatoire de Paris-Meudon	In situ study of Titan atmospheric physical and electrical properties
IDS – Titan Aeronomy	D. Gautier (IDS), Observatoire de Paris-Meudon	Interdisciplinary study of the aeronomy of Titan's atmosphere
IDS – Titan Atmosphere-Surface Interactions	J. Lunine (IDS), Cornell University	Interdisciplinary study of Titan atmosphere-surface interactions
IDS – Titan Organic Chemistry	F. Raulin (IDS), Université Paris, Val de Marne	Interdisciplinary study of Titan's chemistry and exobiology
Surface Science Package (SSP)	J. Zarnecki (PI), University of Kent	Measurement of the physical properties of Titan's surface

Defining Scientific Objectives

Further development of the AO scientific objectives for Cassini-Huygens was carried out by the Project Science Group (PSG) and the Huygens Science Working Team (HSWT). These groups, chartered by the AOs, were the Program's scientific advisory bodies. Chaired and managed by the Cassini Project Scientist and Huygens Project Scientist, they included interdisciplinary scientists, and participants from all instrument teams. They provided more detail than that specified in the AO requirements, developed Science Traceability Matrices post 2007 for the Equinox and Solstice Missions, and kept the requirements up to date with respect to any new discoveries. In the PSG, this work was done by a set of committees called Discipline Working Groups (DWGs) specializing in each discipline's science requirements and co-chaired by Interdisciplinary Scientists (IDSs) as was envisioned in the AO.

The Cassini team was an archetype for effective international collaboration, with nineteen participating countries.

The Cassini team of over 350 scientists was organized into five DWGs: Titan, Icy Satellites, Rings, Magnetospheres and Plasma Science (MAPS), and Saturn overseen by the Cassini Project Scientist. These groups were comprised of representatives from the 12 instrument teams and were typically headed by one or more Interdisciplinary Scientists. The Cassini team was an archetype for effective international collaboration, with 19 participating countries. Over the course of the mission, the Cassini family continued to grow by adding a Cassini Participating Scientist Program in addition to the many team associates, postdoctoral fellows, and graduate students. The first class of 12 Participating Scientists was selected in 2011, and included four international scientists. A total of 41 Participating Scientists were selected over five years. A vast amount of unique scientific data was returned over its 13-year mission and a large volume of that data has yet to be thoroughly analyzed and interpreted. Planetary scientists continue to analyze these data, and will do so for decades to come.

The PSG and the HSWT had the responsibility to translate the science requirements into strategies for observing and measuring. The workload was shared by the five DWGs, special working groups such as the Titan Atmospheric Working Group (TAMWG) and Saturn Atmospheric Working Group (SAMWG), and instrument scientific investigation teams under the direction of the PIs and TLs. These strategies were then translated into specific instrumental observations and measurements by the scientists and the engineering and operations staffs of the individual instruments. All of these steps were closely coordinated with the spacecraft operations staffs at JPL and ESOC (for Huygens instruments). Minute-by-minute observation planning was conducted by PSG-sanctioned Operations Science Teams (OSTs; for Titan and Icy Satellite) and project-sanctioned Target Working Teams (TWTs; for Saturn, Rings, and MAPS), which were comprised of instrument team science and engineering representatives along with project-appointed Investigation Scientists (ISs), science planning and spacecraft engineers, and spacecraft operators.

Cassini Rules of the Road

Before Cassini arrived at Saturn in 2004, the Project Science Group crafted a set of Cassini/Huygens Rules of the Road that were created based on the MAPS Rules of the Road (see Appendix A for more details). The Cassini Rules of the Road offered guidelines for multi-investigation studies using data that were not yet in the PDS. Each Cassini instrument team also crafted its own set of Instrument Rules of the Road to govern their investigations. The Cassini Rules of the Road were the overarching set of Rules of the Road for the mission. The goal of these Rules of the Road was to foster collaboration between the instrument teams.

The Cassini/Huygens Rules of the Road were:

- "Rules of the Road" offers guidelines for multi-investigation studies only and it applies equally and fairly to all Cassini/Huygens teams.
- Cassini/Huygens teams are headed by a PSG member (PI, TL, or IDS). Team members are: TL, official Co-Is, NASA/ESA selected Facility Team Members, and their direct associates. Each associate is "authenticated" by the team lead.
- Each Cassini/Huygens Team has overall responsibility for its investigation, including the initial analysis, interpretation, and publication of their data. Results from single investigations should be published first as much as possible.
- All Cassini/Huygens teams are expected to make available their processed data for Cassini/Huygens team use for multi-investigation studies within a reasonable time (up to 6 months).
- The combined data sets are made available to all interested Cassini/Huygens scientists to identify possible scientifically interesting events.
- The combined data sets may not be published or released without the specific authorization of all contributing Cassini/Huygens teams.
- When data from a Cassini/Huygens team are used in a multi-investigation study:
  - The team lead must be immediately informed of their use.
  - The team must be invited at an early time to participate in the study.
  - The team must be invited to participate in any resulting publication or presentation. First authorship should be fairly divided between the participating teams.
  - Disputes should be resolved at the lowest possible level.
- The Cassini/Huygens science team needs to create a positive atmosphere that strongly discourages misconduct and maximizes science return from the mission.
- It is the responsibility of all Cassini/Huygens teams to make sure that all team members and associates are aware of the Rules of the Road and that they abide by them.

- These principles were unanimously accepted by the Cassini PSG Executive Session on October 24, 2002.

Cassini Project Reviews

As the Cassini mission progressed, NASA held a series of reviews during the mission to assess the completed science objectives and to evaluate proposals for extending the mission. In each successive phase of the mission (see Mission Phases section), new science objectives were defined based on Cassini's new findings and discoveries. For example, after the discovery of the Enceladus plume, Enceladus became a science focus for the remainder of the mission, with the addition of 20 more close Enceladus flybys including seven that flew directly through the plume. Other aspects of the mission, such as observing seasonal and temporal changes, were included as well. NASA reviews of Cassini were held in 2007 (proposal for Equinox Mission), 2011 (briefing to Ed Weiler and NASA HQ team), 2012 (Cassini Senior Review 2012), and 2014 (Senior Review 2014), which also included the final year of the mission.

After each review, Cassini received funding to continue its mission. For the 2012 and 2014 Senior Reviews, the Cassini mission proposals were ranked as "Excellent" and at the top of the list of all planetary missions under review.

System Science

The list of scientific objectives for both the Cassini and Huygens missions was quite extensive. Specific objectives were defined for each type of body in the system—Saturn itself, the rings, Titan, icy satellites, and the magnetosphere. Cassini-Huygens was designed to determine the present state of these bodies, the processes operating on or in them, and the interactions occurring among them. A detailed list of these objectives is given in the Cassini Science Objectives section.

This ability to execute system science was a key aspect of this flagship-class international mission and set this superbly instrumented spacecraft apart. The very complex interactions that occur in systems such as those found at Saturn (e.g., Enceladus jets or Titan's atmosphere and seas) could only be addressed by a diverse, broad array of instruments. The advantage of a flagship-class mission like Cassini-Huygens was its ability to perform an extensive set of exploratory studies, and follow up on those findings. In a number of cases, the Cassini orbiter instruments were used in ways not envisioned when the spacecraft first launched; for instance, flying through Enceladus' plume, and flying through the gap between the innermost ring and the top of Saturn's atmosphere for 22 orbits at the end of the mission.

Mission Summary

Cassini's 13 years of scientific study spanned almost half a Saturn year, covering late northern winter, spring, and northern summer. The mission ended just a few months after northern summer

solstice. Cassini was launched in 1997 and arrived at Saturn in 2004. Cassini's four-year Prime Mission began our exploration of the Saturn system, raising puzzling new questions that were addressed in the extended missions. The two-year Equinox Mission continued observations surrounding the equinox crossing in August 2009 when Saturn's rings were edge-on to the Sun. In 2010, the Cassini Solstice Mission began the final seven years of exploration. It contained equatorial orbits with many targeted icy satellite flybys; inclined orbits with optimal views of Saturn's rings and poles; and finally, highly inclined Ring-Grazing and Grand Finale orbits, diving between the innermost D-ring and upper region of Saturn's atmosphere for the first time by any spacecraft prior to the mission's end on September 15, 2017.

Some of Cassini's most surprising scientific discoveries came from encounters with Saturn's intriguing moons. Enceladus harbors a salty, liquid water ocean beneath its icy crust that is the source for icy jets spewing from its south pole. On giant Titan, methane rain carves river channels and fills lakes and seas with liquid hydrocarbons, mixed with complex prebiotic chemicals that form in its atmosphere and rain to the surface. Titan, too, has an internal liquid water ocean. Cassini's discovery of two ocean worlds at Saturn profoundly changed our ideas of where life might exist in our own solar system and beyond.

Some of Cassini's other amazing findings include a myriad of three-dimensional structures in the dynamic rings driven by interactions with Saturn's moons and interior; a giant Saturn storm that circled the entire planet for most of 2011, while a long-lived hexagonal jet stream discovered by Voyager in 1981 continues to encircle the north polar region. Cassini solved the mystery of Iapetus' dual bright-dark surface, and the true rotation rate of Saturn's interior. The final year of the mission, moving the spacecraft closer to Saturn than ever before, provided an astonishing array of discoveries about the interior of Saturn, its rings, and the gap between the rings and the planet. A summary of some of Cassini's key highlights can be found in the section on Cassini's Top Science Highlights and in Spilker [2019], while more detailed summaries and discussion can be found in the discipline and team reports.

At the conclusion of the Cassini mission, many open questions remained. Some of the top open questions are summarized in the Major Open Questions Resulting from Cassini section. Additional open questions can be found in each discipline and team report. These questions will help guide future missions to Saturn and the outer planets.

Ties to Planetary Science Decadal Survey Key Questions, Goals, and Objectives

The Cassini mission enabled significant advances in planetary science and its findings will guide future missions to the outer planets.

Since July 2004, Cassini returned a wealth of data from the Saturn system, yielding amazing discoveries, breathtaking images, expanded awareness of where and how life might exist beyond Earth, and several thousand publications across five interrelated science disciplines: Titan, Icy Satellites, Rings, Magnetosphere and Plasma Science, and Saturn. Over the course of the

mission, Cassini implemented Objective 1.5 of the *NASA Strategic Plan 2014*, and addressed the three *Vision and Voyages* (2013–2022 Planetary Science Decadal Survey) cross-cutting themes, including eight of its top ten Priority Questions (Table 3-3). Cassini also tackled all 25 of its Giant Planets and Satellites goals (Table 3-4). The Cassini mission enabled significant advances in planetary science and its findings will guide future missions to the outer planets.

The 13-year Cassini mission at Saturn took full advantage of the spacecraft's diverse set of high-performance instruments to provide unique science throughout the mission. Some of the outstanding opportunities included: 1) observed seasonal processes on Saturn, Titan, icy satellites, the rings, and in the magnetosphere from northern winter to northern summer; 2) studied the time variability of many phenomena, including plume activity on Enceladus and changes in the ring system; 3) made and pursued discoveries in this exceptionally complex and dynamic environment over a variety of inclination and solar illumination angles that are not available from Earth; and 4) determined the gravitational and magnetic fields of Saturn's interior, measured the main-ring mass, and sampled the composition of Saturn's ring particles and upper atmosphere. Cassini was a mission of extraordinary depth and breadth that produced rich data sets.

The Cassini mission provided new data for all 25 objectives listed in the Planetary Science Decadal Survey's Giant Planets and Satellites chapters (Table 3-4). The check marks in Table 3-4 indicate which Decadal Questions were answered by each of the five disciplines. Huygens probe science is included as part of the Titan column.

Table 3-3. Cassini addressed eight of top ten 2013–2022 Planetary Science Decadal Key Questions.

Cross-Cutting Themes	Priority Questions	Addressed by Cassini?
Origins *Building New Worlds*	1. What were the initial stages, conditions and processes of solar system formation and the nature of the interstellar matter that was incorporated?	✓
	2. How did the giant planets and their satellite systems accrete, and is there evidence that they migrated to new orbital positions?	✓
	3. What governed the accretion, supply of water, chemistry, and internal differentiation of the inner planets and the evolution of their atmospheres, and what roles did bombardment by large projectiles play?	✓
Habitability *Planetary Habitats*	4. What were the primordial sources of organic matter, and where does organic synthesis continue today?	✓
	5. Did Mars or Venus host ancient aqueous environments conducive to early life, and is there evidence that life emerged?	
	6. Beyond Earth, are there modern habitats elsewhere in the solar system with necessary conditions, organic matter, water, energy, and nutrients to sustain life, and do organisms live there now?	✓
Evolution *Workings of Solar Systems*	7. How do the giant planets serve as laboratories to understand Earth, the solar system and extrasolar planetary systems?	✓
	8. What solar system bodies endanger and what mechanisms shield Earth's biosphere?	
	9. Can understanding the roles of physics, chemistry, geology, and dynamics in driving planetary atmospheres lead to a better understanding of climate change on Earth?	✓
	10. How have the myriad chemical and physical processes that shaped the solar system operated, interacted, and evolved over time?	✓

Table 3-4. Cassini's Science Objectives thoroughly addressed all 25 of the Planetary Science Decadal Survey Goals and Objectives for Giant Planets and Satellites.

Vision & Voyages Planetary Science Decadal Survey 2013–022			Cassini Science Disciplines				
Chapters	Science Goals	Objectives	Titan (includes Huygens)	Icy Satellites	Rings	MAPS	Saturn
The Giant Planets: Local Laboratories and Ground Truth for Planets Beyond	Giant planets as ground truth for exoplanets	Understand heat flow and radiation balance in giant planets					✓
		Investigate the chemistry of giant-planet atmospheres				✓	✓

		What determines the abundance and composition of satellite volatiles?	✓	✓	✓		
		How are satellite thermal and orbital evolution and internal structure related?	✓	✓	✓		
		What is the diversity of geologic activity and how has it changed over time?	✓	✓			
	What processes control the present-day behavior of these bodies?	How do active endogenic processes shape the satellites' surfaces and influence their interiors?	✓	✓			
		What processes control the chemistry and dynamics of satellite atmospheres?	✓	✓		✓	
		How do exogenic processes modify these bodies?	✓	✓	✓	✓	
		How do satellites influence their own magnetospheres and those of their parent planets?	✓	✓		✓	
	What are the processes that result in habitable environments?	Where are subsurface bodies of liquid water located, and what are their characteristics and histories?	✓	✓			
		What are the sources, sinks, and evolution of organic material?	✓	✓		✓	
		What energy sources are available to sustain life?	✓	✓		✓	
		Is there evidence for life on the satellites?	✓	✓			

Cassini also responded to 41 of 75 of the Giant Planets and Satellites chapters “Important Questions for the next decade,” and also inspired 29 of them. Some of the Cassini-inspired questions, many of which Cassini answered over the course of the mission, included:

- Does Titan have an internal liquid water ocean?
- Is there active cryovolcanism on Titan?
- How do Titan’s clouds originate and evolve?
- What is the spatial distribution of Enceladus’ heat output, and how has it varied with time?
- Does Enceladus have an internal ocean or some other means of providing large tidal dissipation?
- What mechanisms drive and sustain Enceladus’ plumes and tiger stripe tectonics?
- What is the source of the organic material in the plume of Enceladus?
- Do other Saturnian icy satellites such as Dione and Rhea contribute measurable amounts of neutrals or plasma to Saturn’s magnetosphere?

Other Planetary Science Decadal Important Questions included:

- What mechanism has prolonged Saturn’s thermal evolution?
- How is energy dissipated within giant planets?
- Does helium rain play a role in reducing the He/H in Saturn’s molecular envelope?
- What are the natures of periodic outbursts such as the global upheavals on Jupiter and the infrequent great white spots on Saturn?
- How and why does the atmospheric temperature and cloud composition vary with depth and location on the planet?
- What is the source of energy for the hot coronas/upper atmospheres of all four giant planets?
- What processes control Titan’s weather?
- What can our understanding of the giant planet magnetospheres tell us about the conditions to be expected at extra-solar giant planets?
- How do magnetospheres interact with the solar wind?
- What can the significant differences among ring systems teach us about the differing origins, histories, or current states of these giant planet systems?
- What drives orbital evolution of embedded moonlets; how do they interact with their disks?
- What drives mass accretion in a ring system?

Overall, the Cassini mission was a tremendous success. It addressed objectives across a broad array of scientific disciplines, and followed up on many unexpected discoveries. Cassini's many findings and discoveries will provide a pathfinder for outer planet science in the next Planetary Science Decadal Survey.

MISSION OVERVIEW

Mission Phases

Cassini was designed to address a broad array of objectives across five science disciplines: Titan, Icy Satellites, Rings, Magnetospheres and Plasma Science, and Saturn.

The spacecraft flew with 12 science instruments (Table 3-5): four optical remote sensing (ORS) instruments, two microwave remote sensing instruments, and six MAPS instruments. The Class-A spacecraft subsystems launched with full redundancy, and retain full functionality.

Table 3-5. Three suites of instruments enable interdisciplinary science investigations.

Optical Remote-Sensing Instruments (ORS)	
CIRS	Composite Infrared Spectrometer
ISS	Imaging Science Subsystem
UVIS	Ultraviolet Imaging Spectrograph
VIMS	Visible and Infrared Mapping Spectrometer
Microwave Remote-Sensing Instruments	
RADAR	Titan Radar Mapper
RSS	Radio Science Subsystem
Magnetosphere and Plasma Science Instruments (MAPS)	
CAPS	Cassini Plasma Spectrometer
CDA	Cosmic Dust Analyzer
INMS	Ion and Neutral Mass Spectrometer
MAG	Dual Technique Magnetometer
MIMI	Magnetospheric Imaging Instrument
RPWS	Radio and Plasma Wave Science

Cassini-Huygens left the Earth on October 17, 1997, using a Titan IV/Centaur launch vehicle with Solid Rocket Motor Upgrade (SRMU) strap-ons and a Centaur upper stage. During the 6.7-year journey to Saturn, the spacecraft had gravity assistance from Venus on April 26, 1998, and June 24, 1999, from Earth on August 18, 1999, and from Jupiter on December 30, 2000. Cruise activities were planned to checkout, calibrate, and maintain the instruments as well as characterize the instruments and perform limited science observations (limited by flight software available on the spacecraft as well as cost, scheduling, and workforce constraints).

The Venus-1 flyby occurred on April 26, 1998, just six months after launch. The spacecraft approached Venus from a sunward direction and closest approach occurred just after entering the Sun's shadow for a period of about 15 minutes. At closest approach, the altitude was 284 km, with a velocity relative to Venus of 11.8 km/s.

A repetition of the ATLO "Quiet Test" was conducted to allow instruments to monitor other instruments as they turned on and off, thus providing valuable insight into how to integrate science observations during the Saturn tour.

The Instrument Checkout (ICO-1) sub-phase was September 14, 1998, through March 14, 1999. This sub-phase was characterized by the opposition that occurred on January 9, 1999, and which allowed use of the high-gain antenna (HGA) for downlink since the Earth and Sun were nearly aligned as seen from Cassini. All instruments scheduled checkout activities within a 25-day period centered on opposition. This was the first opportunity since launch to exercise most of the instruments and check status other than routine instrument maintenance. A repetition of the ATLO "Quiet Test" was conducted to allow instruments to monitor other instruments as they turned on and off, thus providing valuable insight into how to integrate science observations during the Saturn tour.

The second Venus (Venus-2) flyby occurred on June 24, 1999. Closest approach occurred at 2030 Universal Time (UT) at an altitude of 603 km with a Venus-relative velocity of 13.6 km/s. Approach to Venus was from the dusk side of the planet. Between Venus-2 and the upcoming Earth flyby, about two dozen activities involving maintenance, calibration, checkout, and science observations were carried out, using all of the Cassini instruments except INMS and CIRS, which were subject to thermal constraints.

The Earth flyby occurred 55 days after the Venus 2 flyby on August, 18, 1999. The spacecraft approached the Earth approximately from the direction of the Sun. Closest approach occurred right after the spacecraft entered the Sun occultation zone. The occultation lasted approximately 30 minutes. The altitude at closest approach was 1175 km, with an Earth-relative velocity of 19.0 km/s.

The MAG boom deployment executed 44 hours prior to Earth closest approach. Within the 24-hour period surrounding Earth flyby, the spacecraft passed in and out of the Earth's magnetosphere. Observations during this time were crucial for magnetometer alignment calibration to ensure that measurements at Saturn would be accurate to meet the major science goal of measuring Saturn's magnetic field orientation to an accuracy of 0.1°.

In addition, activities for CAPS, CDA, MIMI, RPWS, RSS, and VIMS were allowed during the approach to Earth, as well as observations of the Earth's moon for ISS, UVIS, and VIMS. After Earth closest approach, RADAR observations were performed as an end-to-end test of the RADAR system using Earth as a target. A few months later, on January 23, 2000, observations by ISS, VIMS, and UVIS of the distant (1,634,000 km) asteroid 2685 Masursky were conducted. No papers or abstracts were written on this observation.

A second Instrument Checkout (ICO-2) was conducted during July and August 2000 when the high-gain antenna was routinely in use and in preparation for the upcoming Jupiter flyby. The Jupiter flyby occurred on December 30, 2000, at a distance of 9.7 million km. On October 1, 2000, Jupiter approach science began using a repeating 5-day template. Science conducted by all instruments at Jupiter provided an opportunity to test Saturn observation techniques, ground and flight software, and building and execution of sequences.

After Jupiter, a Gravitational Wave Experiment (GWE) was executed December 2001 and a Conjunction Experiment in June 2002. The GWE preparation included two 1-week test periods starting in early May 2001 and August 2001. Additional GWEs were performed in December 2002 and October 2003.

Limited calibration and science data collection occurred during the Venus and Earth flybys. The scientific results of this mission phase are described in a collection of 11 scientific articles that appeared together in a special issue, “First Results from Cassini: Venus and Earth Swing-Bys” in the *Journal of Geophysical Research: Space Physics* in December 2001. As the spacecraft approached Jupiter, the number of science activities increased. Jupiter observations served as preparation for the four-year tour of the Saturnian system. Many of the science results are summarized in the Discipline and Instrument Reports that follow in this volume (see Volume 1 Sections 3.1 and 3.2).

Orbit insertion at Saturn occurred on July 1, 2004, thus starting 13 years of Cassini observations. The Saturn year is almost 30 Earth-years long and Saturn has an obliquity of almost 27°. Cassini arrived after the start of northern winter for its Prime Mission (Table 3-6 and Figure 3-1). The Prime Mission, completed in mid-2008, had only begun the exploration of the Saturn system, raising puzzling new questions that focused the science objectives of the upcoming extended missions.

Table 3-6. Summary of Cassini mission phases in the Saturn system.

	Mission Phase	Acronym	Dates (Seasons)
	Prime Mission	PM	July 2004—July 2008
Extended Missions	Cassini Equinox Mission	CEM	July 2008—Oct 2010 (equinox)
	Cassini Solstice Mission	CSM	Oct 2010—Nov 2016 (early northern spring)
	Ring Grazing (F-ring orbits) *Grand Finale (proximal orbits)*	RG *GF*	Nov 2016—April 2017 (late northern spring) April 2017—Sept 2017 (northern summer)

The fully-funded Cassini Equinox Mission (CEM) continued observations throughout a two-year period surrounding the equinox crossing in August 2009. In 2010, the streamlined (reduced budget) Cassini Solstice Mission (CSM) began seven years of exploration in three phases: CSM-1 was characterized by equatorial orbits including many icy-satellite targeted flybys; CSM-2 was characterized by inclined orbits that gave us optimal views of the rings and poles of Saturn; and the Northern Summer Mission (NSM) designed to witnesses the arrival of northern summer continuing the seasonal study of the Saturn system.

The last nine months of the mission was designed to put Cassini onto a collision course with Saturn. For the first five months, the trajectory included a series of 20 inclined orbits with periapses

near the unusually dynamic F-ring and apoapses near Titan's orbit. The last close flyby of Titan put Cassini into orbits with periapse between the innermost D-ring and the upper portions of Saturn's atmosphere for Cassini's last four months. A "goodbye kiss" from Titan, placed Cassini onto its last half orbit and brought the mission to an end collecting data on Saturn's upper atmosphere for as long as the spacecraft could hold steady.

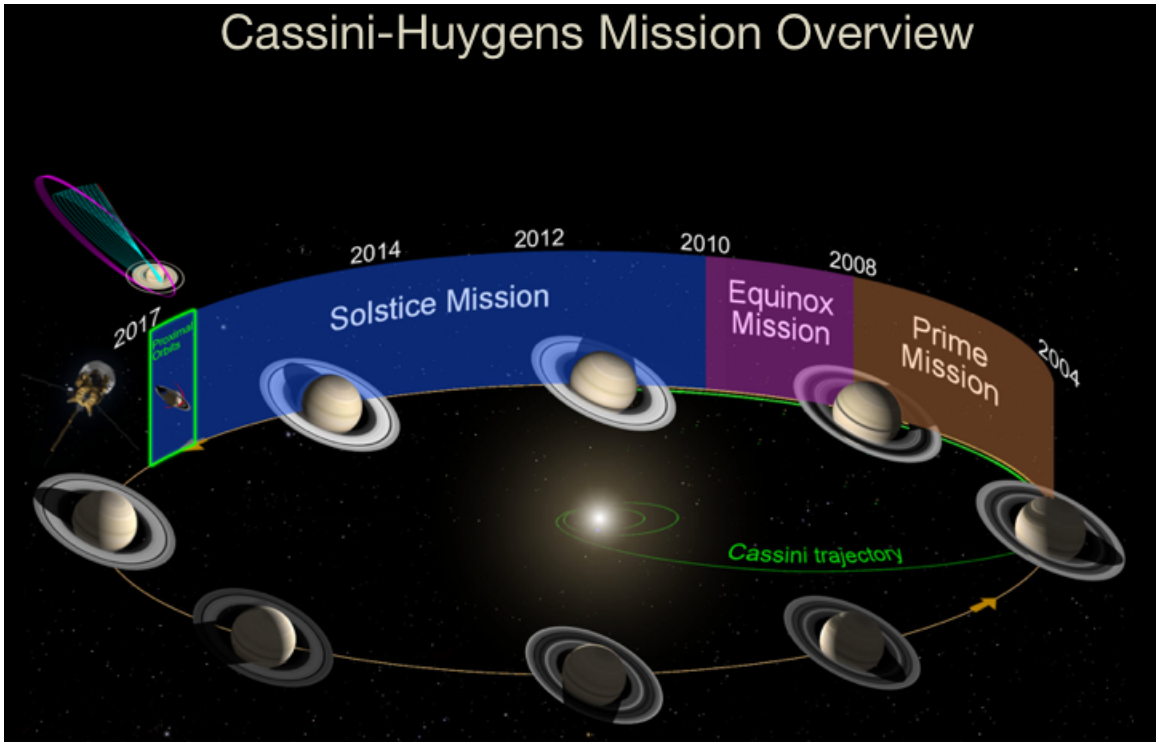

Figure 3-1. Seasonal coverage and associated phases of the Cassini-Huygens mission to Saturn. The Ring Grazing and Grand Finale phases of the mission are shown in the green box.

A Scientifically-Rich Mission

On the surface, Cassini's complete set of orbits, or tour, might look like a giant ball of yarn. When examined more closely, these orbits allowed Cassini to visit multiple targets at key times during the course of half a Saturn year. Multiple flybys of Titan provided gravity assists that shaped the size and orientation of each orbit in Cassini's orbital tour. This unique combination of orbital geometry allowed Cassini to study the complex seasonal changes that occurred throughout the Saturn system as the Sun set in the south and rose to more northerly latitudes in the Saturnian sky. Figure 3-2 illustrates the richness of this tour flown by the spacecraft.

The Prime Mission started roughly two years after northern winter began. It was comprised of 75 orbits, 45 Titan flybys, four (4) Enceladus flyby, and six (6) icy satellite flybys, including Phoebe. Just one year into the exploration, Cassini and Huygens discovered that Titan was an Earth-like world with lakes and rivers and active weather. Cassini also discovered that Enceladus was a

satellite with active plumes for the spacecraft to sample. Already, it was clear that scientists wanted to further study both worlds.

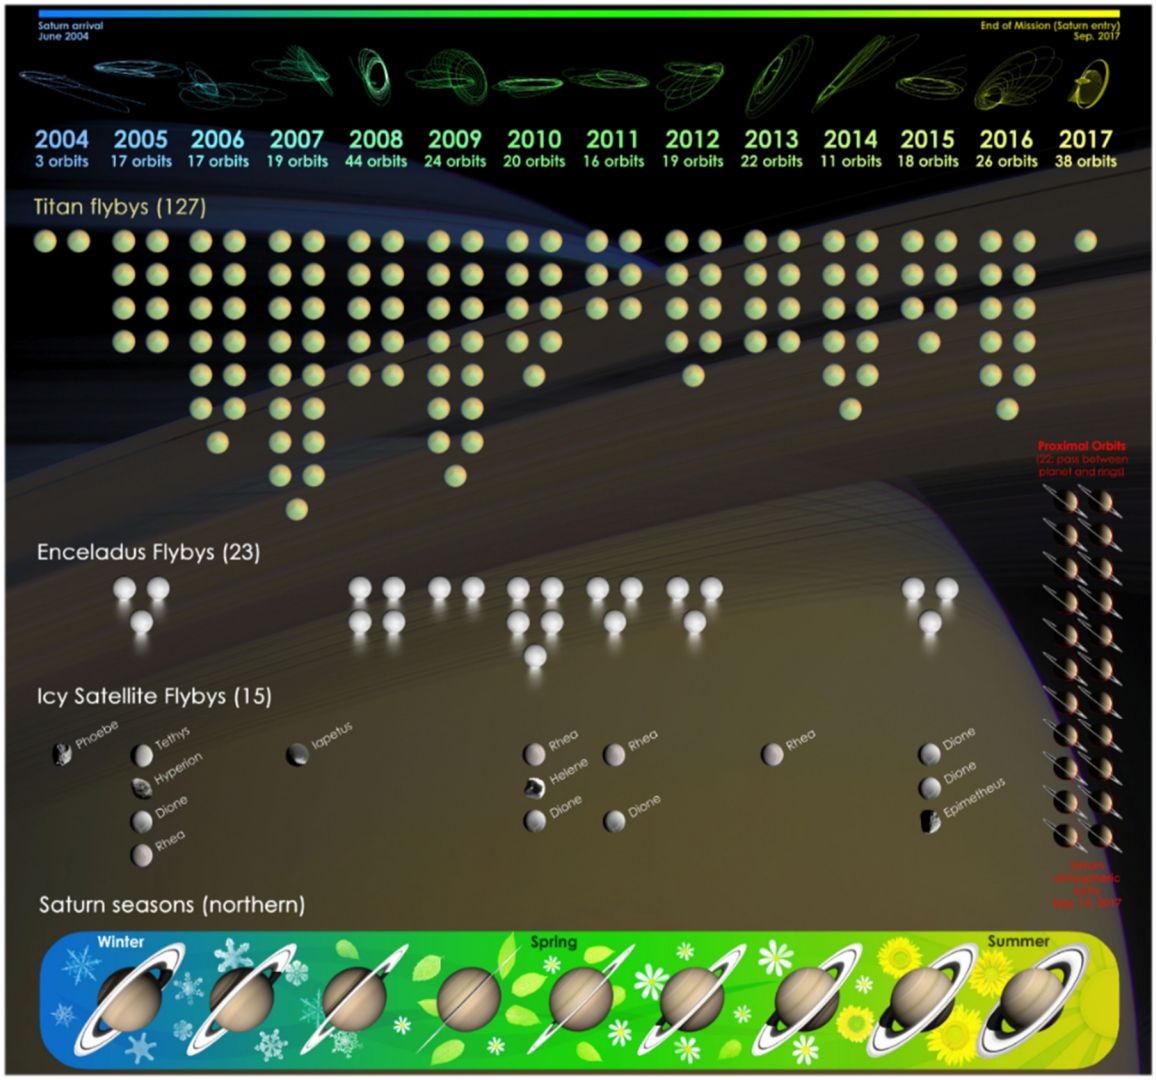

Figure 3-2. A scientifically-rich mission. From top to bottom: year and orbit, number of Titan flybys, number of Enceladus flybys, number of icy satellite flybys, and Saturn seasons. Cassini's 22 Grand Finale orbits are shown at the far right.

Cassini's mission was extended by another two years to encompass the years surrounding Saturn's equinox in August 2009 marking the transition from northern winter to northern spring. Orbits were designed to take advantage of the unique viewing of the rings at the time of equinox and to explore the magnetotail. These 60 orbits contained seven (7) additional Enceladus flybys, 26 Titan flybys, and four (4) icy satellite flybys.

With the knowledge and efficiencies gained from six years of flying a healthy spacecraft, mission designers proposed a plan to effectively make use of the remaining fuel onboard to observe the

Saturn system for the entire spring and into solstice (May 2017). Open scientific questions certainly argued for it and paved the way for profound discoveries to be made and provided the opportunity to observe unexpected events (e.g., Saturn's 2010–2011 Great Storm). A total of 160 orbits were executed containing twelve (12) Enceladus, 56 Titan, and twelve (12) icy satellite flybys. The last nine months, the 42 Ring Grazing and Grand Finale orbits, would be the capstone of a remarkable mission.

Cassini's Last Phase: Capstone of a Remarkable Mission

Ring Grazing Orbits: In late 2016, Cassini's trajectory transitioned to a series of 20 Ring Grazing orbits with periapses located within 10,000 km of Saturn's F-ring (Figure 3-3). These orbits provided the high-resolution views of Saturn's F-ring and outer A-ring, in addition to prime viewing conditions for fine-scale ring structures such as propellers (Figure 3-4). They also included the closest flybys of tiny ring moons, including Pan, Daphnis, and Atlas (Figure 3-4). Plasma and dust composition measurements were also conducted in this region.

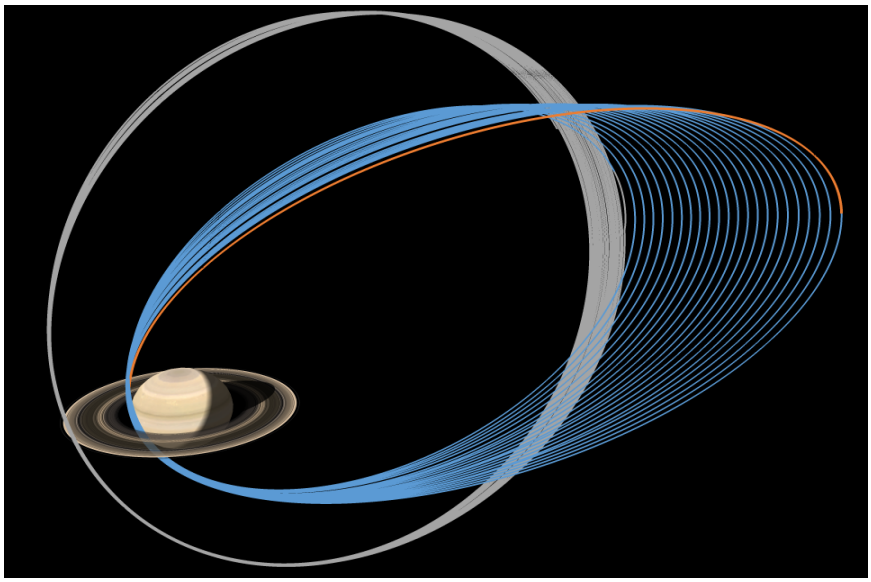

Figure 3-3. Cassini's 20 Ring Grazing (gray) and Grand Finale (blue) orbits. The last half-orbit (orange) took Cassini into Saturn's atmosphere for vaporization.

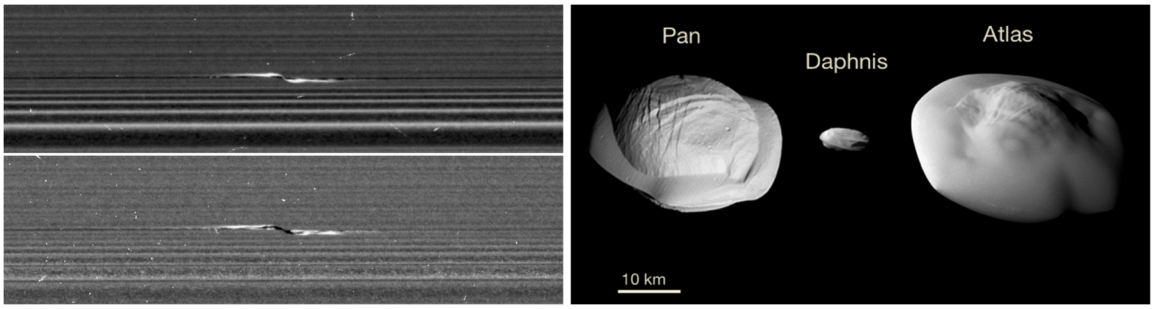

Figure 3-4. Left: Ring propeller Santos-Dumont on lit and unlit sides of the rings. Right: Comparison of highest resolution images of the ring moons, Pan, Daphnis, and Atlas.

Grand Finale Orbits: A final close flyby of Titan in late April 2017 propelled Cassini across Saturn's main rings and into its Grand Finale orbits. Comprised of 22 orbits, the spacecraft repeatedly dove between Saturn's innermost rings and upper atmosphere (Figure 3-4, blue orbits) attempting to answer fundamental questions unattainable earlier in the mission. The Grand Finale was like a brand-new mission, exploring a region of the Saturn system that was unexplored by Cassini and any previous outer planet spacecraft.

Saturn's gravitational field was measured to unprecedented accuracy, providing information from which constraints on the interior structure of the planet, winds in the deep atmosphere, and mass distribution in the rings could be derived (Figure 3-5). Probing the magnetic field provided data for insight into the physics of the magnetic dynamo, on the structure of the internal magnetic field, and on the location of the metallic hydrogen transition region.

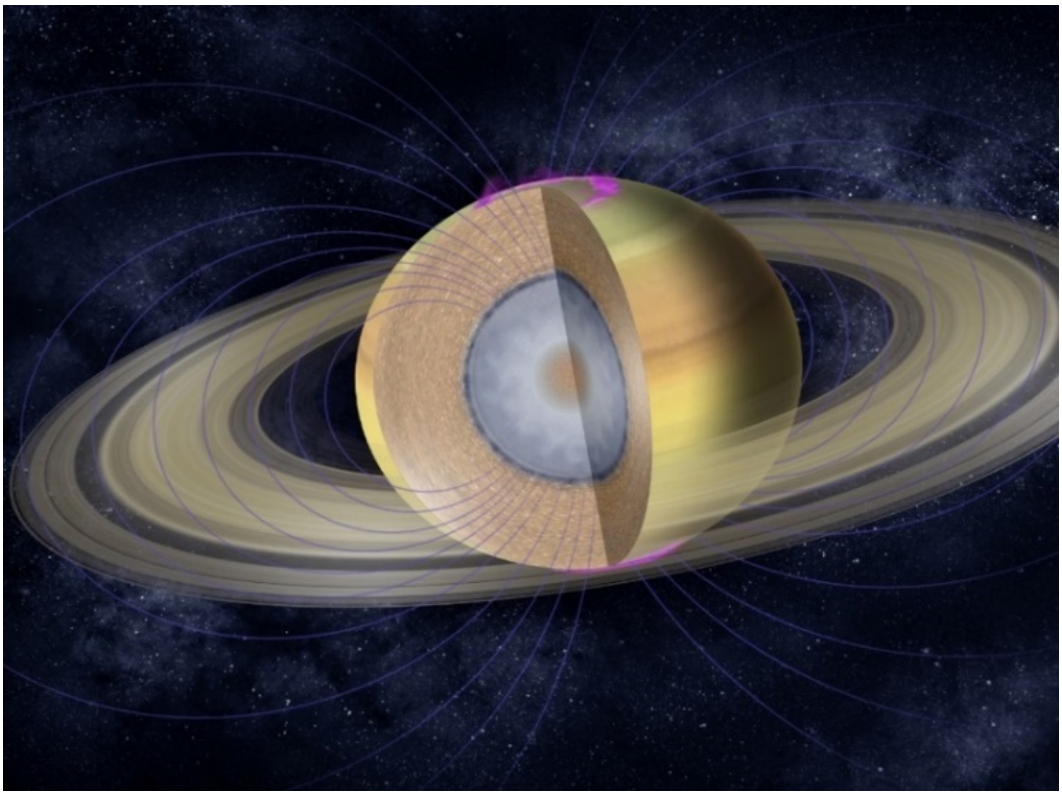

Figure 3-5. Grand Finale science goals focused on studying ring mass and composition, interior structure, magnetic dynamo, aurora, and atmospheric composition.

The Grand Finale orbits provided the highest resolution observations ever of both Saturn's C- and D-rings and Saturn's atmospheric weather layer (Figure 3-6). Direct in situ sampling of the ring particle composition and the innermost radiation belts was also achieved. The INMS sampled the exosphere and upper atmosphere for molecules entering and escaping from the atmosphere and water-based molecules originating from the rings. The CDA directly sampled the composition of ring particles from different regions of the main rings for the first time.

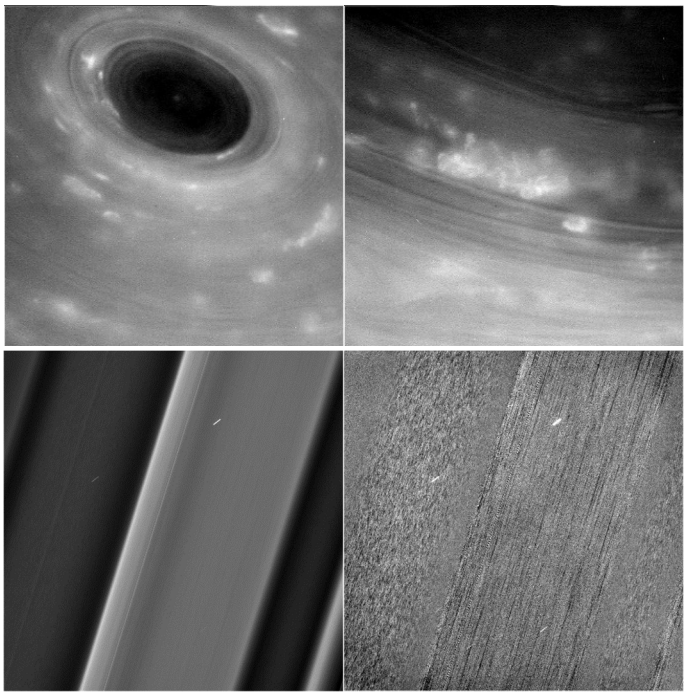

Figure 3-6. Saturn's north polar vortex (upper left) and convective clouds over the hexagon jet stream (upper right). Image of C-ring "Plateau" features (lower left) and same image after processing (lower right) to reveal differing ring particle "textures" in neighboring regions.

Cassini's Final Half-orbit: The last half-orbit turned the spacecraft into the first Saturn atmosphere probe with all of fields and particle instruments gathering data as long as the spacecraft remained stable. Approximately one additional scale height of atmosphere was probed prior to loss of the radio signal from the spacecraft.

The Cassini mission was a remarkable endeavor, revealing the Saturn system in unprecedented detail. Numerous Cassini discoveries reshaped our thinking about this astoundingly complex system.

CASSINI-HUYGENS SCIENCE OBJECTIVES

The Cassini-Huygens science objectives were first defined in the NASA and ESA AOs [ESA 1989; NASA 1989, 1991]. An expanded set of science objectives were later defined in a set of Traceability Matrices that were developed in 2007 as a part of Cassini's first mission extension. As the mission progressed, the Traceability Matrices were updated and refined through three mission extensions, including Senior Reviews in 2012 and 2014 [JPL 2012, 2014], based on Cassini's latest findings. Science objectives from both the AO and Traceability Matrices are briefly listed in the next section, and are explored in more detail in the discipline and instrument team reports in Section 3.2. The Traceability Matrix objectives listed in the following section are those defined for the Cassini Solstice Mission (CSM), and in Cassini's 2014 Senior Review. For the Traceability Matrix objectives, the second letter is either a "C" for seasonal or temporal "Change," or an "N" for "New" science.

Cassini-Huygens Announcements of Opportunity and Traceability Matrices Science Objectives

Huygens Probe AO objectives (see Huygens Discipline Report)

- Titan Atmospheric Formation and Evolution (H_AO1) – Determine abundances of atmospheric constituents (including any noble gases); establish isotope ratios for abundant elements; constrain scenarios of formation and evolution of Titan and its atmosphere.
- Titan Atmospheric Composition and Distribution (H_AO2) – Observe vertical and horizontal distributions of trace gases; search for more complex organic molecules; investigate energy sources for atmospheric chemistry; model the photochemistry of the stratosphere; study formation and composition of aerosols.
- Titan Meteorology (H_AO3) – Measure winds and global temperatures; investigate cloud physics, general circulation and seasonal effects in Titan's atmosphere; search for lightning discharges.
- Titan Surface Characteristics and Internal Structure (H_AO4) – Determine the physical state, topography, and the composition of the surface; infer the internal structure of the satellite.
- Titan Upper Atmosphere (H_AO5) – Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.

Icy Satellites AO objectives (see Icy Satellites Discipline Report)

- Icy Satellite Geology and History (I_AO1) – Determine the general characteristics and geological histories of the satellites.
- Icy Satellite Surface and Crustal Modifications (I_AO2) – Define the mechanisms of crustal and surface modifications, both external and internal.
- Icy Satellite Surface Composition (I_AO3) – Investigate the compositions and distributions of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles.
- Icy Satellite Interior Properties (I_AO4) – Constrain models of the satellites' bulk compositions and internal structures.
- Icy Satellite Magnetosphere and Ring Interactions (I_AO5) – Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.

Icy Satellites CSM Traceability Matrix objectives (see Icy Satellites Discipline Report)

- Enceladus Seasonal Changes (IC1a) – Identify long-term secular and seasonal changes at Enceladus, through observations of the south polar region, jets, and plumes.
- Enceladus Ocean (IN1a) – Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.
- Mid-sized Satellites (IN1b) – Complete the comparative study of Saturn's mid-sized satellites, their geological and cratering histories, and interactions with the Saturn system, with remote sensing of Mimas at the highest resolution possible in order to understand the mechanisms behind its unique thermal properties discovered by Cassini.
- Dione (IN1c) – Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.
- Rhea (IN2a) – Determine whether there is ring material orbiting Rhea, and if so, what its spatial and particle size distribution is.
- Tethys (IN2b) – Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population.
- Satellite Interiors (IN2c) – Determine the extent of differentiation and internal inhomogeneity within the icy satellites, especially Rhea and Dione.
- Small Moons (IN2d) – Observe selected small satellites to quantify the movement of Enceladus material through the system, the history of satellite collisions/breakup, interaction with ring material as indicated by surface properties/composition, and cratering rates deep in the Saturnian system.
- Hyperion (IN2e) – Understand the unusual appearance of Hyperion with remote sensing observations of the highest resolution possible.
- Iapetus (IN2f) – Use remote sensing of Iapetus to test models for the albedo heterogeneity of the satellite. Quantify the effect of the newly-discovered Phoebe ring on the properties of Iapetus' surface.

Titan AO objectives (see Titan Discipline Report)

- Titan Atmospheric Formation and Evolution (T_AO1) – Determine abundances of atmospheric constituents (including any noble gases), establish isotope ratios for abundant elements, constrain scenarios of formation and evolution of Titan and its atmosphere.

- Titan Atmospheric Composition and Distribution (T_AO2) – Observe vertical and horizontal distributions of trace gases, search for more complex organic molecules, investigate energy sources for atmospheric chemistry, model the photochemistry of the stratosphere, study formation and composition of aerosols.
- Titan Meteorology (T_AO3) – Measure winds and global temperatures; investigate cloud physics, general circulation, and seasonal effects in Titan's atmosphere; search for lightning discharges.
- Titan Surface Characteristics and Internal Structure (T_AO4) – Determine the physical state, topography, and composition of the surface; infer the internal structure of the satellite.
- Titan Upper Atmosphere (T_AO5) – Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.

Titan CSM Traceability Matrix objectives (see Titan Discipline Report)

- Titan's Great Seas (TC1a) – Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport.
- Titan's Global Seasons (TC1b) – Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.
- Titan-Magnetosphere Interaction (TC2a) – Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.
- Titan's Surface (TN1a) – Determine the types, composition, distribution, and ages, of surface units and materials, most notably lakes (i.e., filled vs. dry and depth; liquid vs. solid and composition; polar vs. other latitudes and lake basin origin).
- Titan's Interior Ocean (TN1b) – Determine internal and crustal structure: Liquid mantle, crustal mass distribution, rotational state of the surface with time, intrinsic and/or internal induced magnetic field.
- Titan Atmospheric Composition (TN1c) – Measure aerosol and heavy molecule layers and properties.
- Titan Atmospheric Structure (TN2a) – Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission).
- Titan's Icy Shell (TN2b) – Determine icy shell topography and viscosity.
- Titan Meteorology (TN2c) – Determine the surface temperature distribution, cloud distribution, and tropospheric winds.

Saturn AO objectives (see Saturn Discipline Report)

- Saturn Temperature, Clouds, Composition (S_AO1) – Determine temperature field, cloud properties, and composition of the atmosphere of Saturn.
- Saturn Winds and Weather (S_AO2) – Measure the global wind field, including wave and eddy components; observe synoptic cloud features and processes.
- Saturn Interior Structure and Rotation (S_AO3) – Infer the internal structure and rotation of the deep atmosphere.
- Saturn Ionosphere-Magnetosphere Interaction (S_AO4) – Study the diurnal variations and magnetic control of the ionosphere of Saturn.
- Saturn Formation and Evolution (S_AO5) – Provide observational constraints (gas composition, isotope ratios, heat flux, ...) on scenarios for the formation and the evolution of Saturn.
- Saturn Lightning Sources and Morphology (S_AO6) – Investigate the sources and the morphology of Saturn lightning (Saturn electrostatic discharges (SEDs), lightning whistlers).

Saturn CSM Traceability Matrix objectives (see Saturn Discipline Report)

- Seasonal Variations (SC1a) – Observe seasonal variations in temperature, clouds, and composition in three spatial dimensions.
- Saturn's Winds (SC1b) – Observe seasonal changes in the winds at all accessible altitudes coupled with simultaneous observations of clouds, temperatures, composition, and lightning.
- Aurorae, Chemistry, and Upper Atmosphere (SC2a) – Observe the magnetosphere, ionosphere, and aurora as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.
- Saturn's Rotation Rate (SN1a) – Determine Saturn's rotation rate and internal structure despite the planet's unexpected high degree of axisymmetry.
- 2010–2011 Great Storm (SN1b) – Observe the aftermath of the 2010–2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon.
- Saturn Trace Gases (SN1c) – Measure the spatial and temporal variability of trace gases and isotopes.
- Saturn Storms and Lightning (SN2a) – Monitor the planet for new storms and respond with new observations when the new storms occur.

Rings AO objectives (see Rings Discipline Report)

- Ring Structure and Dynamics (R_AO1) – Study configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.
- Ring Particle Composition and Size (R_AO2) – Map composition and size distribution of ring material.
- Ring-Satellite Interaction (R_AO3) – Investigate interrelation of rings and satellites, including embedded satellites.
- Dust and Meteoroid Distribution (R_AO4) – Determine dust and meteoroid distribution both in the vicinity of the rings and in interplanetary space.
- Ring Magnetosphere-Ionosphere Interactions (R_AO5) – Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.

Rings CSM Traceability Matrix objectives (see Rings Discipline Report)

- Changing Rings (RC1a) – Determine the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near solstice.
- Ring Temporal Variability (RC1b) – Determine the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations.
- F-Ring (RC2a) – Focus on F-ring structure, and distribution of associated moonlets or clumps, as sparse observations show clumps, arcs, and possibly transient objects appearing and disappearing.
- Ring Age and Origin (RN1a) – Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejecta trapped on field lines.
- Ring Composition (RN1b) – Determine the composition of the close-in "ringmoons" as targets of opportunity.
- Ring Structure (RN1c) – Determine structural and compositional variations at high resolution across selected ring features of greatest interest, using remote and in situ observations.
- Ring Microstructure (RN2a) – Conduct in-depth studies of ring microstructure such as self-gravity wakes, which permeate the rings.
- New Ring Structures (RN2b) – Perform focused studies of the evolution of newly discovered "propeller" objects.

MAPS AO objectives (see MAPS Discipline Report)

- Saturn Magnetic Field Configuration and SKR (M_AO1) – Determine the configuration of the nearly axially symmetric magnetic field and its relation to the modulation of Saturn kilometric radiation (SKR).
- Magnetosphere Charged Particles (M_AO2) – Determine current systems, composition, sources, and sinks of magnetosphere charged particles.
- Magnetosphere Wave-Particle Interactions (M_AO3) – Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.
- Magnetosphere and Solar Interactions with Titan (M_AO4) – Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.
- Plasma Interactions with Titan's Atmosphere and Ionosphere (M_AO5) – Investigate interactions of Titan's atmosphere and exosphere with the surrounding plasma.

MAPS CSM Traceability Matrix objectives (see MAPS Discipline Report)

- Enceladus Plume Variability (MC1a) – Determine the temporal variability of Enceladus' plumes.
- Seasonal and Solar Cycle Variations (MC1b) – Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.
- Titan's Ionosphere (MC2a) – Observe seasonal variation of Titan's ionosphere, from one solstice to the next.
- Magnetotail (MN1a) – Determine the dynamics of Saturn's magnetotail.
- Saturn's Ionosphere and Radiation Belts (MN1b) – Conduct in situ studies of Saturn's ionosphere and inner radiation belt.
- Magntosphere Periodicities (MN1c) – Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the SKR periods are imposed from close to the planet (3–5 Rs) out to the deep tail.
- Ionosphere and Ring Coupling (MN2a) – Determine the coupling between Saturn's rings and ionosphere.

Cruise Science AO objectives

- Cruise Interstellar Ion Composition (C_AO1) – Extend the sensitivity of composition measurements of interstellar ions by approximately three orders of magnitude.
- Cruise Solar Wind Investigations (C_AO2) – Investigate the behavior of the solar wind during solar minimum, for comparison with earlier Galileo and Ulysses measurements.

- Cruise Gravitational Wave Searches (C_AO3) – Extend spacecraft searches for gravitational waves.
- Cruise Interplanetary Dust Studies (C_AO4) – Extend studies of interplanetary dust to the orbit of Saturn.
- Cruise Planetary and Stellar Internal Oscillations (C_AO5) – Attempt to detect internal oscillations of Saturn, Jupiter, and some stars.

Jupiter Flyby AO objectives

- Jupiter and Satellite Studies (J_AO1) – Extend the time for studies of atmospheric dynamics and variable satellite phenomena, specifically Io volcanism, beyond the period accessible to the Galileo nominal mission.
- Jupiter Global Atmospheric Structure and Composition (J_AO2) – Infer global atmospheric thermal structure and composition with instrumentation not carried by the Galileo orbiter, complementing the local in situ measurements of the Galileo probe.
- Jupiter Magnetospheric Studies (J_AO3) – Explore the dusk side of the magnetosphere and intermediate regions of the magnetotail unvisited by previous spacecraft.
- Jupiter Io Torus (J_AO4) – Obtain the first high-resolution images of the Io torus.

Venus Flyby AO objectives

- N/A – There were no specific Venus science objectives called out in the Announcement of Opportunity. It was, however, an opportunity to calibrate and gauge the performance of instruments and test spacecraft functionality.

Asteroid Flyby AO objectives

- Asteroid Flyby Investigation (A_AO1) – Investigate an asteroid not seen by previous missions, possibly a new class of asteroid, thereby adding important new information to the study of asteroids.
  - On January 23, 2000, observations by ISS, VIMS, and UVIS of the distant (1,634,000 km) asteroid 2685 Masursky were conducted. No papers or abstracts were written on the observation.
- Asteroid Global Characteristics (A_AO2) – Characterize global properties, determine composition and morphology of the surface, investigate properties of the regolith.
  - On January 23, 2000, observations by ISS, VIMS, and UVIS of the distant (1,634,000 km) asteroid 2685 Masursky were conducted. No papers or abstracts were written on the observation.

PROJECT SCIENCE ASSESSMENT

Overall, the Cassini-Huygens mission was a tremendous success, accomplishing or exceeding almost all of the science objectives defined in the Cassini and Huygens AOs and in the Cassini Solstice Mission Traceability Matrices. Tables 3-7, 3-8, and 3-9 contain color-coded assessments of the science objectives for the Cassini-Huygens mission. If a science objective was accomplished or exceeded, its box is colored green. The rare exceptions, which are colored yellow or lime green, are instances where an objective was only partially accomplished. A full explanation of why it was not met is included in each yellow or lime green box.

Overall, the Cassini-Huygens mission was a tremendous success, accomplishing or exceeding almost all of the science objectives defined in the Cassini and Huygens AOs and in the Cassini Solstice Mission Traceability Matrices.

The project science assessments shown in Tables 3-7, 3-8, and 3-9 are a compilation of each discipline assessment and Huygens probe assessment. Table 3-7 includes the science assessments for the Icy Satellites, Titan, and Enceladus disciplines. Table 3-8 includes the science assessments for Saturn, Rings, and MAPS disciplines, while Table 3-9 includes the science assessments for Cruise and Jupiter science.

Future analysis of Cassini data may result in some unmet objectives being fully met. For example, at the writing of this report, Saturn's internal rotation rate could not be determined from the magnetometer data taken during Cassini's Grand Finale orbits at the end of the mission. The offset between Saturn's rotation axis and magnetic field axis appears to be too small to provide an estimate of Saturn's internal rotation rate. However, a paper by Mankovich et al. [2019] uses Saturn-driven waves detected in the main rings (kronoseismology) to determine an internal rotation rate for Saturn. Future analysis of Cassini data may provide additional information on Saturn's internal rotation rate. For more details on the specifics of the science assessments for each science objective, please see the discipline and team reports in Section 3, which also include their own color-coded science assessment tables.

Table 3-7. Project Science Assessment (1 of 3 tables): Icy Satellites, Titan disciplines and Huygens.

Table Legend: Green: Fully Accomplished Yellow: Partially Accomplished

Cassini & Huygens Science Objectives		
Icy Satellites	**Titan**	**Huygens**
Prime Mission AO Objectives		
Icy Satellite Geology and History (I_AO1) - Determine the general characteristics and geological histories of the satellites.	**Titan Atmospheric Formation and Evolution (T_AO1)** - Determine abundances of atmospheric constituents (including any noble gases), establish isotope ratios for abundant elements, constrain scenarios of formation and evolution of Titan and its atmosphere.	**Titan Atmospheric Formation and Evolution (H_AO1)** - Determine abundances of atmospheric constituents (including any noble gases); establish isotope ratios for abundant elements; constrain scenarios of formation and evolution of Titan and its atmosphere.

Table 3-7. Project Science Assessment (1 of 3 tables): Icy Satellites, Titan disciplines and Huygens.

Table Legend: Green: Fully Accomplished Yellow: Partially Accomplished

Cassini & Huygens Science Objectives		
Icy Satellites	**Titan**	**Huygens**
Icy Satellite Surface and Crustal Modifications (I_AO2) - Define the mechanisms of crustal and surface modifications, both external and internal.	**Titan Atmospheric Composition and Distribution (T_AO2)** - Observe vertical and horizontal distributions of trace gases, search for more complex organic molecules, investigate energy sources for atmospheric chemistry, model the photochemistry of the stratosphere, study formation and composition of aerosols.	**Titan Atmospheric Composition and Distribution (H_AO2)** - Observe vertical and horizontal distributions of trace gases; search for more complex organic molecules; investigate energy sources for atmospheric chemistry; model the photochemistry of the stratosphere; study formation and composition of aerosols. *Note: This box is not green because the very low concentrations of aerosols collected by ACP limited the results to simple species, rather than complex hydrocarbon hazes.*
Icy Satellite Surface Composition (I_AO3) - Investigate the compositions and distributions of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles.	**Titan Meteorology (T_AO3)** - Measure winds and global temperatures; investigate cloud physics, general circulation, and seasonal effects in Titan's atmosphere; search for lightning discharges.	**Titan Meteorology (H_AO3)** - Measure winds and global temperatures; investigate cloud physics, general circulation and seasonal effects in Titan's atmosphere; search for lightning discharges.
Icy Satellite Interior Properties (I_AO4) - Constrain models of the satellites' bulk compositions and internal structures.	**Titan Surface Characteristics and Internal Structure (T_AO4)** - Determine the physical state, topography, and composition of the surface; infer the internal structure of the satellite. *Note: This box is not green because "Some work was done, but more work remains for future missions."*	**Titan Surface Characteristics and Internal Structure (H_AO4)** - Determine the physical state, topography and the composition of the surface; infer the internal structure of the satellite.
Icy Satellite Magnetosphere and Ring Interactions (I_AO5) - Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.	**Titan Upper Atmosphere (T_AO5)** - Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.	**Titan Upper Atmosphere (H_AO5)** - Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.
Science Traceability Matrix		
Enceladus Seasonal Changes (IC1a) - Identify long-term secular and seasonal changes at Enceladus, through observations of the south polar region, jets, and plumes.	**Titan's Great Seas (TC1a)** - Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport.	
Enceladus Ocean (IN1a) - Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.	**Titan's Global Seasons (TC1b)** - Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.	

Table 3-7. Project Science Assessment (1 of 3 tables): Icy Satellites, Titan disciplines and Huygens.

Table Legend: Green: Fully Accomplished Yellow: Partially Accomplished

Cassini & Huygens Science Objectives		
Icy Satellites	**Titan**	**Huygens**
Mid-sized Satellites (IN1b) - Complete the comparative study of Saturn's mid-sized satellites, their geological and cratering histories, and interactions with the Saturn system, with remote sensing of Mimas at the highest resolution possible in order to understand the mechanisms behind its unique thermal properties discovered by Cassini.	**Titan-Magnetosphere Interaction (TC2a)** - Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.	
Dione (IN1c) - Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time. *Note: This box is not green because extensive data were gathered, but the current results are still ambiguous. No current activity was detected.*	**Titan's Surface (TN1a)** - Determine the types, composition, distribution, and ages, of surface units and materials, most notably lakes (i.e., filled vs. dry & depth; liquid vs. solid & composition; polar vs. other latitudes & lake basin origin).	
Rhea (IN2a) - Determine whether there is ring material orbiting Rhea, and if so, what its spatial and particle size distribution is.	**Titan's Interior Ocean (TN1b)** - Determine internal and crustal structure: Liquid mantle, crustal mass distribution, rotational state of the surface with time, intrinsic and/or internal induced magnetic field. *Note: This box is not green because 1) Cassini only studied a few crustal structures locally and crustal viscosity was not determined by data taken, and 2) induced magnetic fields were difficult to determine due to ionospheric currents.*	
Tethys (IN2b) - Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population. *Note: From a CDA/icy dust perspective, this box is not green because during the Solstice Mission there were no close Tethys flybys to measure potential ejecta [Kempf, Beckmann, and Schmidt 2010]. For MAPS as a whole, enough data were obtained to determine that Tethys does not contribute to the E-ring and magnetospheric ion and neutral population [Burch et al. 2007; Khurana, Russell, and Dougherty 2008], yielding an overall yellow box.*	**Titan Atmospheric Composition (TN1c)** - Measure aerosol and heavy molecule layers and properties.	
Satellite Interiors (IN2c) - Determine the extent of differentiation and internal inhomogeneity within the icy satellites, especially Rhea and Dione.	**Titan Atmospheric Structure (TN2a)** - Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission).	

Table 3-7. Project Science Assessment (1 of 3 tables): Icy Satellites, Titan disciplines and Huygens.

Table Legend: Green: Fully Accomplished Yellow: Partially Accomplished

Cassini & Huygens Science Objectives		
Icy Satellites	**Titan**	**Huygens**
Small Moons (IN2d) - Observe selected small satellites to quantify the movement of Enceladus material through the system, the history of satellite collisions/breakup, interaction with ring material as indicated by surface properties/composition, and cratering rates deep in the Saturnian system.	**Titan's Icy Shell (TN2b)** - Determine icy shell topography and viscosity. *Note: This box is not green because crustal viscosity could not be determined to date from data taken.*	
Hyperion (IN2e) - Understand the unusual appearance of Hyperion with remote sensing observations of the highest resolution possible.	**Titan Meteorology (TN2c)** - Determine the surface temperature distribution, cloud distribution, and tropospheric winds.	
Iapetus (IN2f) - Use remote sensing of Iapetus to test models for the albedo heterogeneity of the satellite. Quantify the effect of the newly-discovered Phoebe ring on the properties of Iapetus' surface.		

Table 3-8. Project Science Assessment (2 of 3 tables): Saturn, Rings and MAPS disciplines.

Table Legend: Green: Fully Accomplished Yellow: Partially Accomplished

Cassini Science Objectives		
Saturn	**Rings**	**MAPS**
Prime Mission AO Objectives		
Saturn Temperature, Clouds, Composition (S_AO1) - Determine temperature field, cloud properties, and composition of the atmosphere of Saturn.	**Ring Structure and Dynamics (R_AO1)** - Study configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.	**Saturn Magnetic Field Configuration and SKR (M_AO1)** - Determine the configuration of the nearly axially symmetric magnetic field and its relation to the modulation of SKR.
Saturn Winds and Weather (S_AO2) - Measure the global wind field, including wave and eddy components; observe synoptic cloud features and processes.	**Ring Particle Composition and Size (R_AO2)** - Map composition and size distribution of ring material.	**Magnetosphere Charged Particles (M_AO2)** - Determine current systems, composition, sources, and sinks of magnetosphere charged particles.
Saturn Interior Structure and Rotation (S_AO3) - Infer the internal structure and rotation of the deep atmosphere. *Note: This box is not green because at the time of this report, Saturn's internal rotation rate could not be determined from the Grand Finale magnetic field data. Mankovich et al. [2019] may have finally determined the rotation rate from patterns related to kronoseismology in Saturn's rings, at which point this box would become green.*	**Ring-Satellite Interaction (R_AO3)** - Investigate interrelation of rings and satellites, including embedded satellites.	**Magnetosphere Wave-Particle Interactions (M_AO3)** - Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.
Saturn Ionosphere-Magnetosphere Interaction (S_AO4) - Study the diurnal variations and magnetic control of the ionosphere of Saturn.	**Dust and Meteoroid Distribution (R_AO4)** - Determine dust and meteoroid distribution both in the vicinity of the rings and in interplanetary space.	**Magnetosphere and Solar Interactions with Titan (M_AO4)** - Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.

Table 3-8. Project Science Assessment (2 of 3 tables): Saturn, Rings and MAPS disciplines.

Table Legend: Green: Fully Accomplished Yellow: Partially Accomplished

Cassini Science Objectives		
Saturn	**Rings**	**MAPS**
Saturn Formation and Evolution (S_AO5) - Provide observational constraints (gas composition, isotope ratios, heat flux, ...) on scenarios for the formation and the evolution of Saturn.	**Ring Magnetosphere-Ionosphere Interactions (R_AO5)** - Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.	**Plasma Interactions with Titan's Atmosphere and Ionosphere (M_AO5)** - Investigate interactions of Titan's atmosphere and exosphere with the surrounding plasma.
Saturn Lightning Sources and Morphology (S_AO6) - Investigate the sources and the morphology of Saturn lightning (Saturn electrostatic discharges (SEDs), lightning whistlers).		
Science Traceability Matrix		
Seasonal Variations (SC1a) - Observe seasonal variations in temperature, clouds, and composition in three spatial dimensions.	**Changing Rings (RC1a)** - Determine the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near solstice.	**Enceladus Plume Variability (MC1a)** - Determine the temporal variability of Enceladus' plumes.
Saturn's Winds (SC1b) - Observe seasonal changes in the winds at all accessible altitudes coupled with simultaneous observations of clouds, temperatures, composition, and lightning.	**Ring Temporal Variability (RC1b)** - Determine the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations.	**Seasonal and Solar Cycle Variations (MC1b)** - Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.
Aurorae, Chemistry, and Upper Atmosphere (SC2a) - Observe the magnetosphere, ionosphere, and aurora as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.	**F-ring (RC2a)** - Focus on F-ring structure, and distribution of associated moonlets or clumps, as sparse observations show clumps, arcs, and possibly transient objects appearing and disappearing.	**Titan's Ionosphere (MC2a)** - Observe seasonal variation of Titan's ionosphere, from one solstice to the next.
Saturn's Rotation Rate (SN1a) - Determine Saturn's rotation rate and internal structure despite the planet's unexpected high degree of axisymmetry.	**Ring Age and Origin (RN1a)** - Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejecta trapped on field lines.	**Magnetotail (MN1a)** - Determine the dynamics of Saturn's magnetotail.
2010—2011 Great Storm (SN1b) - Observe the aftermath of the 2010—2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon.	**Ring Composition (RN1b)** - Determine the composition of the close-in "ringmoons" as targets of opportunity.	**Saturn's Ionosphere and Radiation Belts (MN1b)** - Conduct in situ studies of Saturn's ionosphere and inner radiation belt.

Table 3-8. Project Science Assessment (2 of 3 tables): Saturn, Rings and MAPS disciplines.

CASSINI'S TOP SCIENCE HIGHLIGHTS

Many of Cassini's findings revolutionized our understanding of the Saturn system. Some of Cassini's most surprising scientific discoveries came from encounters with Saturn's intriguing moons. Enceladus harbors a salty, liquid water ocean beneath its icy crust that is the source for icy jets and huge plume spewing from fractures at its south pole. On giant Titan, methane rain carves river channels and fills lakes and seas with hydrocarbons, mixed with complex prebiotic chemicals that form in its atmosphere and rain to the surface. From Huygens probe data it was determined that Titan, too, has an internal liquid water ocean. Some of Cassini's other amazing findings include a myriad of three-dimensional structures in the dynamic rings driven by interactions with Saturn's moons and interior; a giant Saturn storm that circled the entire planet for most of 2011, while a long-lived hexagonal jet stream discovered by Voyager in 1981 continues to encircle the north polar region. Cassini solved the mystery of Iapetus' dual bright-dark surface, and the true rotation rate of Saturn's interior. During the final year of the mission, moving closer to Saturn than ever before, provided an astonishing array of discoveries about the interior of Saturn, its rings and tiny ringmoons, and the gap between the rings and the planet. This section highlights some of Cassini's top scientific discoveries. Additional details about each of them can be found in the discipline and instrument team reports in Section 3 and in Spilker [2019].

Enceladus: Discovery of an Ocean World

The discovery of Enceladus' massive plume spewing into space was such a surprise that mission designers completely reshaped the mission to get a more detailed look, adding 20 more close Enceladus flybys, for a total of 23 during the mission. The discovery became even more important when Cassini found evidence of water vapor and water ice in the plume. Life as we know it relies on water, so the search for life suddenly extended to this small, bright moon. The discovery of a subsurface ocean makes Enceladus one of the most exciting science destinations in our solar system.

Prior to Cassini's arrival, Enceladus, a small moon only about 500 km across, was puzzling because of its very bright surface. As the brightest moon in our solar system, it reflects almost 90% of the sunlight it receives. During Cassini's early flybys, images of the moon (Figure 3-7) revealed a system of extensive cracks and large regions completely devoid of craters. The south polar region contains large tectonic features, is devoid of craters, and is the youngest surface on Enceladus. It includes a system of four nearly parallel fractures, nicknamed "tiger stripes," that are centered near the pole [Helfenstein 2010]. Each "tiger stripe" is about 130 km long and 2–4 km wide. They are separated from each other by approximately 35 km.

Activity on Enceladus was first detected by Cassini's magnetometer as a deflection of Saturn's magnetic field [Dougherty et al. 2006]. During a close targeted flyby in 2005, Cassini's thermal infrared spectrometer discovered a hot spot centered near the South Pole [Spencer et al. 2006]. The four tiger stripe fractures were the warmest regions—more than 100 degrees Celsius warmer than the surrounding areas [Howett et al. 2011]—and were the source of an immense ice plume

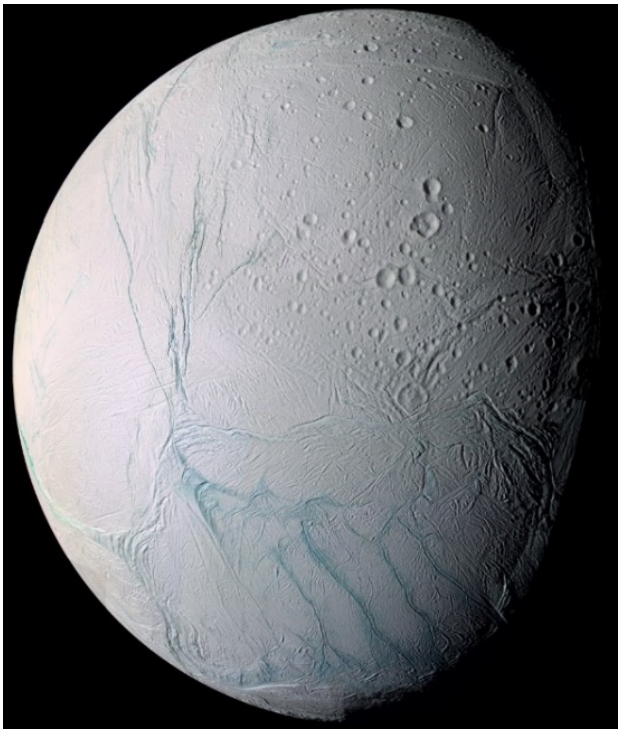

Figure 3-7. Enceladus' bright surface, with very few craters, indicates a young surface. Four bluish "tiger stripe" fractures at the South Pole are the source of the icy jets and plume.

imaged by Cassini's camera [Porco et al. 2006]. The giant cryovolcanic plume of water vapor and ice grains is fed by both discrete jets [Porco, DiNino, and Nimmo 2014] and curtains of material [Spitale et al. 2015] originating inside each tiger stripe (Figure 3-8). The localized jets in the tiger stripes are the warmest regions on the moon [Spencer and Nimmo 2013; Goguen et al. 2013]. The unexpected discovery of Enceladus' extensive water vapor and ice particle plume was such a surprise that future mission phases were reshaped to capitalize on this discovery. Cassini ultimately flew through the Enceladus plume seven times, directly sampling its gas and icy particles.

The lack of impact craters in the tiger stripe region demonstrates that it is a geologically fresh surface that is constantly renewing itself. A fair fraction of the plume material eventually re-impacts Enceladus but some of the smallest grains are the source of the tenuous, distended E-ring [Spencer et al. 2006; Kempf, Beckmann, and Schmidt 2010; Mitchell, Porco, and Weiss 2015], which is densest at the orbit of Enceladus and spreads throughout the system. The E-ring interacts with the inner moons, coating one side with bright, fresh material. Cassini discovered that the source of the plume is a global liquid water ocean beneath Enceladus' crust [Iess et al. 2014; Thomas et al. 2016]. The ocean is about 10 km deep beneath an ice shell that is about 26–31 km thick, and perhaps considerably thinner, as thin as 5 km, in the south polar region.

In addition to water vapor [Hansen et al. 2006], Cassini's INMS discovered that the plume gasses contain carbon dioxide and simple hydrocarbons such as methane, propane, and acetylene [Waite et al. 2009; Waite et al. 2017]. During Cassini's closest dive through the plume in 2015,

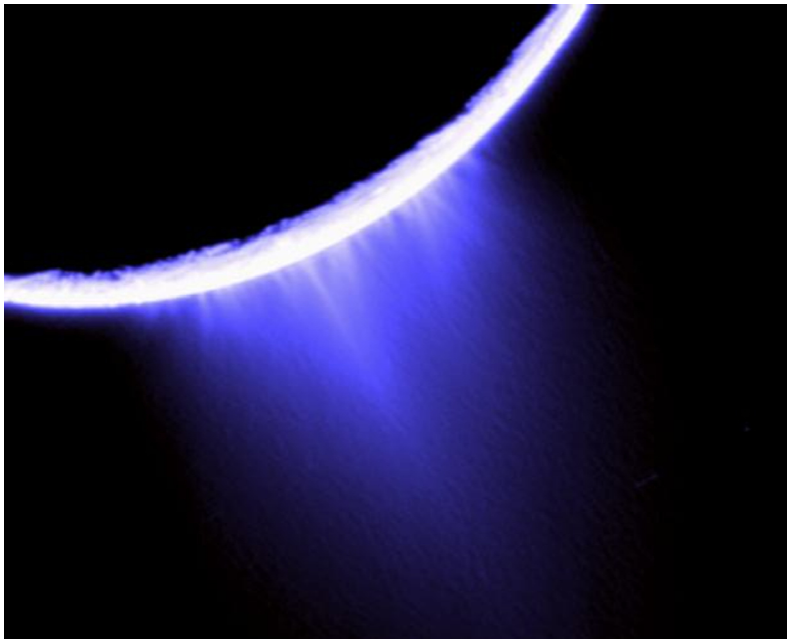

Figure 3-8. Icy jets shoot from Enceladus' South Pole. Jets form a ghostly plume of particles, some fall back to the moon and others create the E-ring. This false-color image was taken by NASA's Cassini spacecraft.

INMS discovered molecular hydrogen (H_2) [Waite et al. 2017]. Cassini's CDA found icy particles as well as salt-rich ice grains containing sodium and potassium that are probably frozen droplets from the underground salty ocean [Postberg et al. 2009; Postberg et al. 2011; Glein, Baross, and Waite 2015]. CDA also discovered tiny grains of silica, less than 10 nanometers in size, originating from Enceladus' ocean [Hsu et al. 2015]. These tiny silica grains most likely condensed from hot water spewing from hydrothermal vents on Enceladus' seafloor. The excess hydrogen discovered by INMS could also be coming from the hydrothermal vents. CDA and INMS also detected evidence for large organic fragments, indicative of complex organic molecules that are created in chemical processes, perhaps including those related to life [Postberg et al. 2018]. The source of energy for the hydrothermal activity on Enceladus is tidal interactions among Enceladus, Dione, and Saturn [Tobie, Cadek, and Sotin 2008]. With liquid water, an energy source, and organic molecules, the subsurface ocean of Enceladus could harbor the ingredients for primitive life. The Cassini orbiter did not carry the instruments needed to detect life so that goal remains for a future mission. Enceladus and the other icy moons of Saturn are discussed in detail in the book edited by Schenk et al. [2018]. For more details about Enceladus science, see the Icy Satellite report and the team reports.

Titan: Earth-like World with Rain, Rivers, Lakes and Seas, Global Ocean, and Prebiotic Chemistry

Titan is the largest moon in the Saturn system, slightly larger than the planet Mercury, and the only moon in our solar system with a dense atmosphere. Titan is also the only body other than Earth that

displays clear evidence for surface liquids: liquid hydrocarbons. Titan's atmosphere is mostly nitrogen with some methane and a haze layer of organics that give Titan its orange appearance. Key Titan results can be found in the books, *Titan: Interior, surface, atmosphere, and space environment* [Müller-Wodarg et al. 2014] and *Titan from Cassini-Huygens* [Brown, Lebreton, and Waite 2009].

Titan has many geologic processes similar to that of Earth. These processes generate methane rains, which build river channels and form lakes and seas containing liquid methane and ethane. Titan's atmosphere is teaming with a variety of molecules—the most chemically complex in the solar system. Beginning with sunlight and methane, ever more complex molecules form until they become large enough to form the smog that covers the giant moon. Nearer the surface, methane, ethane, and other organics condense and fall to the surface where likely other prebiotic chemistry can take place.

Cassini revealed an array of complex hydrocarbons in Titan's atmosphere, created as methane gas is broken apart by sunlight in the upper atmosphere, generating active chemistry [Waite et al. 2007] and a link to haze formation [Lavvas et al. 2013]. The mechanism by which methane is replenished remains a mystery. Over the course of the mission, methane rainfall darkened parts of Titan's surface [Turtle et al. 2009; Turtle et al. 2011], and methane clouds formed and dissipated [Rodriguez et al. 2009]. As the seasons changed, the evolution and breakup of Titan's northern winter polar vortex and the early formation of Titan's southern winter polar vortex were observed [Vinatier et al. 2015; Achterberg et al. 2011]. The polar vortices appear to be tilted by a few degrees relative to the rotational pole of Titan, and the entire stratosphere is also tilted by several degrees [Achterberg et al. 2008].

The surface of Titan was examined from orbit using radar and imaging at both visible and infrared wavelengths, which showed that Titan has many geologic processes reminiscent of those on Earth. Radar wavelengths can pierce the haze, allowing us to see Titan's surface. These processes generate methane clouds and rain, build river channels, form lakes and seas (Figure 3-9) containing liquid methane and ethane, form complex atmospheric hydrocarbons, and generate dunes of hydrocarbon particles. Cassini's studies revealed Titan to be remarkably like a prebiotic Earth. On Titan, methane plays the role of water on Earth and water ice is a key ingredient of the rocky soil. Titan's methane cycle is analogous to Earth's hydrologic cycle, but at temperatures about 200 K lower.

Titan's surface consists of broad regions of light and dark terrain. Some of the dark, equatorial regions generally consist of long, linear dunes [Radebaugh et al. 2008]. Titan's lakes and seas are confined primarily to the polar regions. In the south polar region, one lake, Ontario Lacus, was seen by Cassini while the north polar region small lakes, and large seas about the size of the Great Lakes, abound [Stofan et al. 2007]. A specular reflection observed by VIMS definitively verified that the dark lake regions contain liquid [Stephan et al. 2010]. For more details about Titan, see the Titan report and team reports in Sections 3.1 and 3.2.

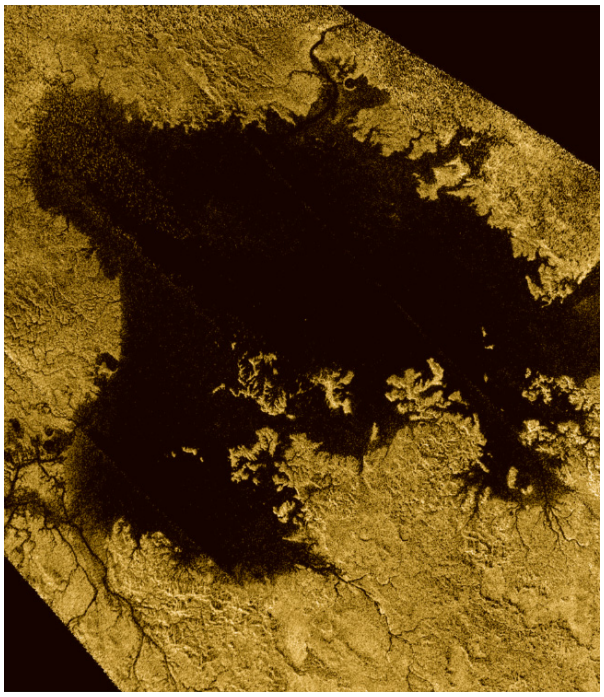

Figure 3-9. Radar view of Titan sea Ligeia Mare with river channels flowing into it. Ligeia Mare is 50% larger than Earth's Lake Superior and ~500 feet deep, also similar to the Great Lakes.

Huygens Probe: First Landing on an Outer Solar System Moon (Titan)

The Huygens probe became the first human-made object to land on Titan. Huygens was built and operated by ESA and was carried as a passenger on the Cassini spacecraft. Huygens separated from Cassini in December 2004 and landed on Titan three weeks later, on January 14, 2005.

Huygens's historic 2005 landing on Titan was the most distant in our solar system to date. The probe's descent revealed Titan to be remarkably like Earth before life evolved, with methane rain, erosion and drainage channels, and dry lake beds. An array of complex hydrocarbons was found in Titan's atmosphere, created by the break-up of methane high in the atmosphere.

Huygen's 2 hour 27 min parachuted descent provided the first in situ atmospheric profile of temperature, pressure, density, wind, and composition, as well as detailed images of the surface. The surface pressure was 1.47 times that on Earth [Fulchignoni et al. 2005]; super-rotating prograde, zonal winds peaked at 430 km hour^{-1}, much greater than Titan's equatorial rotation velocity [Bird et al. 2005]; and atmospheric composition included the noble gases argon, krypton, and xenon [Niemann et al. 2005], whereas nitrogen and methane were confirmed as the primary constituents [Niemann et al. 2010]. After landing, the GCMS measured an increase in abundance of methane gas as the relatively warm GCMS inlet heated Titan's surface [Niemann et al. 2005].

The Cassini spacecraft flew overhead and collected the Huygens data, including about 72 minutes on Titan's surface, before Huygen's link to Cassini was lost as Cassini set over the

horizon. Huygens landed in a dry lakebed filled with rounded pebbles (Figure 3-10), near the Xanadu region, an equatorial area about the size of Australia. Images taken at about 10 km altitude captured dendritic erosional patterns on a hillside with very steep slopes. The rounded, smoothed pebbles at the landing site are evidence of fluid flow [Tomasko et al. 2005].

An overview of Huygens science can be found in Lebreton et al. [2009] and in the Huygens report.

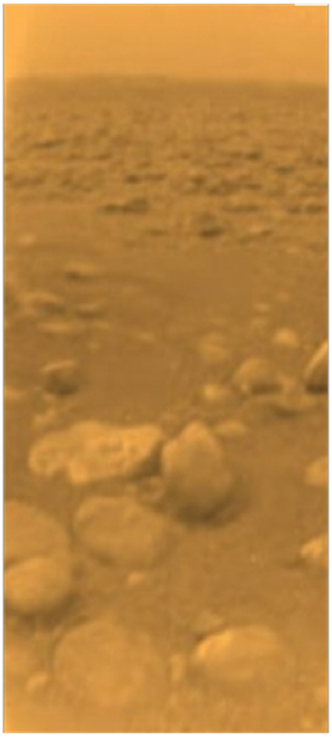

Figure 3-10. Huygens image from the surface of Titan. This colored view was processed to add reflection spectral data, and gives a better indication of the actual color of the surface.

Iapetus: Mystery of the Dual, Bright-dark Surface of the Moon Solved

The origin of Iapetus's two-face, bright-dark surface has been a mystery for more than 300 years (Figure 3-11). The Cassini spacecraft solved the puzzle. Dark, reddish dust in Iapetus' orbital path is swept up and lands on the leading face of the moon. The dark areas absorb energy and become warmer, while uncontaminated areas remain cooler. The moon's long rotation period contributes to this yin-yang effect.

One hemisphere of Iapetus is as dark as charcoal while the other half is nearly as bright as snow. The reason for this light-dark dichotomy was not known prior to Cassini's arrival at Saturn. An Earth-orbiting infrared telescope discovered a very tenuous ring at the orbit of Phoebe [Verbiscer, Skrutskie, and Hamilton 2009], probably dust thrown off the moon by tiny meteor impacts. This dust is swept up by Iapetus as it orbits Saturn. The darkest side of the moon is

centered exactly in the direction of motion of the satellite. A handful of small impact craters on the dark side punch through to bright material below, suggesting that the dark material is not very deep.

Cassini discovered a 20 km high ridge that circles most of the equator [Porco et al. 2005]. The ridge breaks up into mountains in some of the lowest albedo regions. The ridge must have been formed early in the history of Iapetus because it is heavily cratered and eroded. The surface of Iapetus is mainly water ice with small amounts of carbon dioxide, carbon, and complex organic molecules present.

Figure 3-11. The dark surface of Iapetus and the dark, heavily cratered region called Cassini Regio are visible, along with the giant ridge that circles Iapetus's equator.

Moons Mimas and Phoebe

The Saturn system contains 62 known moons, many of them small, captured objects that are distant from Saturn and irregular in shape. Much closer to Saturn are 24 regular moons that probably formed from the same sub-nebula as Saturn. Some of these moons have strong interactions with the ring system, opening gaps and sculpting the rings. More information about Enceladus and the icy satellites can be found in Schenk et al. [2018].

Mimas is the innermost and smallest of the intermediate-sized moons with a diameter of 394 km. During a close flyby in February 2010 the infrared spectrometer discovered that the leading side of Mimas—the hemisphere that faces forward in the moon's orbit about Saturn—is about 15 degrees K colder than the other side [Howett et al. 2011]. This thermal anomaly, in the shape of "Pac-Man," is a result of a contrast in thermal inertia between the leading and trailing sides of Mimas. The leading face is altered by bombardment of highly energetic electrons. This bombardment increases the contact between regolith grains, decreases their porosity and increases thermal inertia [Schenk et al. 2011]. Models of Saturn's E-ring suggest that the side of

Mimas that faces away from the direction of motion should be preferentially coated by particles from the E-ring. Mimas' exceptionally high reflectivity (it is the second most reflective moon in the solar system) supports this hypothesis. Water ice is the primary compound detected on its surface. Its heavily cratered appearance argues against current activity on the moon.

Two weeks before Saturn Orbit Insertion (SOI), Cassini-Huygens flew close to Phoebe, the largest outer irregular moon of Saturn. Phoebe moves in an inclined, retrograde orbit that is 13 million kilometers from Saturn. It is covered with impact craters that were probably created by collisions with smaller outer moons. Some of the craters contain icy patches and layered structures; others have unusual conical shapes. Phoebe reflects only a few percent of the sunlight that falls on it, about the same as that reflected by the dark regions of Earth's moon. In addition to water ice, its surface is composed of carbon and carbon dioxide [Clark et al. 2005]. The presence of carbon and the fact that its density is higher than that of the other medium-sized moons of Saturn suggest that Phoebe was formed near the edge of the solar system and migrated inward to be captured by Saturn [Johnson and Lunine 2005]. Phoebe may have originated in the Kuiper Belt, the reservoir of ice/rock bodies that dwell beyond the orbit of Neptune and that may provide clues to the architecture of the early solar system and its subsequent evolution.

Discovery of seven small moons

Cassini discovered seven small moons in the inner Saturn system [Thomas et al. 2016]. Pallene and Aegaeon are associated with diffuse, dusty rings, and Anthe and Methone are associated with ring arcs. A tiny moon, Daphnis, orbits in the Keeler gap and may help to keep it clear. An even smaller moon causes propeller-like structures in a ring of Saturn (S/2009 S). A new moon, Aegaeon, was discovered inside Saturn's G-ring [Hedman et al. 2010]. Another Cassini discovery is the moon Polydeuces, which moves in a gravitationally stable zone in Dione's orbit known as the Lagrangian point.

Prior to Cassini, Saturn already had a unique family of small satellites, including the co-orbitals Janus and Epimetheus, which switch orbits every four years and appear to have been one body until their violent separation. Other previously known moons include the F-ring shepherds, Prometheus and Pandora, as well as Atlas, orbiting just outside the A-ring edge, and Pan, which clears the Encke gap.

Saturn's Rings: Revealed as Active and Dynamic—A Laboratory for How Planets Form

Cassini's 13 years in orbit made it possible to watch changes in Saturn's dynamic ring system. The spacecraft discovered propeller-like formations, witnessed the possible birth of a new moon and observed what may be one of the most active, chaotic rings in our solar system, Saturn's F-ring.

Saturn's rings are both beautiful and complex, and the processes observed there provide a laboratory for how planets might form. Some of the highest resolution data on the rings were obtained

at SOI in 2004. Tiny propellers and straw-like clumping in the strongest density wave peaks were first detected in the images from the SOI unlit ring scan. For more detailed summaries, see ring chapters in the books, *Saturn from Cassini-Huygens* [Dougherty, Esposito, and Krimigis 2009], and *Planetary Ring Systems: Properties, Structure, and Evolution* [Tiscareno and Murray 2018].

Some places in Saturn's rings were changing on very short timescales of weeks or months. Dozens of objects, 0.1–1 km in size, orbiting in the A-ring, changed their locations as they interacted with neighboring material. These unseen objects opened up tiny propeller-shaped gaps that were captured in the Cassini cameras and in stellar occultations of the rings [Tiscareno et al. 2010] (Figure 3-12). Cassini observed channels opening and closing in the F-ring, in response to close approaches by the tiny moon Prometheus [Murray et al. 2005]. Clumps and dusty jets appeared and disappeared in the F-ring core, excited by embedded moonlets and disturbed by objects with orbits eccentric enough to dive through the ring [Murray et al. 2008; Beurle et al. 2010]. Several new ringlets appeared during Cassini's 13 years in orbit [Hedman et al. 2009]. They were composed mostly of fine dust grains; one in the outer Cassini division was barely visible when Cassini arrived but was among the dustiest features in the rings by the end of the mission.

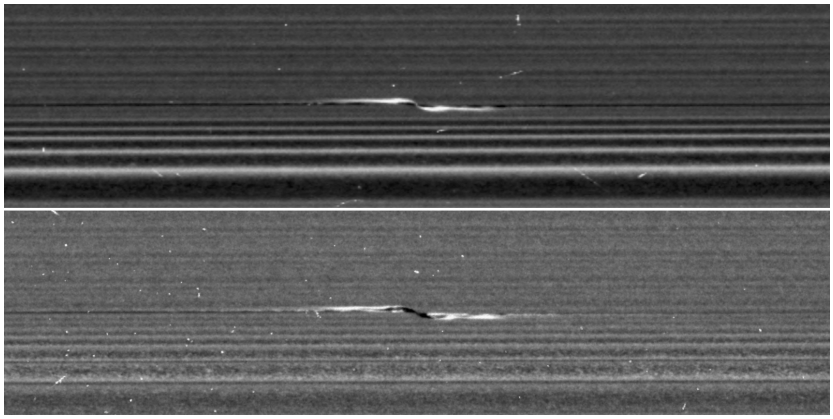

Figure 3-12. Propeller structures are caused by embedded moonlets at their centers, and have much in common with baby planets embedded in protoplanetary disks. View of propeller Santos Dumont on the sunlit side of the rings (top panel) and unlit side of the rings (bottom panel).

The ring particles in Saturn's main A- and B-rings are nearly pure water ice but show a strong ultraviolet absorption that varies in strength from place to place. A reddish color of varying intensity in the rings is deeper where the ice signature is strongest. The rings probably darken with time as they are polluted by meteoroid bombardment. The less massive C-ring and Cassini division look more polluted (redder) than the more massive A-ring and B-ring [Cuzzi et al. 2010].

Hundreds of stellar and radio occultations of the rings were obtained throughout the mission at a large variety of ring geometries, including some of the best-ever radio occultations during the Grand Finale as the radio signal was beamed through the rings while Cassini flew close to Saturn. Detailed horizontal and vertical structure in the rings was revealed at multiple wavelengths. They provided a detailed map of Saturn's rings, including three-dimensional measurements of tendril-like, ephemeral structures in the rings called self-gravity wakes [Colwell, Esposito, and Sremcevic 2006]. These

transient gravitational instabilities form but are torn apart by Saturn's tides. Similar behavior in a protoplanetary disk might play a role in formation of planets in our own solar system and beyond. A different kind of microstructure, which behaves like self-gravity but is due more to viscous forces in the rings than self-gravity, can also be seen throughout the densest parts of the rings [Colwell et al. 2007].

Modeling of the damping behavior of dozens of spiral density and bending waves constrained the mass of most of Saturn's main rings [Tiscareno et al. 2007]. However, occultations were not able to directly probe the densest parts of the B-ring so its mass remained uncertain until gravity measurements in the Grand Finale orbits found that the total mass of the rings was less than all previous estimates, hinting at a young age for the rings [Iess et al. 2019].

Vertical Structures in the Rings Imaged for the First Time

Once about every 15 years, the Sun shines on the edge of the ring plane and northern and southern sides of the rings receive little sunlight. Cassini measured the long shadows from this rare event to determine the heights of structures within the rings.

Many new discoveries were made during equinox in August 2009, the time when the Sun was edge-on to the rings. Once every half Saturn year, the ring plane aligns with the center of the Sun, and for a brief time, the northern and southern sides of the rings receive essentially no sunlight. Vertically extended objects cast long shadows on the rings that provided a measurement of the height of these ring structures. During this unique time, Cassini observed long shadows up to 2.5 km long (Figure 3-13) created by objects larger than the 5-meter vertical thickness of the rings. They included shadows from towering km-sized objects near the outer edge of the B-ring, and the vertical extent of edge waves in the Keeler gap created by the tiny moon Daphnis [Tiscareno and Murray 2018]. The rings also cooled to their lowest temperatures, heated for a few days only by Saturn shine [Spilker, Ferrari, and Morishima 2013].

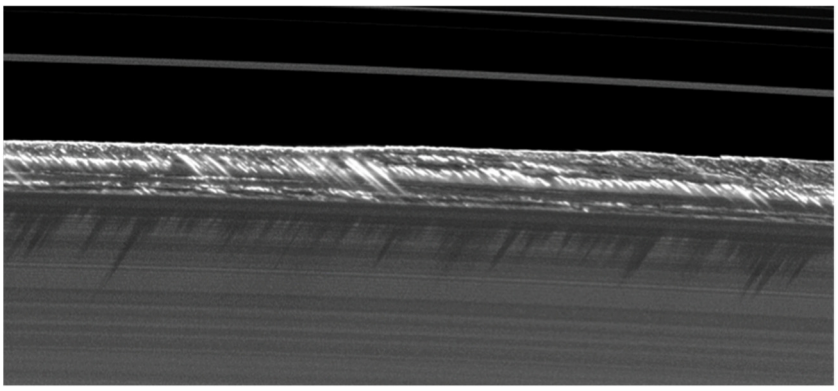

Figure 3-13. Vertical structures at the edge of Saturn's B-ring. Among the tallest structures seen in Saturn's main rings, large objects rise abruptly from the edge of the B ring to cast long shadows on the ring. This image was taken by NASA's Cassini spacecraft two weeks before the planet's August 2009 equinox. (Credit: NASA/JPL/Space Science Institute)

Saturn's Great Northern Storm of 2010–2011

Late in 2010, a giant storm quickly erupted in Saturn's relatively bland atmosphere (Figure 3-14). This type of storm typically occurs only once every 30 years, but this one arrived 10 years early, providing a unique observing opportunity for Cassini [Baines et al. 2018]. Within months, this storm completely encircled the planet with a swirling band of clouds and vortices [Sayanagi et al. 2013]. The largest temperature increases ever recorded for any planet were measured in the stratosphere and molecules never seen before in Saturn's upper atmosphere were detected. The storm began to fade away shortly after the vortex in its "head" collided with one in its "tail," about nine months after it began [Fletcher et al. 2011].

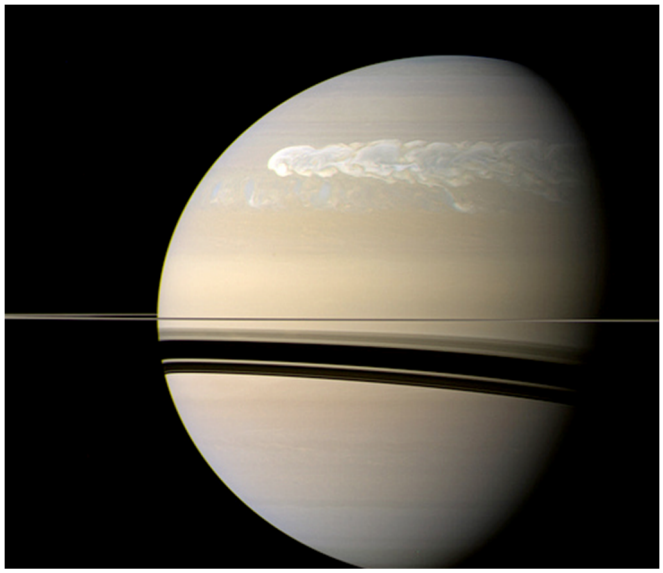

Figure 3-14. Saturn's relatively tranquil atmosphere erupted with a storm of gigantic proportions in late 2010.

Saturn's North Polar Hexagon and Discovery of Giant Hurricanes at Both of Saturn's Poles

Saturn's polar regions surprised scientists with the presence of a long-lived hexagonal-shaped jet stream in the north and two hurricane-like storms at both poles. Their driving forces remain a mystery.

Saturn's alternating eastward and westward jet streams define the cloud bands that circle the planet on lines of constant latitude to within about one degree of each pole. One of the jet streams, near 75 degrees north latitude, forms a hexagonal pattern that is two Earth diameters across [Baines et al. 2009]. Voyager first discovered the hexagon, and it is still present at the same location after 35 years. Small clouds move eastward around the corners of the pattern. This hexagonal-shaped jet stream (Figure 3-15) is remarkable for its stability and longevity. Its source remains a mystery. Using Cassini CIRS thermal data of Saturn's North Pole, a new hexagonal structure,

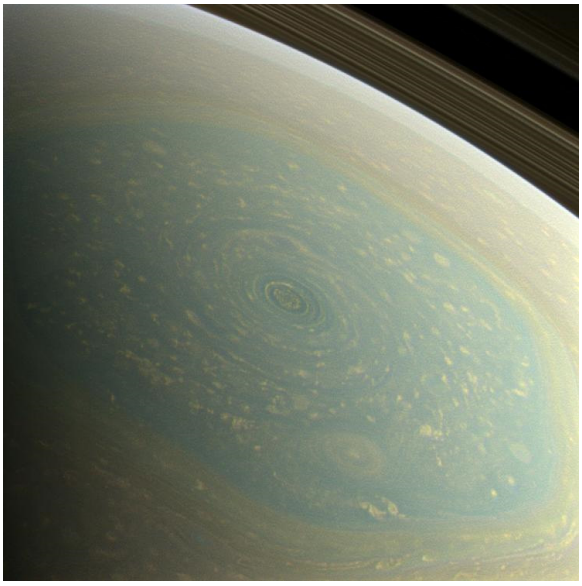

Figure 3-15. The greenish hexagon, about two Earth diameters across, is clearly seen at Saturn's North Pole. (Credit: NASA/JPL/Space Science Institute).

precisely matching the well-known hexagon, was recently discovered towering hundreds of kilometers above the cloud tops [Fletcher et al. 2018]. The presence of a newly detected hexagon in Saturn's northern summer stratosphere, which is connected to the familiar hexagon in some way, suggests that there is a great deal more to be learned about the dynamics at play in Saturn's atmosphere.

Cassini discovered hurricane-like storms at both of Saturn's pole. The hurricanes are about 50 times larger than a typical Earth hurricane and are centered exactly at the poles [Fletcher et al. 2008; Sayanagi et al. 2017]. In the south, Cassini discovered the clear eye of a hurricane-like vortex, with eyewall clouds towering 70 kilometers above the clouds in the center. There is a warm vortex at Saturn's North Pole as well. Each vortex shows well-developed eye walls [Dyudina et al. 2008].

Length of Saturn's day

Saturn emits radio waves known as SKR that were first observed by Voyager in the early 1980s and were interpreted as an indicator of Saturn's internal rotation period. Cassini results showed that the SKR signals were not coming from the interior of Saturn as originally assumed. The SKR period changed from year to year, an impossibility if the SKR is tied to the interior. When Cassini first arrived at Saturn and measured the SKR period, data from the radio and plasma wave instrument also showed that the radio waves' frequencies were different in the northern and southern hemispheres [Gurnett et al. 2009]. In addition, planetary period oscillations observed in magnetic field data reveal a similar story: the period of these oscillations (although close to the expected planetary period of about 10.7 hours) changed over time, particularly with season, and were different in the northern and southern hemispheres [Provan, Cowley, and Nichols 2009]. Clearly the observations of SKR and its associated magnetic field are not coming from the interior.

The origin of the multiple periodicities is not well understood but they are not related to Saturn's internal rotation rate. The magnetometer team searched for an offset between Saturn's rotation axis and magnetic field axis, to use the magnetic field variations from this offset to determine the length of Saturn's day. However, the offset was too small to determine Saturn's internal rotation rate [Dougherty et al. 2018].

Clues to the length of Saturn's day actually came from small waves detected in the rings. Saturn's ring system acts like a sensitive seismograph, providing a measure of Saturn's internal oscillations that allow a determination of its interior rotation rate. These vibrations, determined by Saturn's non-uniform internal structure, are probably driven by convection inside the planet, which cause oscillations in Saturn's gravity field that manifest themselves as waves in the rings. Modeling the propagation behavior of this collection of waves provides an interior rotation rate for Saturn of 10 hours 35.3 minutes ±2 minutes [Mankovich et al. 2019].

Unexplored Territory: Probing the Gap between the Rings and Saturn

After 13 years in orbit, the Cassini-Huygens mission to Saturn ended with a truly unique set of science data. Cassini sent back its final bits of distinctive science data on September 15, 2017, as it plunged into Saturn's atmosphere, vaporizing to satisfy planetary protection requirements. Cassini's final phase covered roughly 10 months and ended after the first ever exploration of the region between the planet and its rings.

In late 2016, Cassini transitioned to a series of 20 Ring Grazing orbits with the closest approach (periapsis) just outside Saturn's F-ring, providing close flybys of tiny ring moons, and high-resolution views of Saturn's A- and F-rings. A final Titan flyby in late April 2017 propelled Cassini's periapsis across Saturn's main rings to initiate the Grand Finale orbits. Comprised of 22 orbits, Cassini repeatedly dove between Saturn's innermost rings and upper atmosphere to answer fundamental questions unaddressed earlier in the mission. The last orbit turned the spacecraft into the first Saturn atmospheric entry probe. Additional details about the science in these final orbits can be found in the discipline and team reports in Sections 3.1 and 3.2.

Close to Saturn: rings and ringmoons

The Ring Grazing and Grand Finale orbits provided some of the highest-resolution remote sensing observations of the mission for studies of the five tiny ringmoons and Saturn's main rings. These orbits also provided a rare opportunity to fly through and directly sample the SKR region.

In the Ring Grazing orbits, Cassini performed the closest ever flybys of five of Saturn's tiny ringmoons, Pan, Daphnis, Atlas, Pandora, and Epimetheus. The surface characteristics of these moons are regulated by both accretion of a reddish material from Saturn's main rings and of icy grains originating in the Enceladus plume [Buratti et al. 2019]. The color and brightness of the moons inside or closest to the main rings (Pan, Daphnis, and Atlas) strongly resemble that of the rings. Figure 3-16 shows a central core surrounded by an equatorial ridge of ring particles for each

of these three moons [Buratti et al. 2019]. For more details about these tiny ringmoons, see the Icy Satellites report in Section 3.1.

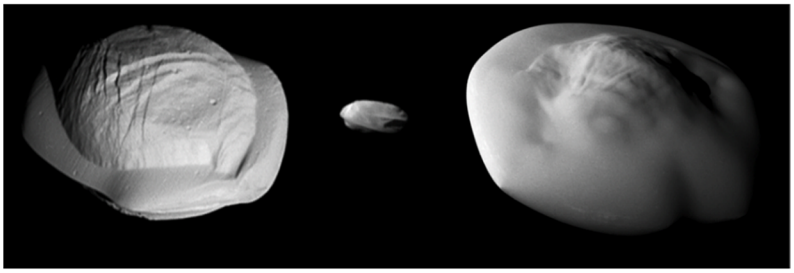

Figure 3-16. Cassini images of Pan (left), Daphnis (center) and Atlas (right) as observed in 2017 during the closest flybys ever of these moons.

The Cassini spacecraft passed very close to Saturn's main rings during its final year, and obtained very high-spatial-resolution images, spectral scans, and temperature scans [Tiscareno et al. 2019]. Embedded masses sculpt the main rings and new structures were discovered in the images, including new ring textures such as streaky C-ring plateaus and unexpected bands of particle clumping throughout the rings (Figure 3-17). Water ice band depths vary across the rings, and weaker ice bands were identified outside the Keeler gap in the A-ring. Many structures throughout the main rings and F-ring were studied in more detail—see Tiscareno and Murray [2018]. For more details about these ring observations, see the Ring report and team reports in Sections 3.1 and 3.2.

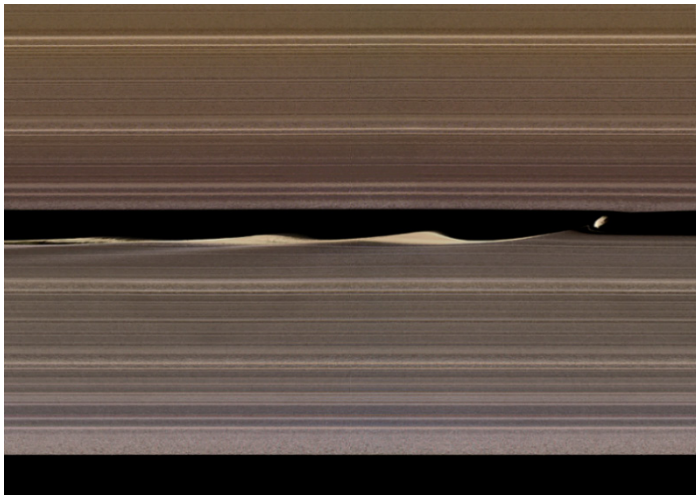

Figure 3-17. Tiny Daphnis opens the Keeler gap and generates waves along one gap edge. The speckled texture is created by ring particles clumping together. This clumping is seen throughout the rings.

The orbits during the final year provided an excellent opportunity to directly and repeatedly sample the top of the SKR emission region to determine its source [Lamy et al. 2018]. SKR is a sensitive diagnostic of Saturn's magnetospheric dynamics and auroral processes. In situ measurements are required to understand how these planetary radio emissions are generated. These emissions were found to be strongly time-variable from orbit to orbit, with a dependence on

local time around Saturn. Only three SKR source regions were identified, all on the dawn side of Saturn, and controlled by the electron densities in the vicinity [Lamy et al. 2018]. These regions were embedded in upward currents associated with Saturn's auroral oval.

Diving through the gap

During the Grand Finale orbits, numerous instruments performed in situ measurements while traversing the gap between the inner D-ring and the planet. MIMI, designed to measure energetic particles, measured an unexpected response to very small dust grains, about the size of large organic molecules [Mitchell et al. 2018]. Ring dust in the submicron range was detected by CDA, and ring composition was directly measured for the first time [Hsu et al. 2018]. The composition of the volatiles in the gap was revealed by INMS, indicating an array of gases and organic compounds [Waite et al. 2018]. The MIMI instrument also identified an inner radiation belt in this gap region [Roussos et al. 2018].

MIMI detected tiny nanograin ring particles, within ±2° of the equator, entering Saturn's equatorial atmosphere directly from the inner D-ring, possibly from the bright D68 ringlet [Mitchell et al. 2018]. Collisions with hydrogen atoms provide enough drag to decelerate the particles, until they plunge into Saturn's atmosphere. This continuous rain of particles produces a lower limit of ~5 kg s^{-1} into the atmosphere. Particles at higher latitudes are charged and transported along the magnetic field lines as "ring rain" [Hsu et al. 2018; Mitchell et al. 2018].

CDA directly measured the mass and composition of particles originating in Saturn's main rings to characterize the material falling into Saturn's atmosphere. CDA primarily detected tiny nanograins with the highest peak flux near Saturn's equator and two secondary peaks at mid-latitudes, one on each side of the rings [Hsu et al. 2018], consistent with previously detected "ring rain" [O'Donoghue et al. 2013]. Two separate nanograin compositions were identified, water ice grains and silicate grains [Hsu et al. 2018]. Silicate grains comprised about one-third of the identified nanograins, much greater than the estimated bulk silicate composition of typically only a few percent [Cuzzi et al. 2010].

The INMS instrument directly observed the interaction between the rings and Saturn's atmosphere, measuring the in situ atmospheric and ionospheric composition of Saturn's equatorial atmosphere for the first time. Ring volatiles from the D-ring were detected, including water, methane, ammonia, carbon monoxide and/or molecular nitrogen, and carbon dioxide enter Saturn's atmosphere along the ring plane. INMS also measured an influx of organic-rich nanoparticles from the rings that further modifies the composition and structure of the equatorial atmosphere (Figure 3-18). The estimated mass influx rate was 5,000 to 40,000 kg s^{-1}, considerably higher than the MIMI estimates [Mitchell et al. 2018; Waite et al. 2018].

During the final orbits, an inner radiation belt was detected by MIMI in the gap between the D-ring and top of Saturn's atmosphere [Roussos et al. 2018]. Saturn's main rings inhibit the inward passage of trapped charged particles that form radiation belts. Hence, the radiation belts outside the main rings cannot interact with the inner radiation belt, providing an opportunity to study the

inner belt and its interactions with the D-ring. One possible source for the inner radiation belt is the Cosmic Ray Albedo Neutron Decay (CRAND). Ringlets in the D-ring, including D68 and D73, control the structure and outer boundary, respectively, of this radiation belt [Roussos et al. 2018].

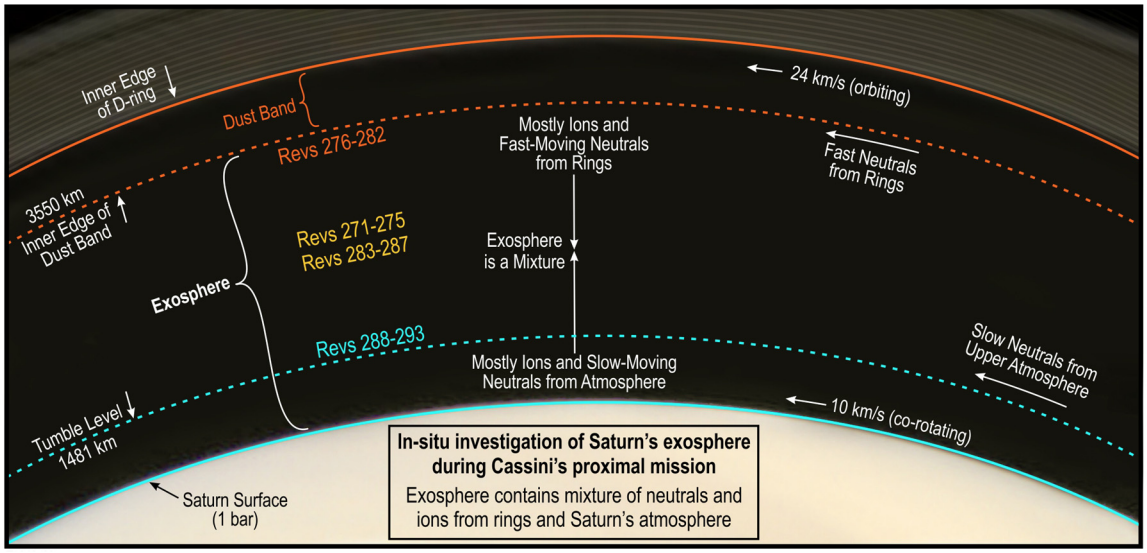

Figure 3-18. Geometry of Cassini's Grand Finale orbits. Left panel: A schematic drawing showing the altitude coverage of the orbits (revs) during the Grand Finale phase of the Cassini mission from a polar perspective. The region is bounded above by the D-ring and below by the 1 bar pressure level of Saturn's atmosphere. From Waite et al. [2018].

Window inside Saturn: Internal Structure from Gravity and Magnetic Fields

Cassini's Grand Finale orbits enabled the highest resolution gravity and magnetic field measurements of Saturn for the entire mission. The behavior of Saturn's internal gravity and magnetic fields provides a window into the interior of the planet.

Six of the Grand Finale orbits were designed for gravity measurements. During these orbits unique gravity signatures were recorded to determine the mass distribution in Saturn's interior and the mass of Saturn's main rings [Iess et al. 2019]. The measured values of Saturn's gravitational harmonics require deep differential rotation to a depth of about ~9,000 km inside the planet (down to about 0.7 Saturn radii). This depth may correspond to the levels of magnetic dissipation. Saturn's rocky core is about 15–18 Earth masses. The ring mass is 0.41 Mimas masses, pointing to a relatively young ring age, perhaps only 10^7–10^8 years old [Iess et al. 2019].

All 22 orbits provided the highest resolution magnetic field measurements of Saturn's internal and external fields since Cassini's passage above

> Cassini's final year was like a brand-new mission as it explored a region of the Saturn system unexplored by any previous outer planet spacecraft.

the rings during SOI. One of the Grand Finale surprises was the exceptionally small observed tilt (less than 0.0095°) between Saturn's spin-axis and its magnetic axis [Dougherty et al. 2018]. Saturn's magnetic field is considerably more axisymmetric than any other planetary magnetic field in our solar system, making it challenging to explain with current theories. MAG data provide interesting insights into Saturn's conducting magnetic region. For instance, zonal flows imply differential rotation, which is consistent with Cassini's gravity measurements [Iess et al. 2019], while the higher order magnetic moments hint that secondary dynamo action may be at work in the semi-conducting region of Saturn [Dougherty et al. 2018].

The magnetometer team also discovered a strong, low latitude field-aligned current (FAC) system, situated between the inner edge of the D-ring and the top of Saturn's atmosphere [Dougherty et al. 2018]. This current is comparable in strength to the currents observed in the auroral zone and as such, may be part of a global current system.

Cassini's final year was like a brand-new mission as it explored a region of the Saturn system unexplored by any previous outer planet spacecraft. These new data required new theories and new ideas. Cassini's final Earth-bound transmission occurred on September 15, 2017, as it plunged into the planet, sending its last bits about the directly sampled atmosphere to Earth, then vaporizing in Saturn's atmosphere. This protective measure ensured that any hardy, Earthly microbes that might have survived onboard Cassini did not inadvertently contaminate either Enceladus or Titan.

Only a few of the many Cassini scientific highlights were discussed here. In the coming years many more Cassini discoveries remain to be found in this incredibly rich data set.

A list of some of Cassini's key discoveries and findings is given in Table 3-10 to illustrate the breadth and depth of this incredible mission. Cassini's rich set of science instruments led to many new discoveries across all five science disciplines. Many more discoveries and findings are discussed in the discipline and team reports in Sections 3.1 and 3.2.

Table 3-10. Cassini discoveries: A partial list of Cassini's key findings and discoveries.

Huygens landing on Titan. Huygens probe lands on the surface of Titan and makes critical atmospheric and surface measurements.
Geologic activity at Enceladus. Active plume discovered at south pole; Enceladus' plume creates Saturn's E-ring and alters other moons' surfaces; spectacular south polar terrain tectonics; enormous measurable endogenic heat.
Lakes and seas on Titan. Discovery of Titan's polar lakes/seas; specular reflection of sunlight confirms liquid in Kraken Mare.
Saturn giant storm. Saturn daytime lightning seen for the first time. Unprecedented, long-lasting 80K stratospheric temperature increase and new molecules observed in aftermath. Thunderstorms uplift carbon, water ice, and ammonia ice from depth.
Saturn kilometric radiation. North-south periods are different and change unpredictably.
Vertical structure in Saturn's rings. The 10 m thick rings, edge-on, show huge vertical structures created by gravitational interaction with moons; rippled rings show evidence for large impacts over the centuries.
Enceladus' variable plume emission. Gravitational tides cause fissures to periodically open and close depending on orbital distance from Saturn.
Subsurface ocean on Titan. Gravity and radar measurements indicate the presence of a subsurface ocean and soft interior.
Two new populations of objects in the rings. Propellers and self-gravity wakes reveal dynamic structure of the rings.

Table 3-10. Cassini discoveries: A partial list of Cassini's key findings and discoveries.

Depth of a Titan sea. Radar sees secondary echo while sounding Ligea Mare, detecting sea bottom. Depth of other seas and small lakes detected also.
Enceladus global ocean. Global ocean discovered beneath Enceladus' icy crust from radio science measurements and detection of excess libration.
Ring impact clouds. The rings make good detectors of meteorite impacts, based on generated debris clouds.
Massive hurricanes at Saturn's north and south pole. Hurricanes discovered at north and south poles.
Phoebe flyby. First encounter with an object in the Saturn system that likely originated in the Kuiper Belt.
Formation of a polar vortex over Titan's south pole. Seasonal changes caught in the act on Titan.
Enceladus plume composition. Jets are shown to contain salty particles, organic molecules, and ammonia ice.
Enceladus hydrothermal vents. Evidence for hydrothermal vents, including detection of nanosilica grains and excess hydrogen in the plume.
Most of Titan's seas and lakes are at its north pole. Discovery of lakes in Titan's polar regions, but with vast majority at the north pole.
Saturn polar hexagon rediscovered. Discovered by Voyager, Cassini found this jet stream long lived.
Thermal anomalies at Mimas and Tethys. Electron bombardment of parts of their surfaces brings about modification of surface thermal properties.
Weather on Titan. Methane rains (part of Titan's methane "hydrological" cycle) cause visible changes on Titan's surface.
Saturn's magnetosphere plentiful with water. H_2O products dominate the magnetospheric chemical species; expected nitrogen not found.
Iapetus' albedo dichotomy and equatorial ridge. Phoebe dust darkens Iapetus surface. Thermal migration of volatiles causes color dichotomy. Equatorial ridge observed, perhaps a relic of ancient ring of impactors.
Menagerie of Moon Surfaces. Satellites exhibit a striking diversity of surface properties, e.g., Hyperion, Iapetus, and tiny ringmoons.
Saturn rotation mystery. Variable SKR rates and apparent lack of magnetic axis tilt leaves internal rotation rate a mystery.
Rings capture Saturn's internal dynamics. Unique spiral waves in rings provide windows into Saturn's atmospheric oscillations and interior. May provide a rotation rate for the interior of Saturn.
Organic 'building blocks' discovered in Titan's atmosphere. The presence of heavy negative ions in Titan's ionosphere appeared to act as organic building blocks in recombination with large positive ions to create more complex molecules as precursors of aerosol and haze particles.
Supernovae shockwaves. Unusually strong solar wind interacted with magnetosphere to accelerate particles to relativistic speeds, a model for stellar-explosion shockwaves.
Nanograins in gap between innermost ring and top of Saturn's atmosphere. Predominant particle population in the gap is tiny nanograins. Complex organic compounds embedded in water nanograins rain down from Saturn's rings into its upper atmosphere. Composition includes water and silicates, and also methane, ammonia, carbon monoxide, nitrogen and carbon dioxide. Some inner-ring particles and gases fall directly into Saturn's atmosphere.
Ring rain. Some ring particles take on electric charges and spiral along magnetic field lines, falling into Saturn at higher latitudes as "ring rain."
New inner radiation belt. New radiation belt discovered very close to the planet and is made up of very energetic particles.
Tilt of magnetic field axis. Saturn's magnetic field axis is almost completely aligned with its spin axis and is very close to zero.
Electric current connects to top of Saturn's atmosphere. A previously unknown electric current system that connects rings to top of Saturn's atmosphere.
Asymmetric ring structure. Ring particle clumping appear to be ubiquitous across the main rings, including within C-ring plateaus.
Mass of rings points to young ring age. The measured mass of the rings, less than 0.5 Mimas masses, points to a ring age much younger than the age of the solar system.
Saturn differential rotation. Gravity measurements indicate differential rotation inside Saturn and wind depths of about 9.000 km.

Major Open Questions Resulting from Cassini

While making amazing discoveries within the Saturn system and changing the paradigm of where to search for life in the solar system, the Cassini mission left a number of open questions for future study. Some of the answers are buried in the wealth of data that will be analyzed by current and future generations of scientists. Some await future exploration of the Saturn system. Below is a summary of some of these questions, organized by science discipline. For more details and other open questions, please see the Sections 3.1 and 3.2 discipline and team reports, all of which have submitted open questions relevant to their own discipline or team.

Icy Satellites

- What are some of the minor constituents of the Saturnian moons, and are they endogenic or exogenic? If exogenic, is the accretional process still ongoing?
- What is the total heat production on Enceladus and how and why does it vary? What does this imply about the cause of activity on the moon? What is the source of the organic material in the plume of Enceladus?
- Is there residual activity on Dione and Tethys, and if so, what does this imply about their recent history? Are the red streaks on Tethys evidence for such activity?
- What caused the ridge on Iapetus? Is it evidence for a past ring? Did other moons have rings in the past?
- Why does the origin of the moons of Jupiter and Saturn seem to diverge, with the Jovian moons being formed relative to their position from Jupiter, and the Saturnian moons being formed by stochastic events?
- To what extent do magnetospheric particles alter the optical properties of the moons? Does contamination by ring particles, including those from the E-ring dominate this process?

Titan

- What are the abundances of the heavy noble gases in Titan’s atmosphere and surface?
- How do you go from the very heavy ions and molecular species to haze particles?
- What are the origin, evolution, and ultimate fate of Titan’s atmosphere?
- How did the lakes and sea basins form?
- What is the nature and extent of the exchange between the surface/atmosphere and deep subsurface and ocean?
- Is there active cryovolcanism on Titan?

Saturn

- What is Saturn's global water abundance and what is its role in bringing heat to the surface? What is the role of moist convection in maintaining the large-scale motions?
- What is Saturn's rotation period, and what is the spread of periods if differential rotation persists into the interior? Has kronoseismology, as exhibited by the Saturn-driven waves in the main rings, finally yielded an answer to this question?
- How will additional insights from the combination of ring seismometry, gravity sounding, and magnetic field sounding improve the understanding of Saturn's internal equation of state, mass distribution, composition, and temperature distribution?
- What is Saturn's noble gas abundances including helium, as done for Jupiter by the Galileo probe? Does helium rain play a role in reducing the He/H in Saturn's molecular envelope?
- Using the power of ring seismometry and gravity sounding, improve the understanding of Saturn's internal equation of state, mass distribution, composition, and temperature distribution.
- What sustains Saturn's north polar hurricane and hexagonal jet stream?

Rings

- What is the radial profile of ring mass?
- What is causing the myriad of unexplained ring structures? For instance, what is creating and sustaining the entire ensemble of so-called "plateaus" in the outer C-ring?
- What is creating the unusually "red" color of the A and B rings, which are more than 95% water ice? Is it due to organic material, based on a combination of remote and in-situ measurements? How does the composition vary from place to place and on a range of scales?
- What is the age of the rings? Current data indicate that the rings seem to be much younger than the age of the solar system.
- How much about Saturn's internal structure and dynamics can be inferred from ring features?

MAPS

- What is the cause of the rotational modulation in axisymmetric magnetosphere configuration?

- How are mass and magnetic flux transported in the middle and outer magnetosphere?
- Need for more plasma measurements in auroral acceleration and source region of related SKR. Will the previously observed hemispheric dichotomy in the Saturn kilometric radiation period reappear?
- Need for better time resolution and coverage to understand the Enceladus' plume-magnetosphere interaction.
- What is the composition of the negative ions at Titan and >100 amu positive ions?
- What is the source of energy for the hot coronas/upper atmospheres of all four giant planets?

The Cassini mission has successfully answered many scientific questions and posed many new ones. A robust combination of future missions to the Saturn system, along with continued research and analysis, may yield answers to some of the questions listed above questions and generate new ones. The next Planetary Science Decadal Survey will pose its own questions based on Cassini results. One thing is clear: the questions left unanswered by Cassini and Huygens cry out for return missions to the Saturn system.

ACKNOWLEDGEMENTS

The Cassini Program is indebted to the hundreds of engineers, scientists, managers, and support staff on the Cassini and Huygens teams who designed, developed, managed, and operated the Cassini-Huygens mission. Their heart-felt dedication made this mission possible.

The Cassini-Huygens mission is a joint undertaking by the National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA). Agenzia Spaziale Italiana (ASI) is also a major partner via a bilateral agreement with NASA. Cassini is managed by the Jet Propulsion Laboratory, California Institute of Technology, under a contract from NASA.

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

ACP	Aerosol Collector Pyrolyser
AO	Announcements of Opportunity

MAPS Rules of the Road

volume 1 Mission Overview,
Science Objectives and Results

CASSINI FINAL MISSION REPORT 2019

Appendix A

What Are the MAPS Rules of the Road

The original AO for Cassini in 1989 included the following list of goals for the study of the magnetosphere of Saturn.

- Determine the configuration of the nearly axially symmetric magnetic field and its relation to the modulation of the Saturn kilometric radiation.
- Determine current systems, composition, sources and sinks of magnetospheric charged particles.
- Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interaction with the solar wind, satellites and the rings.
- Study the effect of Titan's interaction with the solar wind and the magnetospheric plasma.
- Investigate the interaction of Titan's atmosphere and exosphere with the surrounding plasma.

These goals are very general and broad reaching and it is clear that they could not be achieved by any single instrument and certainly not without the sharing of data between instrument teams. MAPS, led by its two IDSs, started early to make plans to address this.

One of the important actions by the MAPS IDS team was to propose and manage the creation of the "MAPS Rules of the Road" (hereafter RotR). The overarching goal of the RotR document was to create an environment where collaboration between teams was the norm. Such an environment would require the MAPS PIs and their teams to feel comfortable sharing their data with other teams and to have the assurance that their data would be handled fairly. The MAPS RotR contains an itemized description of what data can and should be shared between the MAPS instrument teams, how that data is allowed to be used, and who is responsible for overseeing the proper use of shared data. Although the MAPS RotR are by no means perfect, they provided a foundation on which the scientific success of the Cassini MAPS team could be built.

Development of the MAPS Rules of the Road

Motivation: MAPS science naturally requires collaboration

The scientific questions studied by the MAPS working group are based heavily on fundamental plasma physics including neutral and charged particles, particle sources and losses, particle

energization and transport, the influence of electric and magnetic fields and coupling with Saturn and its moons. The processes are fundamentally governed by Maxwell's equations, which couple particle related quantities (current, charge) with electric and magnetic fields. Furthermore, Saturn's moons (Titan in particular) are places where chemical processes are highly important. The dependence of MAPS science on fundamental principles naturally results in the need for data from multiple instruments because of:

- Interactions of neutral particles, ions and electrons
- Lower energy particles make up the bulk of the plasma density while higher energy particles contribute significantly to the plasma pressure
- Saturn's magnetic field, coupled with fast planetary rotation, drives particle motion and plasma transport
- Identification of neutral and ion species leads to understanding of sources as well as the fundamental chemical processes involved

Because of the inter-instrumental nature of the MAPS Cassini science questions, it was clear that the MAPS instrument teams could not achieve all of their own, individual science goals or the mission science goals without data sharing. Fortunately, because of the fundamental, physics-based need for data sharing in magnetosphere physics, the magnetospheric and plasma science community has a historical track record of sharing data. Although this community has a long history of sharing mission data, it was recognized that formalizing a data sharing plan would further foster the collaborative environment in the MAPS community and would likely greatly enhance the return from the Cassini Mission. I concluded that a data sharing plan needed to be a topic that was addressed and worked out early in the mission.

Venus Express as a Model

The MAPS RotR were modeled after the Pioneer Venus Orbiter (PVO) rules of the road. Unfortunately, it was not possible to find the original PVO RotR documents to include here and it was also not possible to determine who wrote the original RotR for the PVO. I was a member of the PVO science team and was familiar with the PVO RotR. I concluded that the Cassini MAPS teams could benefit from a formal data sharing agreement that outlined specific regulations for how data would be shared amongst the instruments team. I presented the PVO RotR document to the MAPS PIs around 1995 and to the entire Cassini PSG meeting soon after launch.

The Design and Implementation Process

IDS Gombosi presented the idea that MAPS needed a data sharing plan and suggested to the PIs that the PVO RotR was a document that provided a good place to start a discussion. The

presentation of the PVO RotR document by IDS Gombosi to the MAPS PIs was generally received positively and a discussion of what the MAPS RotR should look like began. It is important to note that the MAPS RotR is a data sharing plan that was mutually developed and agreed on by each of the MAPS instrument PIs. The document was not created from above and forced on the PIs. It was created together with the PIs through discussion and negotiation. This process allowed each PI to be satisfied that their individual needs would be addressed and created an atmosphere of buy in by all instrument teams.

The MAPS RotR document retained all the initial points of the PVO RotR document. However, the MAPS PIs suggested a few modifications, one of which was very significant. In point 1, the MAPS IDS's added the phrase "It is the responsibility of MAPS PIs to ensure that the Rules-of-the-Road are observed by their team." Although the quantity of added text was minimal, the intent of the text became very important during the mission. The PIs felt that it was important to directly indicate who was responsible for ensuring that the RotR where followed. Asking each PI to be responsible for their own team's use of data from other instruments had several important consequences. First, for a PI to fulfill this responsibility it required them to know what research was being conducted by their teams. The PIs did not micromanage the research, but by being aware of what their team members were doing they could enforce the RotR and foster more collaborations. Second, by assigning responsibility for oversight it was relatively straight forward to handle the occasional violation of the RotR.

It is important to note that final text for the document was accepted in the year 2000, four years before the arrival of Cassini at Saturn and before the flyby of Jupiter. The agreement was in place well before any of the truly important scientific data was beginning to be collected. In fact, having the RotR in place during the cruise phase allowed teams to begin to understand how to operate within the rules and to start sharing data with trust and confidence early on. By the time Cassini arrived at Saturn, teams shared data reasonably well because they already had experience.

Beyond indicating that the responsibility for oversight of the use of shared data belonged to the PIs, the MAPS RotR contained several key stipulations. Perhaps equally important to the data sharing oversight, the document makes it very clear that instrument teams are expected to share their data (item 4). Although such data sharing is typical in the magnetosphere and plasma community, the formalized, agreed upon statement put MAPS on a stable foundation for collaborations during the mission. The RotR also outlines several limitations to what data would be shared and how that data could be used. First, the document makes clear that instrument PIs and their Co-Is are responsible for the initial analysis, interpretation, and publication of these data. This statement was very important because it clarified that PIs and instrument teams would have first right to publish unique data or discoveries made by their instrument before having to share data with the MAPS team. The RotR also makes it clear that data is shared for the purpose of conducting correlative and collaborative studies and should not be used for studies that could be done by the instrument team alone. Finally, when data shared by another instrument is being used for a correlative study, the RotR indicate that the instrument PI and the team should be informed of how the data will be used. In addition, the RotR indicates that researchers using other instruments data

should invite members of the appropriate instrument team, through the PI, to participate in the study and that this invitation should be made very early in the research process.

Because data was expected to be shared broadly between the MAPS instrument teams it was important that the RotR indicate with whom data could be shared. MAPS data was to be shared within the MAPS instruments teams, under the direction of the instrument PIs. The data and summary plots created on MAPSview were not to be shared beyond the MAPS team members without approval of the PIs of the relevant instrument.

Finally, two important stipulations of the MAPS RotR related to roles of the IDSs within the MAPS group: proper role of an IDS and summary plots and a key parameter database. Both of these items are addressed in more detail in the MAPS Data Sharing document. Here we note that as the RotR document was being created the MAPS IDSs expressed their strong belief that their job was not to complete with the instrument teams but rather to facilitate individual teams, facilitate collaboration between teams, and to bring skills or models to the table that none of the instrument teams had access to. The MAPS RotR formalized this role. In the context of facilitating collaboration, the MAPS IDSs felt it was important create a key parameter database and summary plots including all MAPS instrument data. These resources where to be used for quickly finding correlations or to quickly evaluate observed events. The RotR document indicates that this key parameter data and the quick look plots are to be treated the same as full quality instrument data products.

Rules of the Road during the Mission

Successes

The most important success of the MAPS RotR is the incredible science return that has come from the MAPS working group. A quick review of papers produced by MAPS investigators shows that a majority of papers have co-authors from more than one instrument. Although it is not possible to determine the quantitative impact the RotR had on the number of collaborative papers published by MAPS, our feeling is that the RotR greatly enhanced the ease of sharing data and teams willingness to share and therefore greatly increased the number of papers produced by MAPS.

During the mission, there was only one serious breach of the MAPS RotR. Given the considerable amount of data shared and the breadth and quality of the collaborations this is clearly a success.

Finally, as mentioned above, the process for creating the MAPS RotR was not top down. It was suggested by the MAPS IDS but it was not forced on the PIs. The process of modifying the PVO RotR to meet the needs of the Cassini mission and of implementing the RotR was in the hands of the PIs. This process assured that each PI could be satisfied that the needs of their individual team would be addressed and that the MAPS RotR would be consistent with individual team's internal policies.

The active support of the PIs for the development and implementation resulted in an atmosphere where sharing of data was the norm and where teams trusted that their data and their interests would be protected.

Challenges

Because the MAPS RotR were agreed upon by each of the MAPS PIs early in the mission, there were no problems with teams complaining about sharing data or teams restricting access to data that was important for collaborative studies. However, with a group as large as the Cassini MAPS team, and with the generally open sharing of data from all the MAPS instruments, it was likely that at some point data would be treated out of accordance with the RotR.

Although the RotR worked remarkably well in helping MAPS teams to share data openly and conduct many collaborative studies, there were a few occasions when the RotR were not followed. In almost every case, the breach was inadvertent, not malicious and did not result from a blatant lack of ethics. Nevertheless, some of the breaches where quite problematic and caused justified concern for the PIs involved. Very minor breaches where typically handled between the PIs whose teams were involved. However, in one or two cases, the RotR had to be reiterated at a MAPS working group meeting at a PSG and the MAPS IDSs were called on to reaffirm the data sharing agreement. At the same time, PIs were reminded to talk with their teams about the issue and to take a firmer role in overseeing how data from other instruments was being used. In each case, the value of the RotR was amplified because it provided a foundation for the discussion and resolution. The RotR could be consulted to clearly delineate how the offending action violated the RotR and what the appropriate course of action should have been.

Cassini Mission Rules of the Road

The MAPS RotR document was clearly a success in fostering data sharing between the MAP teams. This success led the Cassini Mission Project Scientist to consult with the MAPS IDS in implementing a RotR document for the broader mission. The creation of that document was discussed during the 1998–2002 period and the final Cassini RotR was accepted by the Executive PSG in 2002.

Lessons Learned

As outlined above, the most important aspect of the RotR was that it clarified the rights of teams with respect to using their own data, their responsibility to share their data and proper use of other team’s data. In addition, it clearly laid out who was responsible for assuring the team members followed the RotR. These key parts of the RotR greatly reduced the data “ownership” conflicts that often prevent the open sharing of data between instrument teams.

Moving from “the data is ours” point of view to the open sharing of data requires a culture change. Although the MAPS community has a track record of sharing data (for the reasons outlined above), the RotR document gave PIs and their teams confidence that their data would be protected and used correctly. This allowed teams to begin to share data and then to observe the mutual benefit that comes from sharing. This is perhaps one of the most important keys to a culture change. Teams have to see that sharing is mutually beneficial to feel truly comfortable openly sharing their data. The MAPS RotR document, or something like it, can have the effect of opening the door enough for teams to gain confidence and move toward the culture change needed for open sharing of data.

Finally, we note that the collaborative, data sharing culture is easier to achieve for in-situ instruments, as opposed to remote sensing instruments, due to the nature of the science addressed. As outlined above, data from multiple in-situ instruments is typically required in order to fully understand a phenomenon or an event. On the other hand, the nature of the science done by remote sensing teams is such that a single instrument can often make major advanced without the need for data from other teams. The nature of images also makes them more prone to someone outside a team being able to make discovery where for in-situ instrument this is much more unlikely. For this reason, it is clear that achieving a collaborative data sharing culture is easier for in-situ (MAPS) instrument teams than it is for remote sensing teams.

Cassini/Huygens Mission MAPS Discipline Working Group Rules of the Road (September 2000)

The MAPS DWG of the Cassini Huygens Mission agrees to the following set of procedures and rules to assure an orderly and efficient analysis and interpretation of the mission's scientific results.

1. Instrument Principal Investigators (PI), Science Team Leaders (TL) and Interdisciplinary Scientists (IDS) will be designated MAPS PIs. It is the responsibility of MAPS PIs to ensure that the Rules-of-the-Road are observed by their team. MAPS instrument PIs and TLs will be referred to as instrument PIs. The MAPS team is composed of all MAPS PIs, their Co-Is, team members and associates (such as students, postdocs, etc.). Each team member must be sponsored by a MAPS PI.

Gombosi: MAPS Rules-of-the Road 6

1. Each instrument PI is responsible for the analysis of data from his/her instrument. The instrument PIs and their Co-Is are responsible for the initial analysis, interpretation, and publication of these data.

2. IDSs are expected, under normal circumstances, to carry out investigations that involve more than one instrument. This may occur either as a result of their proposing such investigation, or their being invited to participate in investigations by other MAPS PIs. When investigations are proposed in an area in which an IDS is known to have an interest, the normal procedure will be to invite him/her to participate.

3. All instrument PIs are expected to contribute their processed data for MAPS team use. However, these data are to be used for correlative studies only.

4. When data from an instrument are used in a correlative study, the instrument PI responsible for the data must be informed of their use, and invited at an early time (preferably before the investigation begins) to participate (directly or through designated associates) in the study. The collaborators from the data providing instrument should be invited, through the PI, to be co-authors of any resulting publication or presentation (including abstract of a presentation).

5. The combined summary plots are made available to MAPS to identify possible scientifically interesting events. These plots are not intended for publication purposes, and may not be published without the specific authorization of the appropriate instrument PI. However, summary plots can be used in oral presentations to demonstrate potential new science. In such cases appropriate credit must be given to the instrument PI.

6. Each MAPS member entrusted with the summary plots are required to see that they are not distributed beyond the MAPS community without the specific permission of the instrument PIs who contributed data to the summary plot.

7. Any instrument PI can release data from his/her instrument to anyone, but no data can be released or published without the permission of the appropriate instrument PI.

HUYGENS PROBE

The European Space Agency (ESA) Huygens Probe was an entry probe designed to study the atmosphere and the surface of Saturn's largest moon, Titan. Huygens was delivered to Titan by the Cassini Orbiter in January 2005 after a seven-year interplanetary cruise. The Huygens scientific objectives were to carry out detailed in situ measurements of the physical properties, the chemical composition and the dynamics of the atmosphere and to provide a local characterization of the surface near the landing site. Titan's Earth-like surface was revealed in images taken during the probe's descent to the surface.

Huygens was a highly sophisticated robotic laboratory equipped with six scientific instruments including: 1) Aerosol Collector Pyrolyser (ACP), 2) Descent Imager and Spectral Radiometer (DISR), 3) Doppler Wind Experiment (DWE), 4) Gas Chromatograph and Mass Spectrometer (GCMS), 5) Huygens Atmospheric Structure Instrument (HASI), and 6) Surface Science Package (SSP). Additionally, an engineering system, the Radar Altimeter, provided some scientific information about the structure along the ground track. The Doppler signature of the transmitted Huygens radio signal was directly detected by the two largest radio telescopes that were included in a network of 17 telescopes that were part of the very long baseline interferometry (VLBI) project put together a couple years before Huygens' release. These instruments allowed the Huygens probe to investigate Titan's atmospheric composition and dynamics, formation and evolution, to study Titan's meteorology, to investigate Titan's organic haze and to examine Titan's surface characteristics and to infer information about Titan's internal structure. The Huygens science team successfully addressed all the Huygens mission science objectives.

EXECUTIVE SUMMARY

The Cassini-Huygens mission comprising the NASA Saturn Orbiter and the ESA Huygens Probe, arrived at Saturn in late June 2004. Following the separation of the Huygens probe from the Cassini Orbiter on December 25, 2004, Huygens arrived at Titan on January 14, 2005. Following entry protected by its heatshield, Huygens descended under two sequentially deployed parachutes to Titan's surface where it landed safely. It continued to fully operate on Titan's surface for several hours, until its batteries were depleted. Huygens findings and discoveries include new and improved understanding of Titan's atmospheric structure and chemical composition, distribution and composition of atmospheric aerosols, morphology and composition of the surface at the Huygens landing site, the altitude profile of zonal and near-surface winds along the Huygens descent trajectory, and atmospheric electrical properties. The data set collected by Huygens provided significant contribution to the understanding of the origin and evolution of Titan [Lebreton et al. 2009]. Furthermore, Huygens data set also served as the ground truth for several orbiter atmosphere and surface observations, proving the complementarity of in situ and remote sensing observations of a newly explored world.

In situ (accelerometry) measurements were made from about 1400 km altitude under the heatshield configuration. They revealed a very wavy atmospheric temperature/density profile attributed to atmospheric gravity waves. Direct in situ measurements of various atmospheric parameters started after parachute deployment (and heatshield release) at an altitude of about 150 km. During the latter stages of the descent, below about 50–60 km altitude above the surface, clear images of the surface were obtained by DISR, revealing a remarkably Earth-like world, showing strong evidence for erosion due to past epochs of flowing liquids, possibly methane. The Huygens descent trajectory carried the probe across a boundary between a bright, icy, rugged terrain and into a darker flat area where Huygens landed. Measured profiles of pressure and temperature below 150 km by HASI were found to be close to those expected based on Voyager observations. At the landing site, the surface temperature and pressure measured by Huygens were 93.7 K and 1,470 mbar, respectively. Reflectance spectra taken during descent show that the surface is primarily composed of dirty water-ice, and images of the landing site from the surface show a scattering of water-ice cobbles up to several centimeters in diameter. The SSP penetrometer found the surface to be unconsolidated, with the consistency of damp sand.

During the latter stages of the descent, below about 50–60 km altitude above the surface, clear images of the surface were obtained by DISR, revealing a remarkably Earth-like world, showing strong evidence for erosion due to past epochs of flowing liquids, possibly methane.

Atmospheric winds measured by Doppler tracking of the Huygens probe were found to blow predominantly in the direction of Titan's rotation (prograde: west–east) with speeds of about

125 m/s (~450 km/hr) detected above an altitude of 120 km. Although the winds diminished with decreasing altitude as expected from both Voyager and ground-based observations, a somewhat unexpected weakening of the winds was found between 100 km and 60 km. In the planetary boundary layer near the surface, the direction of the winds changed to include a significant north-south component.

Haze was detected from the top of the atmosphere to the surface with no evidence of the haze-free atmosphere predicted below 60 km. At an altitude of about 60 km, an ionosphere-like layer likely produced by galactic cosmic rays predicted by models was characterized, but at an altitude slightly lower than predicted by models [Whitten et al. 2007] was characterized, but at an altitude slightly lower than predicted by models.

The GCMS and ACP measurements of Titan's atmospheric composition and aerosols confirmed the presence of a complex organic chemistry in both the gas and the solid phase, and vertical abundance profiles were obtained for the more abundant species. Although primordial argon ^{36}Ar and radiogenic argon ^{40}Ar were detected, there was no detection of either xenon or krypton. Isotopic ratios of carbon, nitrogen, and deuterium to hydrogen (D/H) were measured, helping to further constrain formation scenarios for Titan's atmosphere [Niemann et al. 2010].

Composition measurements made by GCMS from the surface material vaporized after landing included detection of ^{40}Ar. The time profile of the composition of surface vapors indicated the Huygens probe landed on a surface damp with methane which subsequently evaporated as the cold regolith was heated by the GCMS inlet and the DISR lamp. Compounds such as C_6H_6, C_2N_2, and CO_2 were detected in the gas from the surface material.

Huygens Science Assessment

The Huygens science objectives were defined in the ESA's Announcement of Opportunity (AO), 1989.

Table HUYGENS-1. Huygens Science Assessment.

Fully/Mostly Accomplished: **Partially Accomplished:**

H1 Titan Atmosphere Formation and Evolution: Determine Abundance of atmospheric constituents (including noble gases); establish isotope ratios for abundant elements; constrain scenarios of formation and evolution of Titan and its atmosphere.

Huygens Objectives		Status	Instrument	Notes
H1.1	Determine the abundances of atmospheric constituents and noble gases		GCMS	CH_4 mole fraction 5.65 ±0.18% and CH_4 relative humidity near surface ~50%.
H1.2	Establish isotope ratios for abundant elements		GCMS	Measured isotopes of H (D/H), C, N, Ar
H1.3	Constrain scenarios of formation and evolution of Titan and its atmosphere		GCMS	Detected extremely low quantities of ^{36}Ar which rules out primary origin of N_2 and argues N_2 as secondary like on Earth; Measured isotopic ratios of C, N, and D/H helps constrain atmospheric formation &evolution scenarios; Radiogenic ^{40}Ar measured to constrain Titan outgassing history.

H2 Titan Atmosphere Composition and Distribution: Observe vertical and horizontal distributions of trace gases; search for more complex organic molecules; investigate energy sources for atmospheric chemistry; model the photochemistry of the stratosphere; study formation and composition of aerosols.

Huygens Objectives		Status	Instrument	Notes
H2.1	Observe vertical distribution (profile) of trace gases		GCMS, DISR	DISR: low altitudes; GCMS: Vertical distribution of CH_4 and H mole fractions
H2.2	Search for more complex organic molecules		GCMS	Found evidence of heavy organic molecules
H2.3	Investigate energy sources for atmospheric chemistry		DISR, HASI	DISR measured light absorption vs altitude; HASI detected cosmic ray ionization
H2.4	Model the photochemistry of the stratosphere		GCMS, ACP	Data used in multiple photochemical models
H2.5	Study formation and composition of aerosols		GCMS, ACP	Low mass of ACP sample transferred to GCMS limited the results to simple species, rather than complex hydrocarbon hazes

H3 Titan Meteorology: Measure winds and global temperatures; investigate cloud physics, general circulation and seasonal effects in Titan's atmosphere; search for lightning discharges.

Huygens Objectives		Status	Instrument	Notes
H3.1	Measure winds and global temperatures		DWE, HASI, DISR	DISR: Wind drift near surface via feature tracking; PBL detected at ~7 km; Measurements provided ground truth for global Cassini remote sensing measurements.
H3.2	Investigate cloud physics, general circulation and seasonal effects in Titan's atmosphere		DWE, DISR	Huygens measurements provided ground truth for Cassini global remote sensing studies for seasonal effects.
H3.3	Search for lightning discharges		DISR, HASI	Schumann Resonance seen by HASI PWA, but not linked to lightning activity. No optical or RF signature of lightning found.

H4 Titan Surface Characteristics and Internal Structure: Determine the physical state, topography and the composition of the surface; infer the internal structure of the satellite.

Huygens Objectives		Status	Instrument	Notes
H4.1	Determine the physical state, topography and the composition of the surface		SSP, HASI, DISR, GCMS	DISR: Imaging of surface topography show drainage basins, dry riverbeds, dunes; IR reflectance spectroscopy. GCMS: Trace organic species found in surface measurements. HASI: Surface permittivity SSP: Acoustic Sounding; Surface penetrometry and accelerometry. Radar altimeter: surface topography and reflectivity.
H4.2	Infer the internal structure of the satellite;		HASI	HASI PWA: Measurement of Schumann resonance within ionosphere / subsurface ocean waveguide.

H5 Titan Upper Atmosphere: Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.

Huygens Objectives		Status	Instrument	Notes
H5.1	Investigate upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn		DISR, HASI	DISR: Hydrocarbon haze number density in upper atmosphere. HASI PWA: Measurement of Schumann resonance within ionosphere / subsurface ocean waveguide.

HUYGENS MISSION OVERVIEW

The Huygens probe was the ESA contribution to the NASA/ESA/ASI Cassini-Huygens mission. The Cassini-Huygens spacecraft arrived in the Saturnian system on June 30, 2004, following a seven-year cruise, and performed a perfect Saturn Orbit Insertion maneuver to initiate a long series of orbits around Saturn that included frequent regular flybys of Titan. For the first three Titan flybys, Cassini was still carrying the Huygens probe. Following the third Titan encounter on December 13, 2004, the Cassini orbiter main engine was fired on December 17 to bring the orbiter and Huygens probe, still attached, onto a collision trajectory with Titan. Small onboard jets were fired on December 23, 2004, to fine-tune the flight path of Cassini-Huygens to align the spacecraft on a trajectory that would target Huygens to the desired entry location, and on December 25, 2004, at 02:00 UTC the Spin/Eject Device separated Huygens from Cassini with a relative speed of approximately 0.35 m/s and a spin rate of 7.5 revolutions per minute. The Huygens probe was targeted for a low southern-latitude site on the dayside of Titan. Constrained by the heat shield design performance and radio visibility conditions between the probe and the orbiter during the descent, the probe entry flight path angle into the atmosphere was set to −65° (25° from the local vertical) with a tolerance of three degrees. The relative position of Cassini, Huygens, and Titan enabled a theoretical maximum telecommunications link between Huygens and Cassini of 4 hours 30 minutes. Huygens and Cassini were effectively in radio contact from the start of the radio transmission after parachute deployment until after about 72 minutes after landing. Two Earth radio telescopes, first Green Bank in West Virginia, and then Parkes in Australia, detected directly the Huygens radio signal (carrier).

The relative position of Cassini, Huygens, and Titan enabled a theoretical maximum telecommunications link between Huygens and Cassini of 4 hours 30 minutes.

Prior to arrival at the atmospheric entry interface point on January 14, 2005, at 11:04 UTC [Lebreton et al. 2005], the Huygens coast timer woke up Huygens. Four and a half hours later, the Huygens probe encountered the Titan atmosphere at an altitude of about 1500 km above the surface, causing the 300 kg probe to aerobrake from its approaching velocity of around 21,600 km/h (6 km/s) to less than 1,400 km/h at 150 km altitude. During entry, Huygens experienced aerodynamic forces up to 12 g (measurements saturated at 10 b by design) and an estimated entry temperature of 12,000° C (21,600° F) in the shock that formed in front of the probe, leading to an expected heat shield temperature of 1,800° C. After the entry, speed had decreased to about Mach 1.4 (290 km/h at about 160 km altitude). The pilot chute was deployed and the backshell of the heat shield was pulled away by the pilot chute and deployed, within less than 2 seconds the 8.3-meter (diameter) main parachute. The heat shield was released 30 seconds later. Following 15 minutes of descent, the main parachute was discarded and replaced at about 110 km altitude by a smaller 3-meter (diameter) parachute to ensure that the probe would reach the surface at least 30 minutes before the orbiter would pass below the horizon as seen from the

landing site. The descent from atmospheric entry to landing took 2 hours 27 minutes 50 seconds. The radio contact between Huygens and Cassini was operational until the orbiter passed below the horizon 72 minutes after landing.

The light level on the surface of Titan was roughly 1,000 times less than experienced on Earth by day, but 500 times brighter than the light of the full moon.

At an altitude of 60 km, the surface-sensing radar was turned on to provide altitude information to the onboard computers, which then broadcast the altitude to the instruments to allow the instruments to adapt their measurement sequence to the measured, rather than to the predicted altitude. Accurate altitude information was in fact provided only below 20 km. DISR, HASI and SSP adapted their measurement sequence to the measured altitude information provided by the onboard computer. This tuning allowed the Huygens surface lamp to be activated at 700 m altitude and the SSP instrument to activate its high-time resolution impact detection measurement mode while approaching the surface. The light level on the surface of Titan was roughly 1,000 times less than experienced on Earth by day, but 500 times brighter than the light of the full moon. Although the natural lighting by the Sun was sufficient to illuminate the landing site, the surface lamp enabled high signal-to-noise multispectral measurements of surface reflectivity.

Due largely to the thick atmosphere and the excellent performance of the parachutes, the surface impact speed was slightly less than 5 m/s (about 18 km/h). Once on the surface, Huygens' five batteries lasted much longer than expected, allowing the probe to continue functioning several hours after landing, providing time for the orbiter to collect surface data for 1 hour 12 minutes before disappearing below the horizon. The Earth-based radio telescope received the Huygens signal for more than 3 hours after landing, until 16:00 GMT, corresponding to the end of the window assigned to that observation.

More than 350 images and numerous spectra were returned by the DISR camera during descent, while four other probe instruments, the HASI, ACP, GCMS, and the SSP sampled Titan's atmosphere to help determine its composition and structure, and to characterize the aerosols. To retrieve the altitude profile of zonal winds, the DWE was designed to provide Doppler tracking of the probe throughout descent. Once on the surface, the SSP, HASI, GCMS, and DISR continued to acquire data (ACP turned off as planned below 10 km). The Huygens probe was also tracked by a VLBI network of 17 radio telescopes, as part of an experimental project put in place about one year before Huygens landing. Two of the VLBI radio telescopes, the Green Bank Telescope and Parkes were equipped with highly sensitive radio receivers provided by the JPL radio science team. They collected the most accurate Doppler information during the descent, as this information could not be retrieved from the channel of the Huygens radio link equipped with ultra-Stable Oscillators as the receiver onboard Cassini was not activated properly due to a programming error. Limited Doppler information was however retrieved from the

second channel of the Huygens-to-Cassini radio link which itself was equipped with less stable crystal oscillators.

The Huygens science data was relayed to the Cassini orbiter at a rate of 8 kilobits per second and stored in solid-state memory on the orbiter. Although the data were transmitted on two nearly redundant channels, A and B, a programming error in the channel A receiver resulted in no data collected through that channel. In the end, because of the redundancy philosophy applied to the Huygens design, almost all of the measurements were recovered. In particular, the exceedingly weak signal from Huygens was captured by two of the Earth-based radio telescopes, Green Bank and then Parkes, both equipped with highly sensitive radio receivers provided by the JPL radio science team, in effect providing a channel C to Doppler-track the probe throughout descent and enabling the DWE to retrieve the Titan zonal wind profile. In the end, radio telescopes on Earth received 5 hours 42 minutes of Huygens data, including 3 hours 14 minutes from the surface. The probe survived the landing and continued transmitting from the surface for a much longer time than expected because Huygens touched down on a relatively soft solid surface. Once the Cassini orbiter flew beyond the horizon as seen from Huygens, the probe continued transmitting for several hours. The Huygens signal was still detected when Parkes stopped tracking it at 16:00 UTC. Flight performance of the probe allowed an estimate that the batteries became depleted about 20–25 minutes later. [Huygens Flight Performance Report, Huygens data set archive, Lorenz 2017].

TOP TEN HUYGENS FINDINGS

The top 10 Huygens discoveries at Titan are listed below and can be found at ESA website http://sci.esa.int/cassini-huygens/55221-huygens-titan-science-highlights/, [ESA 2017].

On 14 January 2005, at 13:34 CET (12:34 UTC), ESA's Huygens probe entered the history books by descending to the surface of Titan, Saturn's largest moon. This was humanity's first successful attempt to land a probe on another world in the outer solar system.

Huygens hitched a ride to the Saturn system during an epic, seven-year voyage attached to NASA's Cassini spacecraft. The final chapter of the interplanetary trek was a 21-day solo cruise toward the haze-shrouded moon. Plunging into Titan's atmosphere, the probe survived the hazardous 2-hour 27 minute descent to touch down safely on Titan's frozen surface.

Huygens continued to transmit back to Earth for another 72 minutes before contact was lost with Cassini as it dipped below the horizon. The stream of data provided a unique treasure trove of in situ measurements from the planet-sized satellite which scientists are still mining today. In the following articles we present 10 important results from the pioneering mission.

1. Profiling the Atmosphere of Titan

The HASI made the first in situ measurements of Titan's atmosphere. HASI determined the atmospheric temperature, pressure, and density from an altitude of 1400 km down to the surface.

Long before ESA's Huygens probe arrived at Titan, scientists knew that the moon's dense atmosphere was mainly composed of nitrogen, with some methane, but the atmosphere's structure—its temperature and pressure at different altitudes —was poorly understood.

By monitoring the probe's rate of deceleration as it plunged into the atmosphere, the HASI instrument directly determined the density of the upper atmosphere. The temperature was derived from models of how it should change with density and altitude. In the lower atmosphere (below 160 km) and on the surface of Titan, HASI directly measured the pressure and temperature, as well as electrical properties such as permittivity and the distribution of ions.

HASI data showed that the upper atmosphere (the thermosphere) was generally warmer and more dense than expected. Titan's atmosphere was also found to be highly stratified.

Above 500 km, the average temperature was about −100° C but strong variations of 10-20° C were detected due to inversion layers and other phenomena, such as, gravity waves and tides. The mesosphere was virtually absent, in contrast with theoretical predictions.

Below 500 km, the temperature increased quite rapidly, reaching a maximum of -87° C at the top of the stratosphere, at an altitude of 250 km. The temperature then decreased steadily throughout the stratosphere, reaching a minimum of −203° C at an altitude of 44 km. This marked the boundary between the stratosphere and the troposphere.

The temperature increased again as the probe neared the surface, rising to a chilly −180° C at the landing site. The surface pressure was 1.47 times that on Earth.

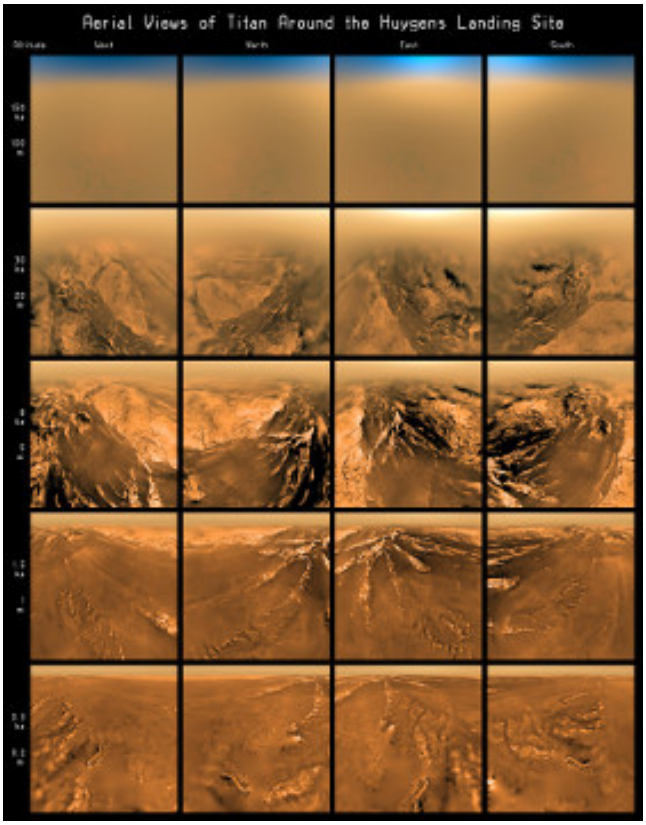

Figure HUYGENS-1. Huygens' view of Titan from five altitudes. Credit: ESA/NASA/JPL/University of Arizona.

2. Titan's Super-rotating Winds

Although spacecraft observations had indicated that strong zonal (east-west) winds may exist in Titan's atmosphere, the first direct measurements were made by the Doppler Wind Experiment on ESA's Huygens probe.

By measuring the Doppler shift of the radio signal from Huygens and studying panoramic mosaics from the onboard imager to work out the descent trajectory, it was possible to create a high resolution vertical profile of Titan's winds, with an estimated accuracy of better than 1 m/s.

Huygens found that the zonal winds were prograde (the same direction as the Moon's rotation) during most of the atmospheric descent. The probe generally drifted east, driven by remarkably strong westerly winds which peaked at roughly 120 m/s (430 km/h) at an altitude of about 120 km.

Down to a height of 60 km, large variations in the Doppler measurements were observed—evidence that Huygens endured a rough ride as the result of significant vertical wind shear. Wind speeds then decreased toward the surface, dropping from 30 m/s (108 km/h) at an altitude of 55 km to 10 m/s (36 km/h) at a height of 30 km, eventually slowing to 4 m/s (14 km/h) at 20 km. The winds dropped to zero and then reversed direction at around 7 km.

The large prograde wind speeds measured between 45 km and 70 km altitude and above 85 km were much faster than Titan's equatorial rotation speed. It was the first in situ confirmation of the predicted super-rotation of the moon's atmosphere, even though the speed observed was slightly lower than expected.

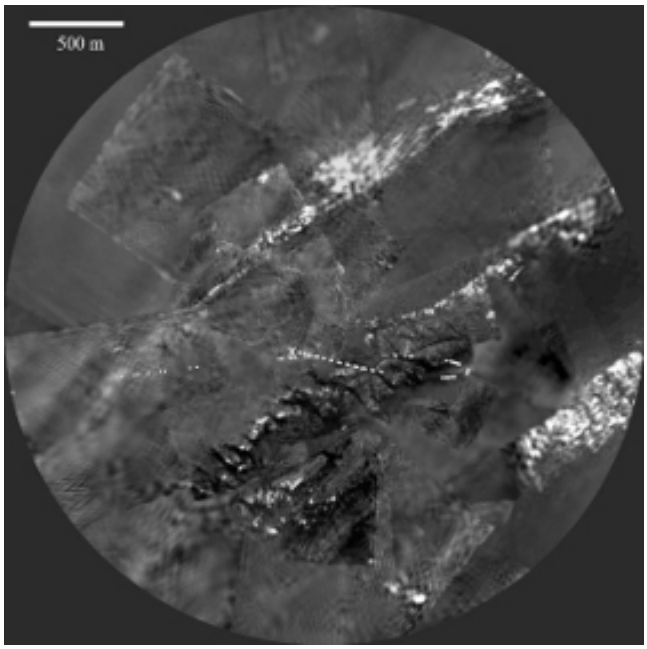

Figure HUYGENS-2. The ground track of Huygens is marked on this aerial view of Titan. Credit: ESA/NASA/JPL/University of Arizona.

A layer with surprisingly slow wind, where the sideways velocity decreased to near zero, was detected at altitudes between 60 km and 100 km.

During the last 15 minutes of the descent, Huygens headed west-northwest at a speed of approximately 1 m/s. The wind speed on the surface was between 0.3 m/s and 1 m/s.

Over the duration of the descent, the probe drifted eastward a distance of 165.8 km with respect to the surface of Titan.

3. Methane Mystery

ESA's Huygens probe made the first direct measurements of the composition of Titan's lower atmosphere. Data returned by the GCMS on Huygens included altitude profiles of the gaseous constituents, isotopic ratios and trace gases (including organic compounds).

Two of the key questions about Titan are the origin of the nitrogen and methane in its atmosphere, and the mechanisms by which methane levels are maintained. Since sunlight destroys methane irreversibly on Titan, its lifetime in the atmosphere is only tens of millions of years. Somehow the methane must be continually or periodically replenished.

The primary constituents of Titan's atmosphere were confirmed to be nitrogen and methane. In the stratosphere, levels of methane were found to be fairly low and the gas was uniformly mixed. Then, at an altitude of 40 km, in the upper troposphere, the relative amount of methane began to increase gradually until approximately 7 km, when it reached 100% relative humidity (saturation level).

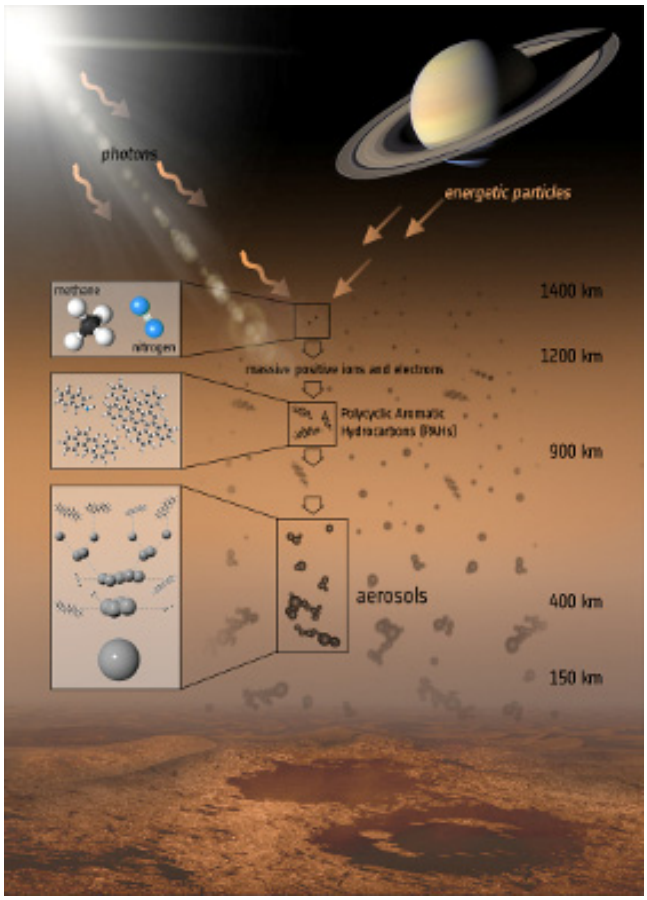

Figure HUYGENS-3. Chemistry in Titan's atmosphere. Credit: ESA/ATG medialab.

For the last part of the descent, methane amounts remained relatively constant until the probe touched down on the surface. A sudden, 40% increase in the methane signal after landing, while the nitrogen count rate remained constant, suggested the presence of liquid methane on the surface. This may have been due to the spacecraft heating the surface material. This increased value for methane remained nearly constant for about one hour, with a hint of a very slight decrease in the level toward the end of this period.

Measurements of the carbon isotopes in the methane provide no support for suggestions that it is generated by active micro-organisms on Titan. The methane was probably accreted by Titan during the moon's formation, and large quantities of liquid methane are now trapped in ices beneath the surface, possibly reaching the surface through some form of cryovolcanism. (Surface features

associated with possible cryovolcanism have been observed by Cassini. See Science highlights from Huygens: #5. Radioactive decay and cryovolcanism [ESA 2019a].) This activity would replace the methane that is lost as a result of photochemistry in the atmosphere.

The spectra taken on the surface also showed signatures characteristic of more complex hydrocarbons, such as ethane, cyanogen and benzene.

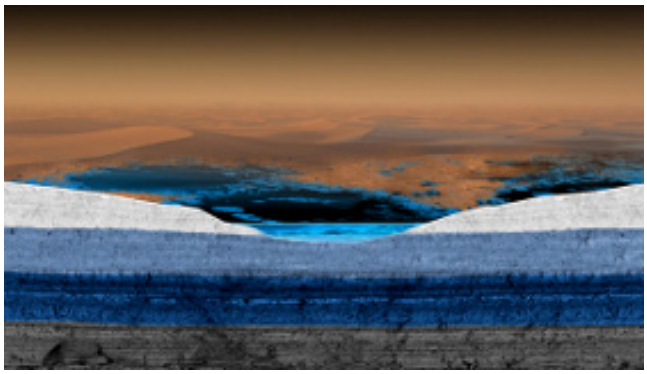

Figure HUYGENS-4. Titan's subsurface reservoirs contain hydrocarbons, including methane. Credit: ESA/ATG medialab.

4. The Origin of Titan's Nitrogen Atmosphere

Titan and Earth are the only worlds in our solar system that have thick nitrogen atmospheres. Although data from the Voyager Mission had implied that nitrogen (N_2) was the main atmospheric gas, the GCMS on ESA's Huygens probe made the first direct identification of bulk atmospheric nitrogen and its abundance. Other GCMS atmospheric measurements provided clues about where this atmosphere came from.

During its descent to the surface, the GCMS measured isotopic ratios and trace species in the atmosphere. One of the objectives for the GCMS was to search for heavy, noble gases such as argon-36 (^{36}Ar), argon-38 (^{38}Ar), krypton (Kr), and xenon (Xe). These primordial gases have been detected and measured in meteorites, in the atmospheres of Earth, Mars, Venus (to some extent), and Jupiter. Differing patterns of relative abundances and isotopic ratios of the gases provide insights into the origin and evolution of these objects. As a result, their measurements in the atmosphere of Titan were eagerly anticipated.

Scientists had theorised that these noble gases were present throughout the solar nebula, and should therefore have been incorporated into both Saturn and Titan during the early stages of planet formation. In the context of the origin of nitrogen, ^{36}Ar is of particular importance, and the GCMS found that the ratio of ^{36}Ar to nitrogen was about one million times less than is found in the Sun.

Direct condensation of gases in the young Titan would have resulted in the capture of ^{36}Ar, as well as nitrogen, in solar proportions. However, the depleted ratio detected by the GCMS on Huygens implies that the nitrogen was captured as ammonia (NH_3) or in other nitrogen-bearing compounds.

The rarity of noble gases on Earth has long been viewed as strong support for the atmosphere having been formed by the impacts of gas-rich planetesimals, and the near absence of noble gases from Titan provides more support for this hypothesis.

5. Radioactive Decay and Cryovolcanism

One of the trace gases detected by the GCMS on ESA's Huygens probe was radiogenic argon-40 (^{40}Ar). This isotope offers a window to the interior of the giant moon.

Radiogenic argon was detected by the GCMS below 18 km. This detection was important because ^{40}Ar originates solely from the decay of potassium-40 (^{40}K), a radioactive isotope of potassium found in rocks. The only possible source of this ^{40}Ar is rocks which exist deep in Titan's interior, below the satellite's mantle of hydrocarbon and water ice.

Since the radioactive half-life of ^{40}K is about 1.3 billion years, much shorter than the lifetime of Titan, the small amount of ^{40}Ar in the atmosphere provides an important indicator of how much outgassing has occurred from the deep interior.

If the rocky component of Titan's interior has the same composition as that of Earth and has outgassed to the same extent, ^{40}Ar should be about ten times more abundant than measured by Huygens, comprising approximately 0.05% of the atmosphere. If the interior was warm enough in the past for a liquid water or water-ammonia mantle to have reached all the way down to the moon's rocky core, potassium could have seeped into the liquid. The radiogenic ^{40}Ar could then have outgassed to the surface.

Certainly, the presence of the ^{40}Ar at the levels seen by Huygens is a strong indication of geological activity on Titan, and consistent with periodic replenishment of atmospheric methane (see Science highlights from Huygens: #3. Methane Mystery [ESA 2019b].) The apparent evidence for cryovolcanism observed by the Cassini orbiter—involving water or a mixture of water and ammonia—provides one possible process for release of both gases from the interior.

6. Hazy Titan

One of the most noticeable features of Titan is the orange blanket of haze that hides its surface. However, no one knew whether the haze extended to the surface until ESA's Huygens probe landed on the icy moon.

The measurements of the DISR on the Huygens probe provided in situ information on the optical properties, size and density of the haze particles. The observations showed that there was a significant amount of haze at all altitudes throughout the descent, extending all the way down to the surface. With decreasing altitude, the haze particles became brighter, and the particle sizes increased, due to collisions which resulted in a 'snowball' effect, as well as condensation of methane, ethane and hydrogen cyanide gases onto small aerosol nuclei at lower levels.

Huygens detected three distinct haze regions (region I above 80 km, region II between 80 and 30 km, and region III between 30 km and the surface), based on the density and optical properties of the atmosphere.

Before the Huygens mission, it was generally believed that the tiny haze particles slowly sink through the stratosphere, eventually acting as condensation nuclei for lower-level clouds. Some scientists theorized that the haze might clear below an altitude of 50 km to 70 km due to condensation of gases such as methane. However, the probe's DISR showed that Huygens began to emerge from the haze only in the troposphere, 30 km above the surface.

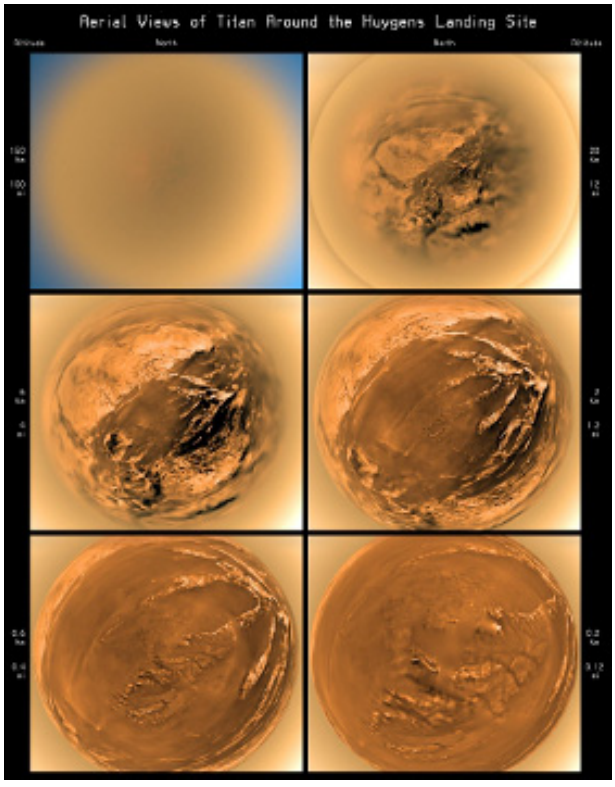

Figure HUYGENS-6. Six stereographic images of Titan's surface taken during Huygens's descent to Titan's surface, showing the haze clearing. Credit: ESA/NASA/JPL/University of Arizona.

Another thin layer of methane haze was detected at an altitude of 21 km, where the local temperature was −197° C and the pressure was 450 mbar. This feature may be an indication of methane condensation. Indeed, the data suggest the presence of layered methane clouds in Titan's troposphere, at altitudes between 8 km and 30 km.

When combined with ground-based measurements, the data suggest an upper methane ice cloud (or haze) between approximately 20 km and 30 km and a liquid methane-nitrogen cloud layer between 8 km and 16 km, perhaps with a gap in between.

7. Titan's Tiny Aerosols

Tiny particles (aerosols) in Titan's atmosphere have long been suspected to play an important role in determining its thermal structure and atmospheric processes. However, until the Huygens mission, no direct measurements had been made of the chemical composition of these particles.

One set of measurements was made by the GCMS and the ACP experiment. The collected aerosol particles were heated in the ACP oven in order to vaporize all volatile components, and the composition of the gases released by each sample was then analyzed by the GCMS.

Two atmospheric samples were obtained during the descent of Huygens. One was taken at 130-35 km (the middle stratosphere) and the other at 25-20 km (the middle troposphere). Ammonia (NH_3) and hydrogen cyanide (HCN) were identified as the main gases released in the oven, confirming that carbon and nitrogen are major constituents of the aerosols.

No substantial difference was found between the two samples, suggesting that the aerosols' composition was the same at both altitudes. This supports the idea that they have a common source in the upper atmosphere, where ultraviolet sunlight photochemically alters gases such as methane.

Meanwhile, the DISR characterized the optical properties of the photochemical aerosols from 150 km altitude to the surface. They were found to match the properties of 'tholins', materials created in laboratories by sending electrical discharges into mixtures of nitrogen and methane.

The aerosols' optical properties can be reproduced by the condensation of hydrogen cyanide close to 80 km, ethane condensation close to the tropopause (44 km), and methane condensation from the tropopause down to 8 km.

8. Dry River Beds and Lakes

Hidden beneath an all-embracing blanket of haze, Titan's surface remained a mystery until the DISR on ESA's Huygens probe sent back a series of unique, spectacular images.

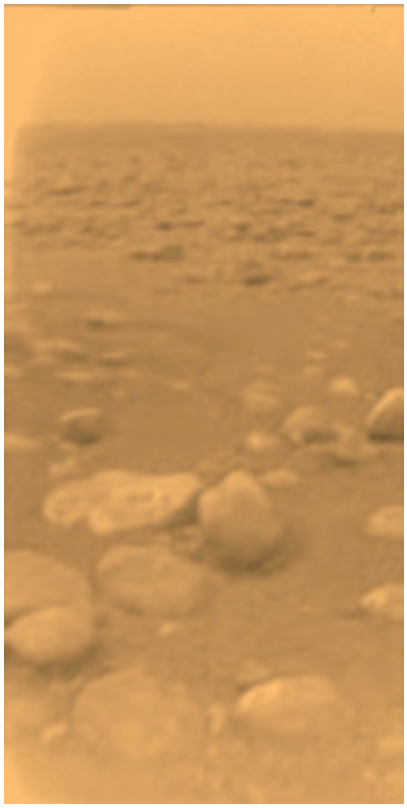

Figure HUYGENS-8. Titan's surface viewed by DISR. Credit: ESA/NASA/JPL/ University of Arizona.

The DISR took several hundred visible-light images with its three cameras during its 2 hour 27 minute descent, including several sets of stereo image pairs which enabled scientists to construct digital terrain models. See Huygens's descent to Titan's surface [ESA 2015] for further details and enhanced video.

The cameras revealed a plateau with a large number of dark channels cut into it, forming drainage networks which bore many similarities to those on Earth. The narrow channels converged into broad rivers, which drained into a broad, dark, lowland region. The ravines cut by the rivers were approximately 100 m deep and their valley slopes were very steep, which suggested rapid erosion due to sudden, violent flows.

No evidence of surface liquid was found at the time of the landing. However, it seems likely that, from time to time, the entire dark region is inundated by floods of liquid methane and ethane. If the darker region is a dry lakebed, it is too large to have been caused by the creeks and channels visible in the images. It may have been created by other larger river systems or some large-scale catastrophic event, which predates deposition by the rivers seen in the images.

Brighter regions north of the landing site displayed two different drainage patterns: 1) bright highlands with rough topography and deeply incised branching (dendritic) drainage networks with dark-floored valleys that indicated erosion by methane rainfall; and 2) short, stubby channels that followed linear fault patterns, forming canyon-like features suggestive of spring sapping by liquid methane.

The topographic data showed that the bright highland terrains are extremely rugged, often with slopes of up to 30 degrees. These drain into relatively flat, dark lowland terrains. The dark material that covers the plains may have been carried along by the flows and could be made up of photochemical deposits rained down from above.

The landing site itself resembled a dried-up riverbed. Rounded cobbles, 10 cm to 15 cm in diameter and probably made of hydrocarbons and water ice, rested on a darker granular surface.

9. Schumann-like Resonances: Hints of a Subsurface Ocean

One of the most surprising discoveries of ESA's Huygens Mission was the detection of an unusual source of electrical excitation in Titan's atmosphere.

Scientists had wondered whether lightning might be generated in Titan's atmosphere, so Huygens was equipped with the permittivity, wave and altimetry (PWA) experiment to detect tell-tale radio signals.

On Earth, thousands of lightning flashes take place every second, and each bolt generates a radio 'crackle'. This means our atmosphere is continuously generating extremely low frequency (ELF) radio signals, known as Schumann resonances. These global electro-magnetic resonances, excited by lightning discharges, occur in the 'cavity' formed between Earth's surface and the ionosphere—a region of electrically charged particles in Earth's upper atmosphere.

Such a resonance is known only on Earth for being released by storm lightning and it had long been considered that its existence on other planets would make it possible to reveal the presence of both storm activity and a conductive ground.

Although no lightning or thunderstorms were detected in Titan's atmosphere, the PWA did detect an unusual ELF signal at a frequency of around 36 Hertz. Huygens also discovered a lower ionospheric layer between 140 km and 40 km, with electrical conductivity peaking near 60 km.

In order to explain the unique pattern of signals, scientists have proposed that Titan's atmosphere behaves like a giant electrical circuit. The electrical currents are generated in the ionosphere when it interacts with Saturn's magnetosphere. This results in a dynamo effect as plasma trapped in the magnetosphere co-rotates with the planet every 10 hours or so.

The lower boundary of Titan's 'cavity', which reflects the radio signals, is thought to be a conductive ocean of water and ammonia which is buried at a depth of 55–80 km below a non-conducting, icy crust.

Huygens' discovery of this unique Schumann resonance is seen as key supporting evidence for the existence of such a subsurface ocean, hidden far beneath the moon's frozen surface.

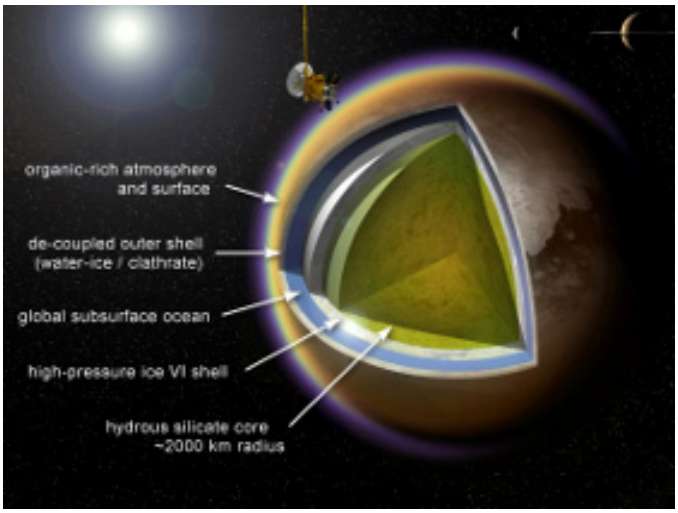

Figure HUYGENS-9. This artist's impression of a possible model for Titan's interior includes a global subsurface ocean. Credit: A. D. Fortes/UCL/STFC.

10. Elusive Dunes

To their surprise, scientists found that locating the Huygens landing site on images taken by the Cassini orbiter was much more difficult than expected.

Although the side-looking imager (SLI), part of the DISR on board ESA's Huygens probe, was able to image surface features located up to 450 km from the Huygens landing site, the images it sent back were hard to match with the synthetic aperture radar (SAR) images obtained by the Cassini orbiter. See Huygens's descent to Titan's surface [ESA 2015] for further details and enhanced video.

The area around the Huygens landing site turned out to be a huge plain of dirty water ice over which lay blankets of organic (carbon-bearing) deposits. These mantles of aerosol were invisible to radar waves, so Cassini SAR images only revealed the underlying water ice. As a result, the boundary between the bright highlands and dark plains that Huygens drifted over simply did not show up in the radar images.

The location of the landing site was only tied down after some time by the detection of two dark, longitudinal "sand" dunes, about 30 km north of the landing site. The elusive landforms were visible in both the SAR and Huygens images. Although dark, longitudinal dunes form vast "sand seas" throughout Titan's optically dark equatorial regions, Huygens descended over a region of bright and dark units that was free of the pervasive dune fields found elsewhere.

The dunes on Titan are probably composed of sand-sized hydrocarbon and/or nitrile grains mixed with lesser amounts of water ice. The particles rained down from above onto the surface and were subsequently eroded and moved by surface and aeolian processes, such as liquid methane runoff and wind erosion.

In order for the sand to migrate across the surface under the influence of Titan's weak surface winds, a process called saltation, scientists have concluded that the dune material must be between 100 microns and 300 microns in diameter.

ICY SATELLITES

The Voyager and Pioneer flybys of the 1970s and 1980s provided incomplete views of Saturn's moons. However, during its many years in Saturn orbit, Cassini discovered previously unknown moons, solved mysteries about known ones, studied their interactions with the rings and revealed how sharply different the moons are from one another. Saturn's moons range in size from about a third of a kilometer in size to larger than the planet Mercury, and they vary in color, texture and composition, and internal structure. Cassini data has also hinted at a possibly young age for several of the innermost icy moons.

For decades, scientists did not know why Enceladus was the brightest world in the solar system, or how it related to Saturn's E-ring. Cassini found that both the fresh coating on its surface, and icy material in the E-ring originate from vents connected to a global subsurface saltwater ocean that might host hydrothermal vents and complex organics.

The **Icy Satellites** Working Group (ISWG) working with the Satellites Orbiter Science Team (SOST) coordinated and implemented the icy satellite observation planning and detailed scheduling for the many icy satellite flybys throughout the mission, including 23 close Enceladus flybys, to ensure that Cassini icy satellite objectives were met. The ISWG Discipline Working Group (DWG) has achieved their Cassini mission objectives and has provided the first extended, comprehensive view of the moons of Saturn.

Executive Summary

The Cassini-Huygens mission offered the first extended, comprehensive view of the moons of Saturn. There are existing and upcoming review books and papers that summarize the results from the Cassini mission; as is the case with so many previous missions, major questions remain even after more than a dozen years of exploration [Buratti et al. 2017]. The questions appropriate to the icy satellite discipline that were proposed at the onset of the mission were far-reaching science goals that provided the driving force behind the mission are listed in the section entitled Key Objectives for Icy Satellites DWG, and summarized in Spilker [1997]. As the section entitled Icy Satellites Science Assessment shows, most mission objectives were fully met with only two (not including two objectives associated with asteroid science) partially met. The asteroid flyby investigations were lacking because the spacecraft trajectory did not bring Cassini sufficiently close to an object in the Main Belt.

> … far-reaching science goals provided the driving force behind the mission …

Key Objectives for Icy Satellites DWG

Icy Satellites AO Objectives

- **Icy Satellite Geology and History (I_AO1)** – Determine the general characteristics and geological histories of the satellites.
- **Icy Satellite Surface and Crustal Modifications (I_AO2)** – Define the mechanisms of crustal and surface modifications, both external and internal.
- **Icy Satellite Surface Composition (I_AO3)** – Investigate the compositions and distributions of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles.
- **Icy Satellite Interior Properties (I_AO4)** – Constrain models of the satellites' bulk compositions and internal structures.
- **Icy Satellite Magnetosphere and Ring Interactions (I_AO5)** – Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.

Icy Satellites CSM Traceability Matrix Objectives

- **Enceladus Seasonal Changes (IC1a)** – Identify long-term secular and seasonal changes at Enceladus through observations of the south polar region, jets, and plumes, and through analysis of heat production.

- **Enceladus Ocean (IN1a)** – Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.
- **Mid-sized Satellites (IN1b)** – Complete the comparative study of Saturn's mid-sized satellites, their geological and cratering histories, and interactions with the Saturn system, with remote sensing of Mimas at the highest resolution possible in order to understand the mechanisms behind its unique thermal properties discovered by Cassini. Understand if other moons exhibit similar thermal properties.
- **Dione (IN1c)** – Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.
- **Rhea (IN2a)** – Determine whether there is ring material orbiting Rhea, and if so, what its spatial and particle size distribution is. Understand the origin of blue pearls discovered on its surface.
- **Tethys (IN2b)** – Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population. Understand the nature of mysterious red streaks discovered on its surface.
- **Satellite Interiors (IN2c)** – Determine the extent of differentiation and internal inhomogeneity within the icy satellites, especially Rhea and Dione. Determine whether Dione has a subsurface ocean.
- **Small Moons (IN2d)** – Observe selected small satellites to quantify the movement of Enceladus material through the system, the history of satellite collisions/breakup, interaction with ring material as indicated by surface properties/composition, and cratering rates deep in the Saturnian system. Understand the composition of these moons and how it relates to kindred bodies in the Saturnian system and beyond.
- **Hyperion (IN2e)** – Understand the unusual appearance of Hyperion with remote sensing observations of the highest resolution possible.
- **Iapetus (IN2f)** – Use remote sensing of Iapetus to test models for the albedo heterogeneity of the satellite. Quantify the effect of the newly-discovered Phoebe ring on the properties of Iapetus' surface.

Jupiter Flyby AO Objectives

- **Jupiter and Satellite Studies (J_AO1)** – Extend the time for studies of atmospheric dynamics and variable satellite phenomena, specifically Io volcanism, beyond the period accessible to the Galileo nominal mission.

Asteroid Flyby AO Objectives

- **Asteroid Flyby Investigation (A_AO1)** – Investigate an asteroid not seen by previous missions, possibly a new class of asteroid, thereby adding important new information to the study of asteroid
- **Asteroid Global Characteristics (A_AO2)** – Characterize global properties, determine composition and morphology of the surface, investigate properties of the regolith.

Icy Satellites Science Assessment

All these objectives have been answered to a large degree (see Table IcySats-1), and specific results can be expressed by this top twenty list of discoveries:

- Discovery of Enceladus jets, their coincidence with small-scale hot spots, the plume they form, and its impact on the Saturnian system.
- Evidence of hydrothermal chemistry and discovery of a strong thermal anomaly on Enceladus.
- Detection of global oceans beneath Enceladus's, and possibly Dione's and Mimas's icy crusts.
- Plume structure connection to both individual jets and curtains along tiger stripes.
- Plume strength modulation by tidal forces and stochastic on/off timing of individual jets.
- The plume of Enceladus as the source of the E-ring of Saturn.
- Detection of plume composition: water (vapor and micron-sized grains), salt, organics, nanograin dust, hydrogen, and ammonia.
- Discovery of supersonic motion in the jets.
- Evidence for subdued ongoing or recently extinguished activity on Dione.
- Red streaks on Tethys signifying potential outgassing along fractures.
- Accretion disks on the ring moons showing they continue to add particles from the main ring system to their bodies.
- Low densities of the small moons.
- Discovery of a globe-girdling equatorial ridge on Iapetus, perhaps akin to those seen on the ring moons.
- Thermal segregation and Phoebe ring particle infall as the cause of the bright/dark dichotomy on Iapetus, first discovered by the astronomer Cassini in 1677.
- Likely formation of Phoebe in the Kuiper Belt.

- The discovery that the high reflectance and albedo/color patterns of the Saturnian inner moons is primarily due to exchange of material between rings and moons specific to the Saturnian system. This includes the accumulation of E-ring particles and subsequent alteration by high-energy elections to produce Pac-Man.
- Discovery of organics and carbon dioxide (and possibly ammonia) on the outer moons. Evidence for iron oxides and space-weathered silicates on the surfaces of Phoebe and Iapetus.
- Wispy streaks on Dione and Rhea are actually fracture systems.
- Evidence for past rings around moons, such as blue pearls on Rhea, and possibly the ridge of Iapetus.
- Evidence that outer irregular moons are low density and slow rotators based on light curve surveys.

It was known before the Cassini mission that the main constituent of the surfaces of the moons is crystalline water ice. CO_2 is present on the surface of most of the moons [Buratti et al. 2005; Brown et al. 2006; Clark et al. 2012, 2008, 2005; Cruikshank et al. 2010], but there are still spectral identifications that are uncertain. Clark et al. [2012] showed that a weak feature at 2.42 μm is due to trapped molecular hydrogen and is observed in dark material on multiple icy satellites, but this feature needs confirmation by an independent instrument. A weak absorption at 2.97 μm corresponds to ammonia [Clark et al. 2012, 2008] and is seen on multiple icy satellites, but the absorption overlaps an order-sorting filter gap in the VIMS instrument where instrument errors are larger. Observations of ammonia need confirmation either by a better calibration of the VIMS data, or by other instruments.

An up-to-date table of the physical and dynamical properties of all the Saturnian moons is given at https://ssd.jpl.nasa.gov/?sat_elem and at https://ssd.jpl.nasa.gov/?phys_data.

The results of the mission can be summarized by Table IcySats-1. The colors refer to the data gathered and the expected results to be obtained by ongoing analyses. Green means the objective was fully met; yellow means it was partially met by the best estimate; and red means it was not met. Note that this assessment is based on whether sufficient data was collected, not on the status of the ongoing analysis and modeling of the data. The first five goals were set out in the mission Announcement of Opportunity, while subsequent goals in the table followed up in Cassini's extended mission on major discoveries. Text below primarily addresses the achievement of the extended mission goals.

IN1b		
Dione (IN1c) – Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.	IN1c		Extensive data were gathered, but the results are still ambiguous. No current activity was detected.
Rhea (IN2a) – Determine whether there is ring material orbiting Rhea, and if so, what its spatial and particle size distribution is.	IN2a		

Table IcySats-1. Assessment of Mission Goals.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

Icy Satellite Science Objectives	AO and TM Science Objectives	Icy Satellite Science Assessment	Comments
Tethys (IN2b) – Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population.	IN2b		From a CDA/icy dust perspective, it is red because during the solstice mission there were no close Tethys flybys to measure potential ejecta [Kempf et al. 2010]. For MAPS as a whole, enough data was obtained to determine that Tethys does not contribute to the E-ring and magnetospheric ion and neutral population [Burch et al. 2007; Khurana et al. 2008].
Satellite Interiors (IN2c) – Determine the extent of differentiation and internal inhomogeneity within the icy satellites, especially Rhea and Dione.	IN2c		
Small Moons (IN2d) – Observe selected small satellites to quantify the movement of Enceladus material through the system, the history of satellite collisions/breakup, interaction with ring material as indicated by surface properties/composition, and cratering rates deep in the Saturnian system.	IN2d		
Hyperion (IN2e) – Understand the unusual appearance of Hyperion with remote sensing observations of the highest resolution possible.	IN2e		
Iapetus (IN2f) – Use remote sensing of Iapetus to test models for the albedo heterogeneity of the satellite. Quantify the effect of the newly-discovered Phoebe ring on the properties of Iapetus' surface.	IN2f		
Jupiter and Satellite Studies (J_AO1) – Extend the time for studies of atmospheric dynamics and variable satellite phenomena, specifically Io volcanism, beyond the period accessible to the Galileo nominal mission.	J_AO1		
Asteroid Flyby Investigation (A_AO1) – Investigate an asteroid not seen by previous missions, possibly a new class of asteroid, thereby adding important new information to the study of asteroid	A_AO1		This objective was present for the case where Cassini would have flown close to an asteroid. No asteroid was found to be nearby.
Asteroid Global Characteristics (A_AO2) – Characterize global properties, determine composition and morphology of the surface, investigate properties of the regolith.	A_AO2		This objective was present for the case where Cassini would have flown close to an asteroid. No asteroid was found to be nearby.

ICY SATELLITES DWG SYSTEM RESULTS

Enceladus Seasonal Changes (IC1a)

Enceladus eruptions are mostly water vapor, with a variable amounts of micron-sized ice grains [Porco et al. 2017, 2006; Hedman et al. 2018]. There are ~100 discrete jets and faint sheets of icy particles fountaining from the four tiger stripe fissures across Enceladus' south polar region [Porco et al. 2014; Spitale et al. 2015; Teolis et al. 2017].

The brightness, and hence mass, of the plume created by the particle jets varies diurnally, most likely due to the cycling of tidal extensional/compressional stresses across the south polar terrain [Hedman et al. 2013; Nimmo et al. 2014]. A phase lag of ~45 deg (or ~4.5 hours), compared to the ice-shell response predicted by simple tidal models for an elastic ice shell, is present though its origin is not clear [Nimmo et al. 2014]. Notable is the observation that the plume never goes to zero strength, as seen in particles [Nimmo et al. 2014] as well as vapor [Hansen et al. 2017]. Individual geysers were observed to be time variable, turning on and/or off on timescales that were not comparable to the diurnal cycling of stresses [Porco et al. 2014; Teolis et al. 2017]. This was taken as an indication that condensation of ice in the vents leads to the stochastic clogging of the vents and consequently the shutoff of geysers, but averaged across the SPT, the plume is continuous in time if variable in strength. The estimated timescale for the clogging process is months to a couple of years [Porco et al. 2014, 2006].

Behounkova et al. [2015], in a 3-D numerical model of the viscoelastic tidal response of the ice shell, showed the diurnal brightness variation is best described by the cycling of the normal stresses across the fractures averaged over the SPT. They proposed that the delay in eruption activity may be a natural consequence of the viscosity structure in the south polar region and the size of the putative subsurface ocean, but there are alternate suggestions [Kite and Rubin 2016].

One hot spot was identified on Enceladus with radar observations [Le Gall et al. 2017]. VIMS data were able to place constraints on the size and temperature of one opening, just 9 m wide [Goguen et al. 2013]. VIMS observations of hot spots [Goguen et al. 2013] were used in conjunction with Imaging Science Subsystem (ISS) observations to show that individual jets are spatially coincident with the small-scale (~10 s meters) hot spots [Porco et al. 2014], a result that indicates the heat emerging from the fractures is largely that due to the latent heat of condensation of vapor in the near-surface portion of the vents, and not due to shear heating, and is consistent with a deep source of the eruptive materials.

An analysis of ISS observations of the plume from 2005–2015 suggested there may be seasonal changes in the plumes' brightness.

An analysis of ISS observations of the plume from 2005–2015 suggested there may be seasonal changes in the plumes' brightness [Ingersoll and Ewald 2017] (Figure ICYSATS-1). However, a later analysis of the full suite of Cassini ISS plume observations through the end of the

mission (August 2017) has shown that the long-timescale variations in the plume's brightness are most likely due to two periods (4-year and 11-year) both associated with the Dione-Enceladus 2:1 orbital resonance that also cause the cycling of tidal stresses across the moon's surface [Porco et al. 2018].

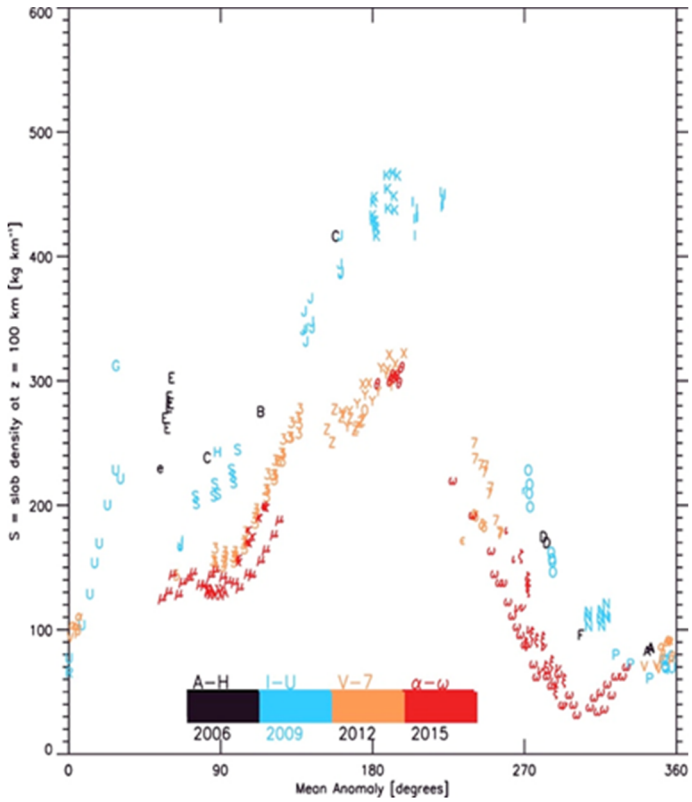

Figure ICYSATS-1. A figure of plume brightness from 2006 through 2015 showing year-to-year changes in the amplitude of the diurnal variations with mean anomaly, including a substantial decrease toward the end of the mission. Figure from Ingersoll and Ewald [2017].

Composite Infrared Spectrometer (CIRS) also carried out a significant investigation on the variability of heat in the tiger stripe region throughout the mission on various time scales, with special focus on this problem at the end of the mission [Howett et al. 2017]. CIRS observations of Enceladus' active south polar region during Cassini's F-ring and Proximal Orbits (FRPO) were designed to investigate whether Enceladus' surface temperatures also vary with time. Preliminary results indicate that Enceladus' surface temperatures vary with mean anomaly, but lag in time behind the plume brightness change. The total heat flux varied by about a factor of two with mean anomaly. A detailed measurement of the heat flux between revs 61 and 91 showed no significant change. Work is continuing in this area, as different analysis techniques give substantially different results for the heat flux (details are in the CIRS Science Results).

A series of Ultraviolet Imaging Spectrograph (UVIS) stellar and solar occulations were spectacularly successful for studying the composition and structure of Enceladus' plume [Hansen et al. 2011, 2008, 2006]. Unlike ISS and CIRS, UVIS detected no significant variations in the

amount of water vapor as seen over the course of the mission, although the strongest jets, which lift the most icy grains, are more variable [Hansen et al. 2017].

Enceladus Ocean (IN1a)

Though the presence of liquid water within the conduits leading to the south polar surface, and then later the proposal that there was liquid water under the ice shell, were suggested early in the mission [Porco et al. 2006; Collins and Goodman 2007; Postberg et al. 2009], the first detection of this long-suspected body of liquid water beneath the moon's crust came from radio science data that showed Enceladus' gravity field combined with topography was consistent with a regional sea beneath Enceladus' south pole, though a global ocean could not be ruled out [Iess et al. 2014]. Subsequent, careful analysis of the rotational motion of Enceladus revealed a libration indicating the ice shell is decoupled from the core and the subsurface liquid ocean is global, as shown in Figure ICYSATS-2 [Thomas et al. 2015]. Figure ICYSATS-2 is a Cassini nugget summarizing our knowledge of the Enceladan Ocean.

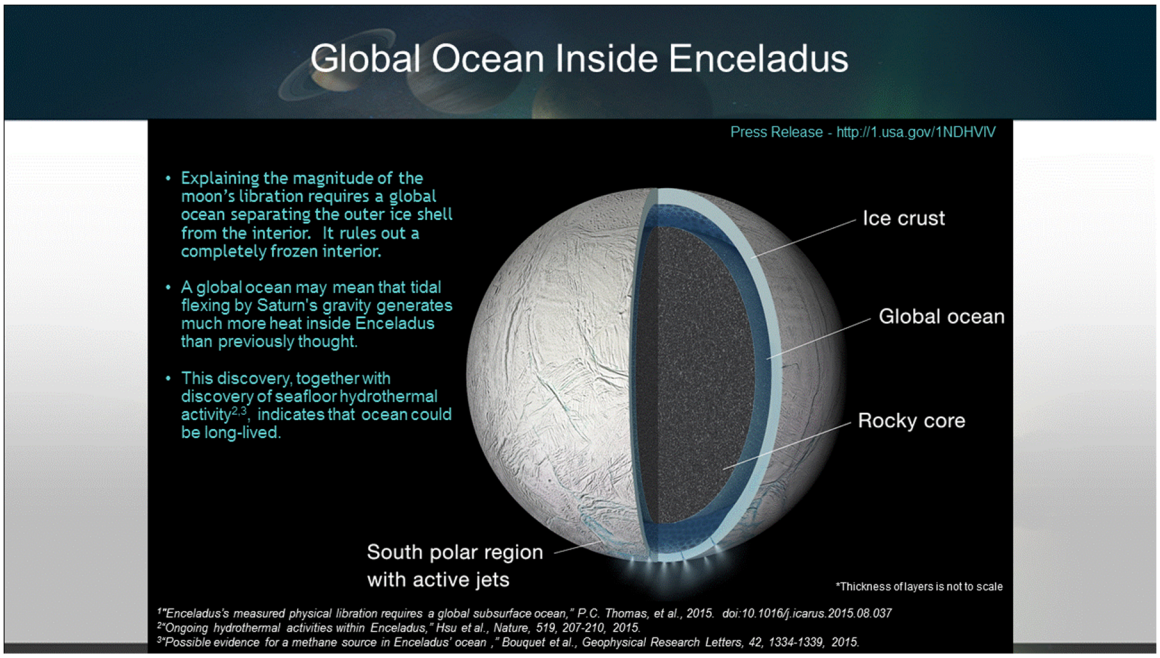

Figure ICYSATS-2. A NASA Nugget summarizing our knowledge of the ocean of Enceladus at the end of the mission.

Cassini's dust analyzer (CDA) determined the particle size and compositional profile for the water ice particles expelled from the tiger stripe fissures [Postberg et al. 2011]. Grain sizes are stratified: the smallest pure-ice particles (< 0.4 micron) condense from gas in the plume, reach escape velocity and go into orbit around Saturn, forming the E-ring. These tiny particles are likely lofted by the supersonic gas jets detected by UVIS [Hansen et al. 2011]. Larger salt-rich particles come from liquid water and may originate as a frozen aerosol spray, which is then carried by the

escaping gas to the surface. These larger grains separate from the gas, fall back to the surface and modify Enceladus' color [Schenk 2014; Postberg et al. 2017].

Observational constraints are necessary to develop models of the nature of the plumbing from the subsurface body of water to the nozzles carrying gas and particles to the surface [Teolis et al. 2017]. Several concepts for the nature of the plumbing that connects the subsurface liquid reservoir to the escaping gas and particles have been proposed. An early idea was a Perrier ocean powered by escaping CO_2: as seawater nears the surface pressure decreases, the dissolved gases come out of solution and bubbles form [Matson et al. 2012]. Another hypothesis is that the gas is accelerated as it goes through nozzle-like channels from the ocean to the surface [Schmidt et al. 2009; Yeoh 2017]. Yet another idea is that water coming up from the ocean separates the solid edges of the fissures and that tidal stresses partially open and close the fissures, keeping the water from freezing [Kite and Rubin 2016].

CDA detected silica nano-particles, confirming that the liquid layer is in contact with the rocky core.

CDA detected silica nano-particles, confirming that the liquid layer is in contact with the rocky core [Hsu et al. 2015]. Very hot water (194° F) is required for these particles to form, suggesting that Enceladus has hydrothermal vents on its seafloor. Furthermore, the abundance of methane gas in the plume can only happen if there are hydrothermal vents preventing the methane from being captured in the icy walls confining the ocean [Bouquet et al. 2015].

What is the pH of Enceladus' ocean? Values reported range from 8 [Hsu et al. 2015] to 12 [Glein et al. 2015], however the most likely range is 9–11 [Waite et al. 2017].

Another important result is provided by the Ion and Neutral Mass Spectrometer (INMS) detection of H_2. The process that likely provides the H_2, serpentinization of rock, could provide the chemical energy required for life [Waite et al. 2017]. Cassini's investigations have shown that Enceladus' ocean is a habitable environment.

Mid-sized Satellites (IN1b)

The mid-sized bodies of Saturn proved to be a collection of unique bodies, ranging from Phoebe, a heavily cratered, relatively dense moon that is probably a captured Kuiper Belt object (KBO) [Johnson and Lunine 2005a] to less dense moons that may have some type of ongoing activity. The optical properties of the surfaces of these moons are largely determined by interactions with rings and high-energy particles. Accurate values for fundamental whole-body physical properties of the moons were obtained. These include mean radii, densities, and shapes—for example, Thomas [2010]; Thomas et al. [2018]; Castillo-Rogez et al. [2018]—and also photometric quantities such as geometric albedo, the phase integral, or Hapke photometric model parameters [Pitman et al. 2013; Verbiscer et al. 2018].

The sizes and shapes of the six mid-sized icy satellites were measured from ISS data. Mimas, Enceladus, Tethys, Dione, and Rhea are well described by triaxial ellipsoids; Iapetus is best represented by an oblate spheroid [Thomas et al. 2007]. Impact craters dominate the surfaces and provide the primary means of estimating terrain ages as well as many other properties of the surfaces [Dones et al. 2009; Kirchoff and Schenk 2010; Schenk et al. 2018; Kirchoff et al. 2018].

None of the unusual crater landforms (such as multi-ring basins or shallow distorted craters on the Galilean moons) seen on icy worlds that have confirmed internal oceans are seen on the mid-sized moons. However, this finding does not preclude possible oceans [Schenk et al. 2018]. Global mapping has revealed geologically complex worlds. All (except perhaps Iapetus) have been tectonically deformed to different degrees. Almost all tectonic landforms are interpreted as extensional structures [Schenk et al. 2018].

All of the icy Saturnian moons are absorbing in the ~0.2–0.5 μm region, making them dark at FUV wavelengths.

The trailing sides of Tethys and Dione, and to a lesser degree of Rhea, are darker than the respective leading sides. This is due to E-ring material infalling preferentially on the leading sides and has originally been discovered in Voyager data [Buratti et al. 1990]. The colors of the trailing sides are also redder than the leading sides of these moons.

All of the icy Saturnian moons are absorbing in the ~0.2–0.5 μm region, making them dark at far ultraviolet (FUV) wavelengths. For instance, Filacchione et al. [2016, 2012] used Cassini VIMS data to show that the spectral slope (0.35–0.55 μm) increases (becomes redder) with distance from Enceladus. While the ultraviolet (UV) absorber causes reddening, sub-micron grains induce increased scattering, causing a bluing effect, so there are competing signatures of these two components throughout the Saturn system.

Deuterium has been found on Phoebe, Iapetus, Hyperion, Rhea, Dione, Enceladus, and the Rings, and carbon 13 has been detected on Phoebe and Iapetus [Clark et al. 2019, 2017a, 2017b, 2016a, 2016b], and the deuterium to hydrogen (D/H) ratio derived. Phoebe is an outlier with D/H more than eight times higher than terrestrial, which the other satellites and rings are close to terrestrial ocean water values, an unexpected result not predicted by current models of solar system formation.

Infrared (IR) spectroscopy is sensitive to grain size of materials, and the multiple absorption in ice allows grain size mapping to be done with VIMS data. On Enceladus, the sizes of ice particles are generally well correlated with geologic features and surface ages, indicating a stratigraphic correlation between tectonic features and cryovolcanic activities [Jaumann et al. 2008]. Grains much smaller than the wavelength of light cause enhanced blue scattering, including a Rayleigh scattering effect. This bluing effect is observed in the Saturn system and quantified by Clark et al. [2012, 2008].

Scipioni et al. [2017] produced image cube maps of Enceladus, and mapped ice grain sizes and identified plume deposits across the surface. The map of the band-depth ratio 1.50/2.02 μm overall shows good agreement with the predicted plumes' deposits on the trailing side, where the amount of sub-micron particles decreases with increasing accumulation of ejecta material. However, this correlation is much weaker, or even absent, on the leading side of Enceladus, where the abundance of sub-micron particles is the highest across the entire surface.

Stephan et al. [2012] showed that the distribution of spectral endmembers as well as global band depth variations of Dione's water ice absorptions measurements imply that the bombardment with charged particles from Saturn's magnetosphere is one of at least two major global processes affecting Dione's surface. Ice deposits dominating its leading hemisphere appear rather associated with rays of the fresh impact crater Creusa on the northern leading hemisphere. These rays cross almost the whole hemisphere masking here any effects of possibly existent but less dominant processes as evident in the transition from the bright to dark regions on the Saturn-facing hemisphere (~0° W). CO_2 is evident in the dark material pointing to a possible formation due to the interaction of the surface material with the impacting particles from Saturn's magnetosphere. Local spectral differences are consistent with impacting particles from the trailing side as described by Clark et al. [2008] with a pronounced ice signature on crater walls facing the leading side direction and shielded from impacting particles and dark material concentrated on interior crater walls facing the trailing hemisphere.

Spectra of ice also varies with temperature, so the surface temperatures of cold icy surfaces can be sensed without needing to measure longer wavelength thermal emission. Filacchione et al. [2016] analyzed the ice spectral to produce daytime temperature maps of the satellite surfaces. Just one more indication of the diversity of science that an imaging spectrometer can provide.

Cassini radar tracks on Saturn's icy satellites through the end of the Prime Mission increased the number of radar albedo estimates to 73.

Cassini radar tracks on Saturn's icy satellites through the end of the Prime Mission increased the number of radar albedo estimates to 73 [Ostro et al. 2010]. The measurements sample diverse subradar locations (and for Dione, Rhea, and Iapetus, almost always use beamwidths less than half the target angular diameters), thereby constraining the satellites' global radar albedo distributions. The echoes result predominantly from volume scattering, and their strength is thus strongly sensitive to ice purity and regolith maturity. The combination of the Cassini data set and Arecibo 13-cm observations of Enceladus, Tethys, Dione, Rhea [Black et al. 2007], and Iapetus [Black et al. 2004] discloses an unexpectedly complex pattern of 13 cm to 2 cm wavelength dependence. The 13-cm albedos are generally smaller than 2-cm albedos and lack the correlation seen between 2 cm and optical geometric albedos. Enceladus and Iapetus are the most interesting cases. The E-ring has a prominent effect on the 13-cm radar lightcurve. The uppermost trailing-side regolith is too fresh for meteoroid bombardment to have developed larger-scale heterogeneities that would be necessary to elevate the 13-cm radar albedo, whereas all of Enceladus is clean and mature enough for the 2-cm albedo to be uniformly high. For, Iapetus, the

2-cm albedo is strongly correlated with optical albedo: low for the optically dark, leading-side material and high for the optically bright, trailing-side material. However, Iapetus' 13-cm albedo values show no significant albedo dichotomy and are several times lower than 2-cm values, being indistinguishable from the weighted mean of 13-cm albedos for main-belt asteroids, 0.15 ±0.10.

A series of UVIS stellar and solar occulations were designed at a wide range of latitudes and longitudes to search for thin atmospheres and plumes indicating possible activity.

The leading side's optically dark contaminant must be present to depths of at least one to several decimeters. A more detailed review of Cassini Radar observations of the icy moons of Saturn is detailed in the RADAR Instrument Science Results.

A series of UVIS stellar and solar occulations were designed at a wide range of latitudes and longitudes to search for thin atmospheres and plumes indicating possible activity. (The Planetary Data System (PDS) includes a list of these occultations.) This technique was spectacularly successful for Enceladus [Hansen et al. 2006]. Searches at Tethys, Iapetus, Rhea, and Dione showed no detectable atmosphere [Hansen et al. 2018].

Under the leadership of the inimitable Amanda Hendrix, UVIS set a gallant lead in obtaining full longitudinal and phase angle coverage of the icy satellites during the long mission, with CIRS, VIMS, and ISS benefitting from ride-a-long observations. The strong UV water absorption band is diagnostic of water ice, a major component of all the icy surfaces. This allows significant constraints on the surface composition and the processes that control the evolution of their surfaces [Hendrix and Hansen 2010, 2008; Hendrix et al. 2018, 2017, 2012; Royer and Hendrix 2014].

Substantial effort was expended on understanding the thermal properties of the medium-sized moons. Observations returned by CIRS and ISS showed a thermal and color anomaly at low latitudes on Mimas and Tethys' leading hemisphere, dubbed Pac-Man, because its shape mimics that of the 1980s' video icon (Figure ICYSATS-3). Pac-Man display warmer nighttime and cooler daytime temperatures than its surroundings and appears darker in IR/UV color ratio maps [Howett et al. 2012, 2011; Schenk et al. 2011]. The color and thermal anomalies are believed to be the result of surface alteration by high-energy electrons, which preferentially bombard this region, altering its surface and increasing its thermal inertia. These high-energy electrons, in Saturn's magnetosphere, drift in a retrograde direction relative to corotation. Recent modeling efforts, supported by the Low Energy Magnetospheric Measurement System (LEMMS) on Cassini's Magnetospheric Imaging Instrument (MIMI), have shown that these electrons preferentially bombard low latitudes on Mimas, Tethys, and Dione's leading hemisphere [Paranicas et al. 2014, 2012; Howett et al. 2011; Schenk et al. 2011]. The thermal anomaly is closely correlated spatially with an IR/UV (0.930/0.338 lm) color ratio anomaly previously observed in global maps of Mimas using Cassini ISS data.

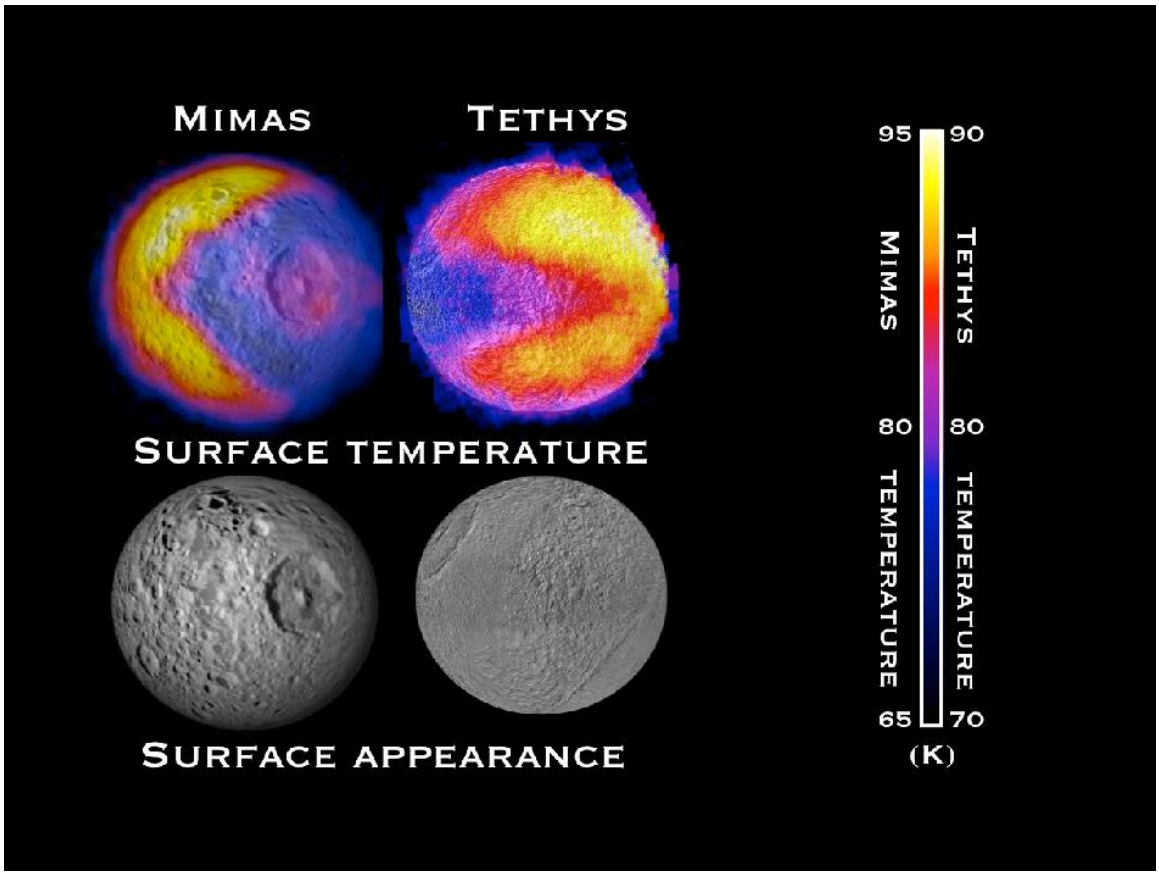

Figure ICYSATS-3. Pac-Man on Mimas and Tethys.

CIRS also measured the bolometric Bond albedo, the thermal inertia, and skindepths of the moons, which are summarized in Table ICYSATS-2 [Howett et al. 2010]. The thermal inertia of all of Saturn's icy satellites is shown to be less than half that of the Galilean satellites, implying less consolidated and more porous surfaces, perhaps partially due to the limited mobility of water ice on the Saturnian satellites due to their low temperatures compared with the Galilean satellites, or to a surface coating of E-ring particles. The latitudinal variation in the thermal inertia of Enceladus implies the surface becomes more consolidated towards the southern pole, whereas the higher albedo in the southern hemisphere implies a cleaner surface, perhaps due to plume fallout. Further work investigating the hemispheric bolometric Bond albedo asymmetries of Dione would be valuable, as although the globally averaged values derived here provide a good fit to the CIRS data, observations of viable wavelength have observed notable differences between the leading and trailing hemispheres [Buratti and Veverka 1984].

In September 2011 (during Cassini's orbit 153), CIRS obtained a daytime medium-spatial resolution observation (the average resolution was 84 km/pixel) of Tethys' leading hemisphere [Howett et al. 2012]. The results clearly show that a thermally anomalous Pac-Man region exists on Tethys' leading hemisphere at low latitudes in both the daytime and nighttime temperatures. The region appears to be ~10 K cooler during the day and ~10 K warmer at night than its

surroundings, quite unlike the pattern expected if surface properties were spatially uniform. The largest thermal contrast occurs at the northern anomaly boundary, particularly towards the east. The thermally anomalous region is lens-shaped with apexes at 0° W and 180° W, and is widest in the center of the leading hemisphere (90° W) reaching latitude ±20°. This anomalous region spatially coincides with a dark (low) albedo region at low latitudes on Tethys' leading hemisphere was first observed in Voyager data [Buratti and Veverka 1984; Buratti et al. 1990; Stooke 2002, 1989]. Photometry applied to Cassini ISS images showed the band to be 2–3% brighter in the narrow angle camera (NAC) CL1-UV3 filter (338 nm) and 8% darker in the NAC CL1-IR3 (930 nm) filter [Elder et al. 2007].

A Pac-Man thermal anomaly was also detected on Mimas [Howett et al. 2011]. It is closely correlated spatially with an IR/UV (0.930/0.338 lm) color ratio anomaly previously observed in global maps of Mimas using Cassini ISS data. The boundaries of the thermal and color anomalies appear to be nearly identical, although the apex of the thermal anomaly appears sharper.

The maximum electron energy flux bombarding Tethys is nearly six times lower than that on Mimas and is constrained to a smaller latitudinal extent, consistent with the relative amplitude and shape of the thermal anomaly on the two bodies [Paranicas et al. 2012; Schenk et al. 2011]. The discovery of Tethys' thermal anomaly, which has a boundary corresponding to an 18 GeV cm 2 s 1 electron flux (compared to 56 GeV cm 2 s 1 on Mimas), greatly strengthens the case that energetic electrons are able to significantly alter an icy satellite surface, and also proves that the threshold electron energy flux able to do so is lower than previously thought. A lower energy flux threshold increases the probability that such alteration occurs on other satellite surfaces. Why high-energy electron bombardment would decrease the IR/UV surface color ratio and why the thermal anomalous region appears darker in visible light images of Tethys, but not on Mimas, remains a mystery.

Dione (IN1c)

The Cassini spacecraft executed five targeted flybys of Dione, passing as close as 500 km to its surface. Three of the flybys were devoted to gravity analysis, designed to understand the interior state of the moon and whether it harbors a subsurface ocean. Such an ocean was inferred from two separate studies: Beuthe et al. [2016] and Hemingway et al. [2016]. Further evidence for a subsurface ocean on Dione, at least at some point, was provided by a geophysical analysis of the formation of Janiculum Dorsae, a raised feature on Dione's surface. The heat flux required to form this feature is 25–60 mW/m^2, much greater than that expected solely from radioactive decay, but which can be generated by tidal heating in a liquid ocean [Hammond et al. 2013]. The evidence for an ocean provides the backdrop to the many lines of evidence for residual geologic activity on Dione.

Another intriguing result was the detection on December 15, 2004, of a transient aura-like ring around Dione at 2.65 μm that suggested the existence of an atmosphere [Clark et al. 2008]. Magnetometer data obtained on October 11, 2005, show a weak field perturbation in the upstream region, indicating a tenuous atmosphere [Simon et al. 2011]. The signature was not seen on April 7, 2010. Observing with CAPS, Tokar et al. [2012] discovered a thin atmosphere (~0.01–0.09 particles/cm^3) of O_2^+ during the close (500 km) flyby on April 7, 2010. A search for forward scattered radiation at solar phase angles > 150°, indicating a plume, was negative [Buratti et al. 2011]. Perhaps the most compelling evidence is the existence of possible cryovolcanic features on Dione. Figure ICYSATS-4 shows an image that includes linear groves and scarps that may be nascent or fossilized activity. Near the center of the image there is an anomalous crater pair that may be a possible volcanic vent. Furthermore, the surrounding area is smooth and relatively crater-free, as if covered by a volcanic deposit. A nearby rampart crater and evidence for amorphous ice suggesting rapid freezing [Newman et al. 2009] also imply some perhaps localized liquid water, although we have previously noted that inferring the existence of amorphous ice is difficult because of the dearth of laboratory data.

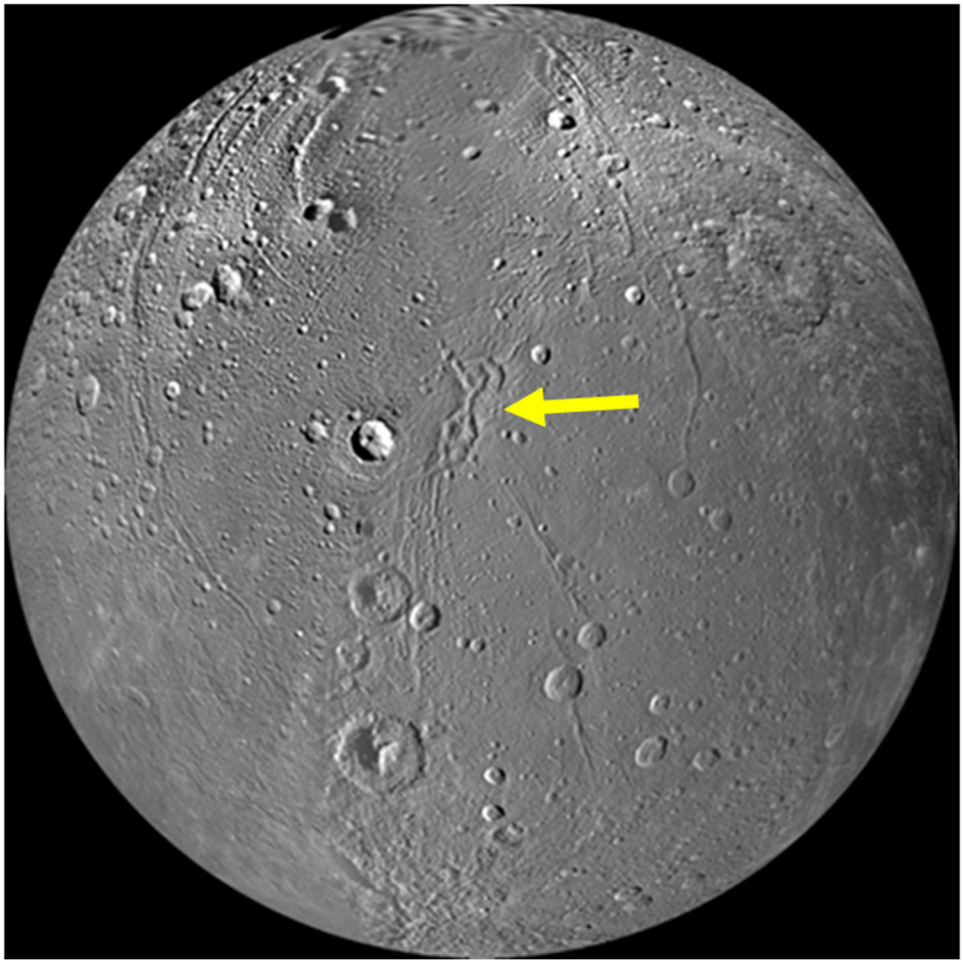

Figure IcySats-4. Possible cryovolcanic features on Dione.

High phase angle observations of Dione and Tethys were sought during the last year of the mission. Analysis of these data failed to detect any evidence for a plume or atmosphere on either body [Hansen et al. 2018; Buratti et al. 2018a]. No thermal signatures were detected either [Schenk et al. 2018]. The atmosphere appears to be transient, as it was seen only one time. Perhaps there is some type of low-level residual activity on Dione that is sporadic in nature. In any case, possible activity on Dione is one of the truly cold cases of the Cassini mission that will be reopened by future missions.

Rhea (IN2a)

The largest of the bright ray craters found in the Saturn system, Inktomi (Ø = 49 km), is a flat-floored crater on Rhea with a ray system radiating several hundred kilometers from the crater rim. It was imaged by ISS in August 2007 in three colors at resolutions up to 32 m/pxl and in stereo. The images are the best for a pristine crater in the Saturnian system and reveal a rugged landscape. Most of the ejecta and floor is essentially free of small craters [Wagner et al. 2011; Schenk et al.

2018]. Many of the tectonic lineaments are normal faults and graben, see for example, Wagner et al. [2010, 2007]. Most of this is concentrated in the trailing hemisphere as two major rift zones (Galunlati and Yasmi Chasmata) that trend roughly northeast–southwest and that are up to 3 km deep. These rifts are morphologically similar to those on Dione.

The blue pearls (bluish spots discovered with ISS in Figure ICYSATS-5) are a series of near-IR dark irregular patches located at the crests of the highest ridges or massifs located along the equator of Rhea. Their origin is speculated to be related to infalling or collapse of a former orbiting debris ring [Schenk et al. 2011]. A dedicated search with ISS showed that present Rhea has no ring system [Tiscareno et al. 2010]. The blue pearls are not associated with any tectonic feature along its length or in near proximity. Instead, they appear to be associated with steep slopes (e.g., crater rims). The lack of any constructional artifacts associated with these color patterns on Rhea implies that they are due to regolith disruption [Schenk et al. 2011].

Wispy streaks seen by Voyager on Dione and Rhea are fracture networks [Schenk et al. 2018].

Tethys (IN2b)

Rugged topography of overlapping craters is typical for wide parts of Tethys [Schenk et al. 2018]. The large 425-km wide impact basin Odysseus is one of the largest well-preserved basins in the Saturnian system. Flat-floor deposits (as commonly found in large craters on the Moon and Mercury) are lacking, suggesting that impact melt ponding did not occur in large quantities. This lack of large melt sheets is characteristic of all craters in the Saturn system [Schenk et al. 2018]. Ithaca Chasma is the dominant tectonic feature. It is a giant rift zone already identified by Voyager, 1,800 km in length and subtending at least 270° of arc, between 70 km and 110 km in width, and 2–5 km deep. It predates the Odysseus basin and thus should not have been formed by this impact feature [Giese et al. 2007].

Red streaks were only found on Tethys and are very enigmatic (Figure ICYSATS-5). They show an enhanced color signature in the near-IR which is a very unusual color for features on Saturn's icy satellites. No associated surface deformation is visible even at image resolutions of 60 m/pxl [Schenk et al. 2015]. The infrared shows distinct compositional changes between the red streaks and the surrounding regions [Buratti et al. 2017].

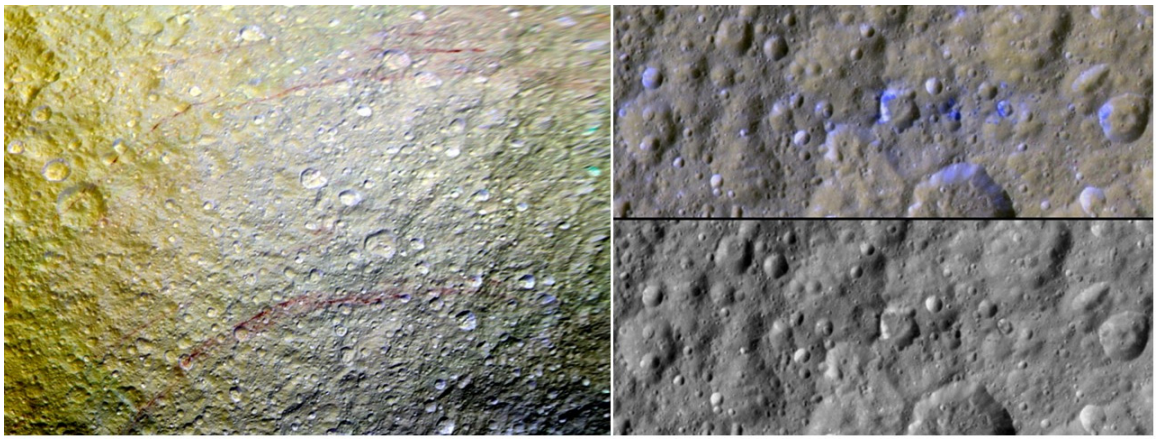

Figure ICYSATS-5. Red streaks on Tethys (left) and blue pearls on Rhea (right).

Tethys' equatorial albedo band, first seen in Voyager images, was analyzed in several ISS NAC wavelengths. The band is symmetric 15° on either side of the equator and extends from 0° to 160° W; that is, almost centered on the leading edge of Tethys. There is no evidence that the band is topographically-based; margins are gradational and there is no visible difference in underlying geology [Elder et al. 2007]. ISS NAC polarization images found no evidence for surface textural variations on size-scales comparable to individual geological features (like crater walls and floors on these size scales, the surface texture of Tethys appears to be uniform). However, a banded pattern on the surface was found and that likely originates in the subtle albedo variations tied to Tethys' equatorial band [Elder et al. 2007] and thermally anomalous terrain [Helfenstein et al. 2005].

Satellite Interiors (IN2c)

Multiple close targeted flybys of the icy moons afforded by an orbital mission as opposed to the single flybys of the Voyager spacecraft provided key data for interior studies. Furthermore, several flybys of Enceladus, Dione, and Rhea were devoted primarily to gravity studies, in which articulations of the spacecraft by reaction wheels or thrusters were avoided. Cassini gravity and imaging experiments teamed up to produce both clear discoveries of internal oceans and interesting mysteries. It appears that multiple Saturnian satellites are well out of hydrostatic equilibrium, reflecting a lack of substantial heat sources and perhaps suggestive of a collisionally dominated history after initial accretion. Rhea is one of these objects, and the gravity data are consistent with a completely undifferentiated body [Tortora et al. 2016]. The lack of evidence for substantial silicates in the surface materials has led to models in which some small amount of differentiation has occurred; however, this is an unstable situation that is difficult to sustain and instead one might look to mechanisms for coating the surface with icy material that obscures a silicate signature.

Cassini data on Mimas and Dione has been interpreted as indicating oceans deep beneath the surfaces of both. For the former, imaging measurements of the moon's unexpectedly large libration imply either a decoupled outer shell (hence, an ocean) or a strongly nonhydrostatic interior

with, for example, an elongated core [Tajeddine et al. 2014]. In the case of Dione, gravity data have been interpreted in terms of a deep ocean via two separate analyses as presented in Beuthe et al. [2016] and Hemingway et al. [2016], but the latter also implies a strongly non-hydrostatic interior. Reconciling these surprising results with models of satellite origin and thermal evolution will be challenging.

The ocean of Enceladus is well-established [Iess et al. 2014; McKinnon 2015; Thomas et al. 2016], but its power source and longevity remain hot topics. Likewise does the question of life, which if present, will (from the point of view of an interiors modeling purist) affect the interpretation of the mass spectrometric data in terms of core-ocean hydrothermal and chemical evolutionary processes.

Iapetus, if in hydrostatic equilibrium, has a shape inconsistent with its present-day spin. This has been interpreted as indicative of a thermal history in which the deep interior was kept hot and dissipative for tidal braking while a thick cold lithosphere retains the shape. If the heat source responsible was short-lived radioactive isotopes, a formation time (since condensation of the first meteorite components) for Iapetus can be derived [Castillo-Rogez et al. 2009]. However, subsequent work revealed that the answer may be very sensitive to ice rheology [Castillo-Rogez et al. 2011], and explanations for the presence of the equatorial ridge in terms of collision with another object [Levison et al. 2011] would severely modify the rotational evolution story.

In contrast with the Jovian system, the intermediate satellite system of Saturn contains objects whose origins and histories, expressed by their interior and surface states, seemed to have been dominated by stochastic events rather than by position relative to their parent planet. Why this is so remains one of the most enduring cold cases left behind by Cassini.

Small Moons (IN2d)

Table IcySats-3 summarizes our current knowledge of the inner small moons of Saturn.

Table IcySats-3. Sizes and mean densities of small Saturnian satellites. Table from Buratti et al. [2018b] and Thomas et al. [2007].

Object	a, km	b, km	c, km	Rm, km	density, kgm^{-3}	gravity, cms^{-2}
Pan	17.3 ±0.2	14.1 ±0.2	10.5 ±0.7	13.7 ±0.3	400 ±32	0.2–1.7
Daphnis	4.9 ±0.3	4.2 ±0.8	2.8 ±0.6	3.9 ±0.5	274 ±142	0.0–0.4
Atlas	20.4 ±0.1	17.7 ±0.2	9.3 ±0.3	14.9 ±0.2	412 ±19	0.0–1.7
Prometheus	68.5 ±0.5	40.5 ±1.4	28.1 ±0.4	42.8 ±0.7	460 ±21	0.8–5.8
Pandora	51.5 ±0.3	39.5 ±0.3	31.5 ±0.2	40.0 ±0.3	509 ±12	2.0–5.9
Epimetheus	64.8 ±0.4	58.1 ±0.8	53.5 ±0.4	58.6 ±0.5	625 ±16	6.6–10.9
Janus	101.8 ±0.9	93.0 ±0.3	74.5 ±0.3	89.0 ±0.5	642 ±10	10.9–16.9
Aegaeon	0.7 ±0.0	0.3 ±0.1	0.2 ±0.0	0.3 ±0.0	539 ±140	0.001–0.005
Methone	1.9 ±0.0	1.3 ±0.0	1.2 ±0.0	1.4 ±0.0	307 ±30	0.1–0.1

Table IcySats-3. Sizes and mean densities of small Saturnian satellites. Table from Buratti et al. [2018b] and Thomas et al. [2007].

Object	a, km	b, km	c, km	Rm, km	density, kgm^{-3}	gravity, cms^{-2}
Pallene	2.9 ±0.4	2.1 ±0.3	1.8 ±0.3	2.2 ±0.3	251 ±75	0.1–0.2
Telesto	16.6 ±0.3	11.7 ±0.3	9.6 ±0.2	12.3 ±0.3		
Calypso	14.7±0.3	9.3 ±0.9	6.4 ±0.3	9.5 ±0.4		
Polydeuces	1.5 ±0.3	1.3 ±0.4	1.0 ±0.2	1.3 ±0.3		
Helene	22.6 ±0.2	19.6 ±0.3	13.3 ±0.2	18.1 ±0.2		
Hyperion	164.1 ±1.7	130.1 ±4.0	107.1 ±4.3	135.9 ±3.1	535 ±37	17.3–20.8

The low densities of the small inner moons of Saturn, which were refined by the close flybys at the end of the mission, is consistent with accretion from ring material. The new data on the moons embedded in the A-ring show that the color of these moons becomes more similar to the rings the closer they are to Saturn. This result suggests there is an ongoing accretion of a reddish chromophore that may be a mixture of organics, silicates, and iron, onto the surfaces of the rings [Buratti et al. 2017]. The difference in color between the moons and their adjacent ring can be explained by the accretion of bright, icy E-ring particles. In essence, each moon's surface is subjected to a balance between these two ongoing processes, with their distance from Saturn and Enceladus determining the final result (Figure IcySats-6). The detection of abundant ice grains by CDA in the region of these moons supports this view. The bluer core of Atlas is also explained by the accretion of E-ring particles, which have a wider range of inclinations than main ring particles. The finding by MIMI of a dearth of high-energy ions also lessens the competing alteration processes from bombardment by magnetospheric particles. The strong crystalline water ice band at 1.65 μm also suggests the lack of importance of these processes. This low energy environment also renders comparisons with the identity of the red chromophore on the trailing hemispheres of main moons of Saturn, especially Dione and Rhea, problematical, as they dwell in a region where alterations by ions is significant and would tend to darken and redden the surfaces. Finally, contamination of Saturn's rings by bright icy particles diminishes the argument that the observed brightness of the rings bespeaks a recent formation [Zhang et al. 2017].

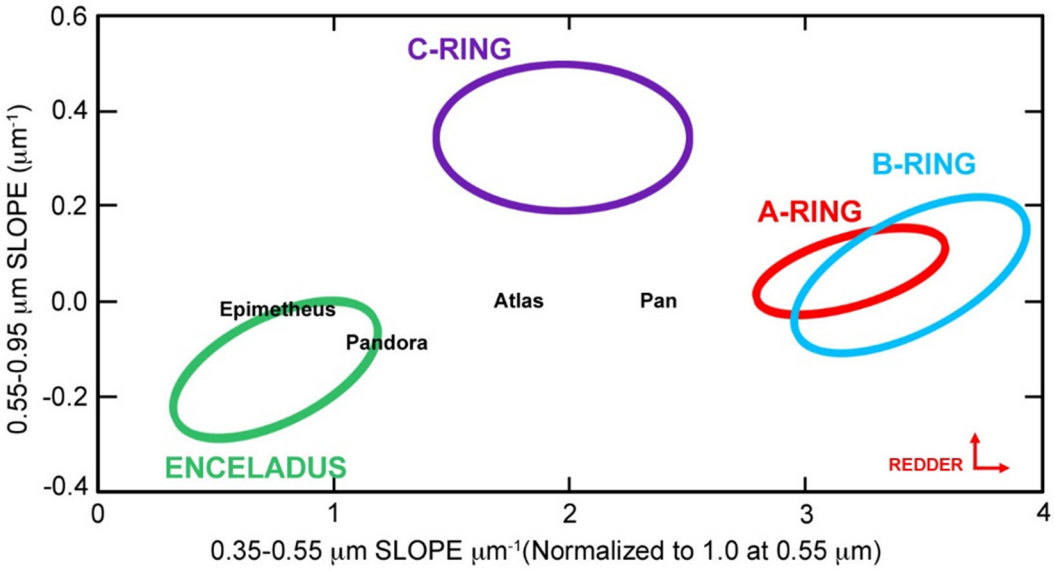

Figure ICYSATS-6. Colors of the ring moons compared to the rings. Figure based on Filacchione et al. [2013, 2012] and Buratti et al. [2018b].

The moons record complex geologic histories including groove formation caused by tidal stresses, accretion of ring particles, and possible accretion of debris from impacts on larger moons. The CDA finding of porous surfaces for the ring moons further supports substantial accretion. Although the topography and surface slopes strongly suggest the equatorial ridges of Pan and Atlas are accreted from rings and are not formed by normal surface transport, the variety of forms of ridges on these objects, and the minimal ridges on Daphnis, show that much remains to be understood about their formation and relation to the main rings. The high-resolution images strongly suggest exposures, especially on Epimetheus, Janus, and Pandora, of a solid substrate distinct from the mobile regolith that generally conceals bedrock on small solar system objects. These exposures may eventually help reveal systematic trends of body history and structures for the whole of the Saturn satellite system. The moons Aegaeon, Methone, and Pallene have shapes of equilibrium ellipsoids indicative of weak or mobile surfaces that cannot support shear stresses [Thomas et al. 2013]. These forms are unique for such small objects, usually fractured or clumpy, and as yet are unexplained. An example of ISS, CIRS, and VIMS data on Atlas is shown in Figure ICYSATS-7.

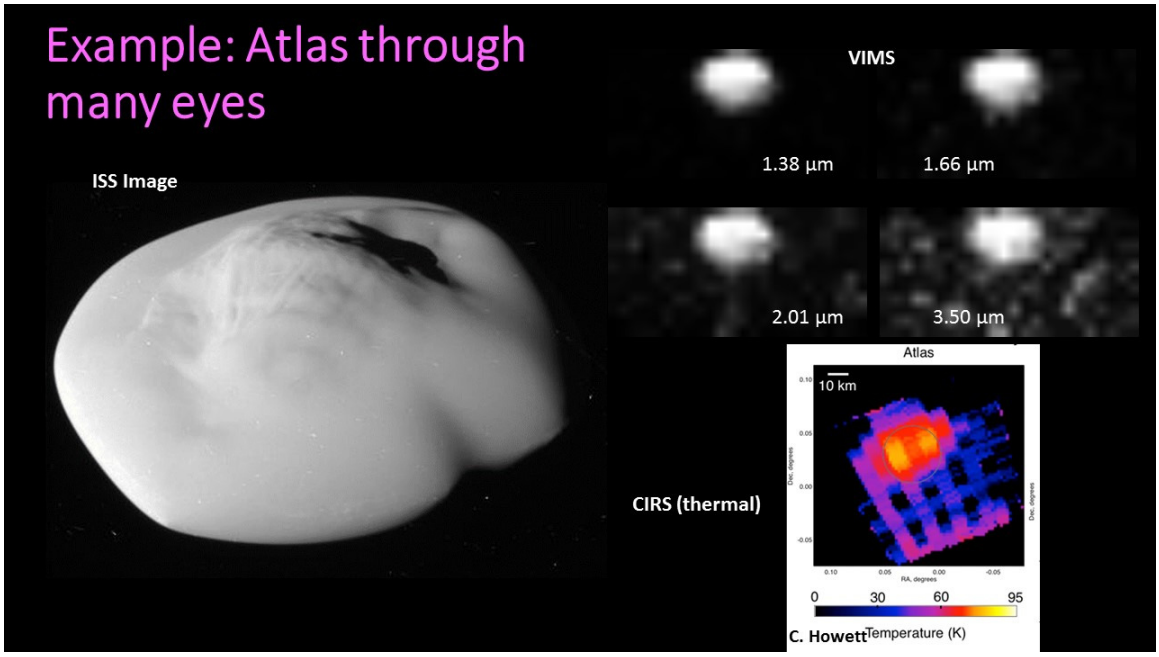

Figure ICYSATS-7. ISS, VIMS, and CIRS observations of Atlas obtained during the F-ring orbits.

Hyperion (IN2e)

The chaotically rotating satellite, Hyperion, has unique sponge-like topography that may reflect sublimation of species more volatile than water ice [Thomas et al. 2007]. The chaotic rotation of Hyperion was analyzed using data from three flybys. The Lyapunov timescale was found to be approximately 100 days [Harbison et al. 2011]. As Iapetus is, Hyperion may be coated with material from the Phoebe ring, but because the moon is in chaotic rotation it is not found preferentially on one hemisphere. Rather, it tends to be located in the bottoms of craters or pits, similar to sun cups on the Earth, in which dark material is concentrated in warmer areas through a process of thermal segregation. This material is rich in organics, including possibly aromatics. The CO_2 on the surface is probably combined in some way with water ice. Dalton et al. [2012] identify aromatic and aliphatic hydrocarbons in the low-albedo material, and possibly H_2. As for Iapetus and the other moons, nanophase iron is thought to act as a coloring agent [Clark et al. 2012].

Iapetus (IN2f)

The global and regional topography of Iapetus is much less smooth than for the other mid-sized icy moons [Thomas et al. 2007; Lee et al. 2010]. A total of 10 basins larger than 300 km have been identified on Iapetus (despite the lack of resolved imaging in some locations), but only four on Rhea. Dione, Tethys, and Mimas are similarly depleted [Schenk et al. 2018]. ISS data show numerous impact craters down to the resolution limit [Denk et al. 2010].

Iapetus' global albedo dichotomy, first described by the spacecraft's eponym Jean-Dominique Cassini in 1677 and unexplained since then, has been solved through Cassini CIRS and ISS data [Spencer and Denk 2010]. Dust from Phoebe or possibly from other retrograde-orbiting irregular moons has likely been painting the surface of Iapetus, forming the newly-detected global color dichotomy of Iapetus [Denk et al. 2010], which triggered the evolution of low-latitude and mid-latitude parts of the leading side into the stark bright and dark patterns we see today as the global albedo dichotomy [Spencer and Denk 2010], accentuated with the thermal migration of water ice [Denk et al. 2010]. A major property of the global color dichotomy is that dark material on the leading side is redder than dark material on the trailing side, and that bright material on the leading side (mainly at high latitudes) is also redder than bright material on the trailing side [Denk et al. 2010]. Cassini ISS data showed that the stark dark-bright contrast is also a local phenomenon. The surface is either bright or dark, but almost never gray, even in the transition zone between the dark Cassini Regio and the bright Roncevaux Terra and Saragossa Terra [Denk et al. 2008].

Observations of small, bright-ray craters within the dark terrain indicate that the dark material corresponds to a blanket of a few meters or less in thickness…

Observations of small, bright-ray craters within the dark terrain indicate that the dark material corresponds to a blanket of a few meters or less in thickness [Denk et al. 2010], a finding also supported by Titan Radar Mapper (RADAR) data [Ostro et al. 2006] and consistent with the thermal migration model of Spencer and Denk [2010].

A huge and enigmatic ridge located exactly at the equator was discovered in ISS images [Porco et al. 2005; Denk et al. 2005a; Denk et al. 2005b]. In places, this ridge is up to 20 km high and 70 km across, and it spans almost 75% of the moon's circumference [Porco et al. 2005; Denk et al. 2008; Giese et al. 2008; Singer and McKinnon 2011]. While the ridge is mainly continuous on the leading side (Toledo Montes), it separates into the isolated mountains of the Carcassone Montes which were already discovered in Voyager data (and thus sometimes dubbed Voyager mountains) [Denk et al. 2000]. In general, it shows a wide range of cross-sections and heights at different longitudes [Denk et al. 2008; Singer et al. 2012]. Singer and McKinnon [2011] did not find potential hints for tectonic or volcanic origin. Defying any obvious explanation, numerous endogenic and exogenic formation mechanisms were proposed, for example, see short review of them by Damptz et al. [2018]. None of them can be favored over the others at this point.

CO_2 was found on Iapetus during an untargeted flyby just prior to the Huygens probe separation [Buratti et al. 2005], and spectra with km-scale resolution were obtained during a targeted flyby on September 10, 2007. Clark et al. [2012] identified additional key components of the surface of Iapetus in addition to CO_2 and H_2O, including bound water, H_2, OH-bearing minerals, trace organics, and possibly ammonia. The CO_2 on Iapetus was enriched in the low-albedo areas, reaching a maximum at the apex of motion where the albedo is lowest. The Clark et al. [2012] posits the presence of nanophase metallic iron particles and an iron oxide, probably hematite to contribute to the observed Rayleigh scattering peak in the visible part of the spectrum. Figure ICYSATS-8 is a summary of the features in the spectrum of Iapetus.

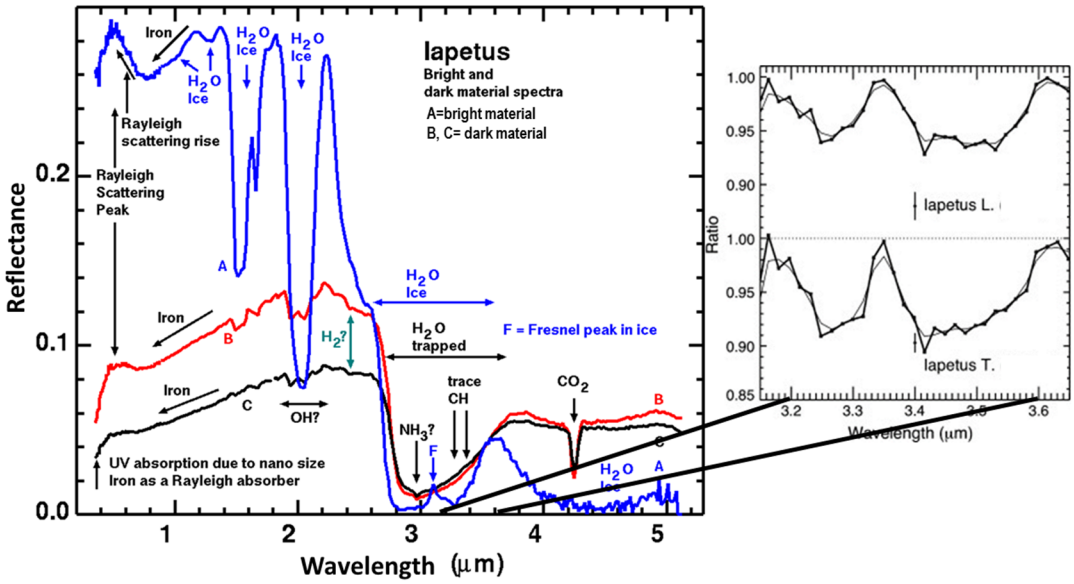

Figure ICYSATS-8. The spectrum of Iapetus showing explanations for the spectral lines of the bright material and two examples of dark material on Iapetus. *B = dark material:* The identification of aromatic hydrocarbons in the spectrum. This graph gives the residuals that result from a best-fit Hapke compositional model to the leading and trailing sides. Absorption bands at 3.28 μm are characteristic of aromatic hydrocarbons, while those between 3.35 and 3.6 μm are characteristic of aliphatic hydrocarbons. *A = bright material:* is based on Clark et al. [2012] and *B = dark material:* is based on Cruikshank et al. [2014].

An analysis of the 2.7 to 4.0 μm spectral region by Cruikshank et al. [2010, 2014] identified the presence of both aromatic and aliphatic hydrocarbons in the dark material on Iapetus. The aromatic band near the CH stretching modes of aromatic hydrocarbons at ~3.28 μm is especially strong, and is likely due to aromatic hydrocarbons. Because surfaces rich in aromatic hydrocarbons are readily carbonized via UV radiation, these substances are not stable on the surface of Iapetus, and thus the process of accretion of Phoebe ring particles must be ongoing.

The dark material on Iapetus is abundant enough to perform compositional modeling. The 3-micron-bound water band was found to match hydrated iron oxides [Clark et al. 2012] and subsequent recalibration of VIMS [Clark et al. 2018] show that spectra of the dark materials also shows a 1.9-micron water absorption that matches hydrated iron oxides. The linear slope, blue peak, and absorption shorter than 0.5 microns, argue for space-weathered silicates (thus nano-metallic iron) as the explanation of the UV-visible spectrum. The lack of any hint of absorptions from tholins in the IR is enough abundance to explain the UV-visible spectrum, and argues for the space-weathered silicates and iron oxide explanation [Clark et al. 2012].

Clark et al. [2012] also explained that the differences in color between the Iapetus dark material and Phoebe is simply due to abundance differences of space-weathered silicates, hydrated iron oxides, and ice. According to this model, the flatter, grayer spectrum of Phoebe compared to Iapetus dark material is due to lower abundance of the iron oxides and space-weathered silicates.

Other Icy Satellites Science not in CSM

Phoebe was the first targeted flyby on June 11, 2004. Its global shape is close to an oblate spheroid, with a = b to within the uncertainties of the data [Thomas 2010; Castillo-Rogez et al. 2012]. Its mean radius is 106.4 ±0.4 km and its mean density is 1.64. This high density along with its compositional differences with the mid-sized regular satellites of Saturn, support the evidence that it is a captured body [Johnson and Lunine 2005b]. Numerous impact craters are visible on the surface; they range in diameter from the lower limit imposed by the ISS image resolution up to ≈100 km [Porco et al. 2005]. Phoebe's topography, relative to an equipotential surface, is within the range of other small objects and is much higher than that for clearly relaxed objects [Thomas 2010]. Digital Terrain Model (DTM) and orthoimage of the surface were produced from ISS data [Giese et al. 2006]. The J2000 spin-axis was found at Dec = 78.0° ±0.1°; RA = 356.6° ±0.3°, substantially different from the former Voyager solution [Giese et al. 2006]. Finally, Phoebe dust ring, discovered from Earth, has also been observed with the ISS Wide Angle Camera [Tamayo et al. 2014].

Mimas was the least studied of the main moons, with no targeted flyby.

Mimas was the least studied of the main moons, with no targeted flyby. The best images obtained at this flyby have a spatial resolution of ~93 m/pxl. There is morphologic evidence for a highly degraded impact basin of ~153 km diameter, northeast of crater Herschel [Schmedemann and Neukum 2011].

All irregular moons except Phoebe were discovered between year 2000 and 2007. Since this was after the launch of Cassini-Huygens, they were not part of the original science goals. Therefore, a dedicated observation campaign with ISS was initiated for the Solstice mission. ISS observed 25 of Saturn's 38 known irregular moons, and precise rotational periods could be derived for most of them. The light curves are indicative for objects with quite different shapes. The rotational periods vary between 5.45 h and 76.13 h. Many asteroids of similar size rotate faster; this indicates that Saturn's irregular moons have rather low densities. Some objects show very distinct 3 maxima/3 minima light curves with an equal spacing of the extrema. Convex-shape models of these moons resemble triangular prisms, but they might actually be contact-binary objects. Other light curves show patterns that might even hint to binary moons. It is likely that non-random correlations were found between the ranges to Saturn, the orbit directions, orbit tilts, object sizes, and the rotation periods. The physical cause, especially for size and spin relations to orbital elements, is unknown at this point. For further reading, we refer to Denk et al. [2018] or Denk and Mottola [2013, 2014].

Open Questions for Icy Satellite Science

The top open questions for icy moon science, as compiled by the Cassini ISWG meeting in March 2018 and compiled in a peer-reviewed paper by Buratti et al. [2017], are:

1. What are some of the minor constituents of the Saturnian moons, and are they endogenic or exogenic? If exogenic, is the accretional process still ongoing?

2. Can the D/H ratio be measured on these moons? If so, how does it compare with that of other regions of the Solar System, and what does that imply about the transport of volatiles on a large scale? Clark et al. [2019] derives the D/H in the ice on the satellites and rings and the 12C/13C on the carbon dioxide. The D/H is similar to terrestrial values for the satellites and rings except for Phoebe, where deuterium and C13 are high.

3. Is ammonia hydrate on the surfaces of any of the moons?

4. What is the identity of the red chromophore on these bodies' surfaces? Is it nano-iron or organic material, and what are the transport processes to move this material around the Solar System? Is it the same chromophore that exists in the main ring system?

5. What is the total heat production on Enceladus; how and why does it vary? What does this imply about the cause of activity on the moon? Why is only the South Pole active and not the North Pole (what is Enceladus' tectonic history)? What is the nature of the plumbing that connects the ocean to the surface? Is there any evidence for seasonal variations in output? Is there life in Enceladus' ocean?

6. Is there residual activity on Dione and Tethys, and if so, what does this imply about their recent history? Are the red streaks on Tethys evidence for such activity?

7. What caused the ridge on Iapetus? Is it evidence for a past ring? Did other moons have rings in the past?

8. Why does the origin of the moons of Jupiter and Saturn seem to diverge, with the Jovian moons being formed relative to their position from Jupiter, and the Saturnian moons being formed by stochastic events?

9. Why are some of the moons not in hydrostatic equilibrium? Rhea and Dione, incompletely, for example.

10. To what extent do magnetospheric particles alter the optical properties of the moons? Does contamination by ring particles, including those from the E-ring, dominate this process?

11. What are the blue pearls on Rhea?

Earth (Moon)

From Clark [2009]:

> "Data from the Visual and Infrared Mapping Spectrometer (VIMS) on Cassini during its flyby of the Moon in 1999 show a broad absorption at 3 micrometers due to adsorbed water and near 2.8 micrometers attributed to hydroxyl in the sunlit surface on the Moon. The amounts of water indicated in the spectra depend on the type of mixing and the grain sizes in the rocks and soils but could be 10 to 1000 parts per million and locally higher. Water in the Polar Regions may be water that has migrated to the colder environments there. Trace hydroxyl is observed in the anorthositic highlands at lower latitudes."

Jupiter (Galilean Satellites)

In December 2000, Cassini flew by Jupiter for a gravity assist to Saturn. The geometry of the flyby was set by the trajectory requirements for Saturn so most of the moons were quite distant, however, several significant new results were obtained. Brown et al. [2003] documents VIMS results from the Jupiter flyby: VIMS documented a surprisingly high opposition surge on Europa, and the first visual-near-IR spectra of Himalia. UVIS observed Europa's O_2 atmosphere. ISS studied Io's volcanic activity.

Io

Io was observed during four eclipses. ISS imaged the glow of Io's ambient atmosphere from the K, Na, O, S_2, and SO_2 coming from its volcanoes. Differences in the altitude of the emissions indicate stratification of the Io atmosphere [Geissler et al. 2004].

Europa

VIMS data provided the first near-IR phase curve of Europa [Simonelli and Buratti 2004]. Europa exhibits a remarkable surge in brightness (~0.2 mag/deg) under 1°, comparable to the lunar opposition surge measured by Clementine [Buratti et al. 1996]. Furthermore, data at small phase angles show a clear trend with albedo, such that wavelengths corresponding to higher albedos have smaller surges, consistent with shadow illumination. The VIMS results suggest that neither CBE nor shadow hiding provide a complete description of Europa's opposition surge below 1° [Brown et al. 2003].

UVIS observed emissions from Europa's O_2 atmosphere and mapped its spatial extent. Atomic oxygen extends further from Europa than O_2, however, it does not form a torus [Hansen et al. 2005]. Analysis of other emissions from other neutrals and ions near Europa constrains the level of eruptive activity and suggests that it can only be intermittent—no plumes comparable to Enceladus were active at the time of the Cassini flyby [Shemansky et al. 2014].

Galilean moons

VIMS spectra of the Galilean satellites confirmed the spectral features in the Galileo Near-Infrared Mapping Spectrometer Subsystem (NIMS) data. Brown et al. [2003] also noted similar spectral structure as in NIMS data attributed to a CN bond near 4.5 microns. This structure was also seen in VIMS data of the Saturnian satellites, see for example, Clark et al. [2005, 2008], but was later found to be due to a calibration error [Clark et al. 2012].

Himalia

The disk of Himalia was resolved in ISS images, and show that it is not spherical [Porco et al. 2003]. If principal axes were visible, the diameters are 150 ±10 km × 120 ±5 km. VIMS data shows that Himalia has a slightly reddish spectrum, an apparent absorption near 3 μm, and a geometric albedo of 0.06 ±0.01 at 2.2 μm (assuming an average 85-km radius). If the 3-μm feature in Himalia's spectrum is eventually confirmed, it would be suggestive of the presence of water in some form, either free, bound, or incorporated in layer-lattice silicates [Brown et al. 2003].

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AO	Announcement of Opportunity
CAPS	Cassini Plasma Spectrometer
CDA	Cosmic Dust Analyzer
CIRS	Composite Infrared Spectrometer
CSM	Cassini Solstice Mission
D/H	Deuterium to Hydrogen
DTM	Digital Terrain Model
DWG	Discipline Working Group
FRPO	F-ring and Proximal Orbits
FUV	far ultraviolet
INMS	Ion and Neutral Mass Spectrometer
IR	infrared
ISS	Imaging Science Subsystem
ISWG	Icy Satellites Working Group
KBO	Kuiper Belt object
LEMMS	Low Energy Magenotospheric Measurement System
MAPS	Magnetospheres and Plasma Science
MIMI	Magnetospheric Imaging Instrument
NAC	narrow angle camera
NIMS	Near Infrared Mapping Spectrometer Subsystem
PDS	Planetary Data System
RADAR	Titan Radar Mapper
SOST	Satellites Orbiter Science Team
TM	Traceability Matrix
UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph
VIMS	Visual and Infrared Imaging Spectrometer

MAPS

Prior to Cassini's arrival, scientists had little information about Saturn's magnetosphere, the giant, invisible magnetic bubble surrounding the planet. Cassini studied Saturn's magnetosphere as never before by mapping the magnetic field, studying the flow of excited plasma within, and observing the influence of the solar wind and how it affects Saturn's auroras. Fields and particles data have provided powerful insights about how Saturn's magnetic field provide linkages between charged particle sources and the rings, moons, and atmospheres, in addition to the inner workings of Saturn's interior.

The **Magnetospheres and Plasma Science (MAPS)** Discipline Working Group (DWG) facilitated and coordinated the data sharing and collective science among the six MAPS instrument teams to ensure that all Cassini's MAPS mission objectives were successfully met. The MAPS DWG has achieved and exceeded in every way the Cassini mission goals and objectives, and has provided a legacy for the outer planets community that will reach far into the future.

EXECUTIVE SUMMARY

…it is clear that the MAPS DWG achieved and exceeded in every way the AO and extended mission goals, and provided a legacy … that will reach far into the future.

The purpose of the Magnetospheres and Plasma Science (MAPS) Discipline Working Group (DWG) was to facilitate and coordinate the data sharing and collective science among the MAPS instruments teams to ensure that all Cassini Announcement of Opportunity (AO) and extended mission objectives were achieved. Without reservation it is clear that the MAPS DWG achieved and exceeded in every way the AO and extended mission goals, and provided a legacy for the outer planets community that will reach far into the future.

Perhaps the most important single contribution to the MAPS science coming from the Interdisciplinary scientist of the MAPS DWG was the creation of the MAPS Rules-of-the-Road. This document outlined a very clear policy that MAPS instruments would share data, that PIs would take responsibility for their teams, and that collaborative work would be the norm for MAPS not the exception. A separate closeout document describes in detail the creation and execution of the Rules-of-the-Road. While the MAPS DWG was not without its conflicts, the legacy of this document was a DWG that shared data that fostered collaborations between instrument teams and created new investigations without significant conflict.

In addition to the MAPS Rules-of-the-Road, another operating principle of the MAPS DWG and the DWG Interdisciplinary Scientists (IDSs) was that the instrument teams should take the lead, and thereby receive the glory, on nearly all investigations. With this guiding principle, the DWG was able to have the most relevant team lead, most investigations, and then have other teams contribute.

KEY SCIENCE RESULTS

Top Science Findings for MAPS

Discovery of the Enceladus plumes and their interaction with Saturn's magnetosphere

One of the most important and surprising discoveries of the entire Cassini mission was the discovery of an atmospheric plume at Enceladus by the magnetometer team [Dougherty et al. 2006] on February 17, 2005. The discovery was confirmed and strengthened by subsequent measurements on later flybys and other instruments. This dynamic atmospheric plume was later shown by the Imaging team to be due to geyser activity on the southern hemisphere of Enceladus. Subsequent modeling based on analytical theory clearly showed that the magnetometer results

required the presence of negatively charged dust particles [Simon et al. 2011]. As a unique feature at Enceladus, dust–plasma interactions play an important role to explain the observations.

The discovery of a large and neutral plasma source at Enceladus led to the potential that the moon's interaction with Saturn would result in currents along the magnetic flux tube that could cause an auroral footprint in Saturn's ionosphere. Although initial Hubble Space Telescope (HST) observations did not detect such an auroral footprint [Wannawichian et al. 2008], a follow-on study discovered an Enceladus-associated aurora in a few percent of the scans of the moon's footprint [Pryor et al. 2011]. The footprint varies in emission magnitude more than can plausibly be explained by changes in magnetospheric parameters, and as such is probably indicative of variable plume activity.

Identifying the highly axisymmetric internal magnetic field of Saturn

Early in the mission the Magnetometer (MAG) team determined that the tilt of Saturn's dipole must be smaller than 0.06 degrees from the spin-axis of Saturn which was further constrained by the Grand Finale measurements to <0.01 degrees [Dougherty et al. 2018]. The time variation of Saturn's intrinsic magnetic field must be an order of magnitude slower than that of Earth's [Cao et al. 2011]. These results are very challenging for dynamo theory, as Cowling's theorem excludes the possibility of a purely axisymmetric magnetic field being maintained by dynamo action. The Cassini Grand Finale gravity measurements indicate that the ~100 m/s zonal flows observed at the cloud deck of Saturn extend almost 10,000 kilometers into the planetary interior. Given that the electrical conductivity at such depth are high enough for significant magnetohydrodynamic (MHD) effects, zonal flow magnetic field interaction in the semi-conducting region of Saturn is now a central issue in understanding the interior dynamics. The amplitude of the wind-induced magnetic perturbations would depend on the amplitude of the deep differential rotation as well as the amplitude of the small-scale deep convective flow. Thus, measuring/constraining wind-induced magnetic perturbations along the Cassini Grand Finale orbits would place important constraints on the properties (profile and amplitude) of deep differential rotation and convective flow in the semi-conducting region of Saturn. This work is still ongoing and we expect additional discoveries.

Discovery of periodicities while the intrinsic rotation rate remains elusive

Many properties of Saturn's magnetosphere exhibit periodicities at approximately the planetary rotation rate, a significant puzzle given the near-alignment of the magnetic and rotational axes. Saturn's kilometric radiation (SKR) is the most intense radio emission component, produced in the auroral regions. The first SKR periodicity measured by Cassini witnessed a value differing by 1% to the SKR period identified from Voyager/Planetary Radio Astronomy (PRA) observations 25 years earlier [Gurnett et al. 2005]. Such a large variation implies that the SKR period does not probe the internal rotation rate. The major discovery was the identification of two SKR periods [Kurth et al. 2008] corresponding to the two Kronian hemispheres, differing by ~1%. Both of those periods were found to vary with time in anti-correlation over yearly timescales and crossed closely after equinox, a trend which was interpreted as a seasonal driving of solar illumination [Gurnett et al. 2011a,

2010a, 2009; Lamy 2011]. These dual periods were also observed in numerous magnetospheric observables including magnetic oscillations, energetic neutral atom (ENA) emissions, and aurorae [Mitchell et al. 2009b; Carbary et al. 2011a, 2010a; Nichols et al. 2010; Andrews et al. 2011, 2010; Provan et al. 2011; Badman et al. 2012a, 2012b]. It is now accepted that these dual rotational modulations all originate from two rotating hemispheric systems of field-aligned currents, whose origin may be atmospheric vortices [Jia et al. 2012].

Discovery of new radiation belts

The Magnetospheric Imaging Instrument (MIMI)/Low Energy Magnetospheric Measurement System (LEMMS) instrument discovered a previously unknown radiation belt collocated with the D-ring and extending up to the dense atmosphere of Saturn. This belt was discovered earlier in the Cassini mission [Kollmann et al. 2015], but its properties were unknown. It was found that the belt is dominated by protons up the GeV range, which is the first time that such high energies were directly observed at any of the giant planets. Their pitch angle distribution is very steep, likely due to a strong interaction with Saturn's atmosphere. The suggested source is Cosmic Ray Albedo Neutron Decay (CRAND). There is no evidence for the presence of energetic electrons or ions heavier than protons [Roussos et al. 2018a; Kollmann et al. 2018].

Identifying the main plasma sources in Saturn's magnetosphere

The dominant ion species seen throughout the magnetosphere are well explained by ionization of material from the water plumes of Enceladus that are estimated to produce ~60–100 kg/s [Fleshman et al. 2013]. Enceladus is also the probable source of most of the N^+ observed in Saturn's inner magnetosphere [Smith et al. 2010]. The finding of very little N^+ in the outer magnetosphere [Smith et al. 2005] indicated that Titan's contribution to the heavy-ion plasma is limited, whereas the fact that H_2^+ becomes comparable to H^+ and W^+ in the outer magnetosphere [Thomsen et al. 2010] indicates that Titan is an important source of lighter ions in that region producing ~0.8 kg/s [Coates et al. 2012]. Observation of probable plasma outflows from Saturn's ionosphere led to an estimate of some 10 s of kg/s lofted from the ionosphere [Felici et al. 2016]. It is, however, not yet clear how often such outflow occurs. During Saturn Orbit Insertion (SOI) a layer of O_2^+ and O^+ was discovered over the A-ring and B-ring [Young et al. 2005]. The ring atmosphere and ionosphere are likely produced by ultraviolet (UV) photo sputtering of the icy rings and subsequent photoionization of O^+. Significant O^+ was also detected outside the main rings, near the F-ring [Tokar et al. 2005], and analysis of the O^+ and W^+ profiles showed seasonal dependence consistent with a ring source that depends on the solar illumination angle [Elrod et al. 2014, 2012]. In contrast, Gurnett et al. [2005] show evidence of deep density depletions over the ring during SOI. These results indicate that the rings are an important source of heavy ions inside the orbit of Mimas.

Global configuration and dynamics of the magnetosphere

Cassini discovered that most of the magnetospheric plasma is produced by Enceladus deep inside the magnetosphere. Combined with very strong centrifugal forces this source controls most of Saturn's magnetospheric dynamics. Cassini has also discovered evidence that, unlike at the Earth, the solar wind plays a relatively small role in magnetospheric dynamics, primarily associated with large dynamic pressure enhancements. Saturn's giant magnetic field is the principal cause of the transport of material between the many bodies in this still evolving system, dumping oxygen into the atmospheres of Titan and Saturn. Cassini detected radially outward plasma flows of ~800 km/s during observation of a plasmoid (magnetically detached plasma bubble) on March 4, 2006.

Understanding the transport of plasma through the magnetosphere and the mechanisms for its eventual loss of plasma has been one of the major points of focus of the MAPS investigation. Plasma transport occurs through convection, plasma interchange, reconnective processes, and plasmoid formation. At the time of Cassini's arrival to Saturn the relative importance of these different processes was poorly understood. Now with 13 years of magnetospheric data we have a much better understanding of these different processes. MAPS studies have addressed the relative importance of Vasyliunas-cycle and Dungey-cycle reconnection, and the formation process and frequency of plasmoids and how they are related to dipolarizations. There have been a whole host of studies on the frequency, distribution, source region, life time, size, and plasma properties of the different interchange events that Cassini has observed.

First in situ measurements of Saturn's topside ionosphere

During the Cassini Grand Finale, Cassini MAPS instruments made an unprecedented series of measurements of Saturn's upper atmosphere, sampling from ~3500–1370 km altitude above the 1 bar pressure level. Prior to these orbits, it was anticipated that Saturn's upper atmosphere consisted primarily of H, H_2, with trace amounts of H_2O and He. The in situ measurements of Saturn's ionosphere allowed the first determination of ion mixing ratios and number densities as well as their temporal variabilities. The measurements of helium provided constraints on possible deep-atmosphere mixing ratios of helium and whether or not Saturn has a solar-like composition or something else. In the equatorial region of Saturn's ionosphere where the ring-ionosphere interaction is important, combined with Radio and Plasma Wave Science (RPWS) and MIMI measurements, Ion and Neutral Mass Spectrometer (INMS) in situ data paint a clear picture of Saturn's equatorial ionosphere being dominated by heavy molecular ions that result from ring-derived material. Near the end of the mission, during the proximal orbits, INMS measured densities of H^+, H_2^+, H_3^+, and He^+ in Saturn's ionosphere.

> All of these unanticipated results have effectively turned our understanding of the high-altitude thermosphere-ionosphere chemistry on its head.

In addition to the primary and expected species, the INMS measurements revealed an atmosphere with an

unexpectedly rich composition, containing significant amounts of organics spanning the entire mass range sampled by INMS and specifically the presence of several species of high mass neutrals, for example, CH_4, CO, CO_2. All of these unanticipated results have effectively turned our understanding of the high-altitude thermosphere-ionosphere chemistry on its head.

Detection of lightning in Saturn's atmosphere and the evolution of a once-per-Saturn-year Great White Spot storm

The first indication of lightning in Saturn's atmosphere was obtained in November 1980 by the radio instrument onboard Voyager 1. Strong impulsive signals in the frequency range of a few MHz were detected and termed SEDs for Saturn Electrostatic Discharges [Warwick et al. 1981]. The Cassini mission has greatly enhanced our knowledge about Saturn lightning, and combined radio and imaging observations, have clearly established the atmospheric origin of the SEDs.

RPWS provided the most complete census of lightning activity from near continuous observations of Saturn electrostatic discharges (SED) and established the frequency of convective storms on Saturn, their duration, and lightning flash rates, see for example, Fischer et al. [2011a, 2011b]. Saturn lightning flashes were first detected optically on the nightside of Saturn around equinox. The Cassini cameras spotted flash-illuminated cloud tops with a diameter of about 200 km, suggesting that the lightning comes from 125–250 km below [Dyudina et al. 2010], and most likely from the water-cloud layer. At Earth the charging of water cloud particles in thunderstorms is most effective in a temperature range of −10° C to −25° C. At Saturn this temperature range is located at a level of 8–10 bars, about 200 km below the cloud tops, i.e., consistent with the altitude range found by Dyudina et al. [2010]. Another indication that the Saturn lightning source is in the water cloud layer comes from Cassini Visual and Infrared Imaging Spectrometer (VIMS) near-infrared spectra of the Great White Spot. They revealed spectroscopic evidence for ammonia and water ices [Sromovsky et al. 2013] brought up to higher altitudes by strong vertical convection. So, it is thought that the same particle charging mechanisms are at work on Saturn and Earth. As most of the sunlight is absorbed above 2 bars, Saturn's weather and thunderstorms at deep pressure levels should be powered by the planet's internal energy [Desch et al. 2006]. It drives the vertical convection which brings up the water cloud to the visible atmospheric level where it is observed as a bright eruption by Cassini Imaging Science Subsystem (ISS) and VIMS. Dyudina et al. [2010] also measured the optical flash energy to be about 10^9 J, which suggests that Saturn lightning is superbolt-like with total energies of about 10^{12} J [Fischer et al. 2011c].

Detailed studies of Saturn's auroras

For the first time, Cassini's presence inside the magnetosphere facilitated the coordinated optical observations of the aurora and in situ measurements of the plasma properties, the magnetic structure, and the field-aligned currents. While there have been various studies of the aurora as reviewed in Grodent [2015], the best way to summarize Cassini work is to highlight one of these coordinated studies. One coordinated auroral observing campaign occurred April 21–22,

2013, involving instruments onboard Cassini and the Hubble Space Telescope. During this campaign both Saturn's northern and southern aurora were observed while Cassini traversed Saturn's high-latitude auroral field lines [Badman et al. 2016]. Signatures of upward field-aligned currents were detected that corresponded to the bright ultraviolet auroral arc seen in the auroral images and various auroral features observed included a bulge that appeared along the pre-dawn auroral oval and an intensification of the auroral field-aligned currents. These observations are interpreted as the response to tail reconnection events instigated by solar wind compression, initially involving Vasyliunas-type reconnection of closed mass-loaded magnetotail field lines, and then proceeding onto open lobe field lines, causing the contraction of the polar cap region on the post-midnight sector. At the same time Kurth et al. [2016] reports on the RPWS monitoring of the Saturn kilometric radiation. This study found that there is a good correlation between the 10 h averages of SKR power flux and the estimated power input to the aurora on the basis of the UV brightness, justifying the SKR as a simple proxy for auroral activity through the campaign. The SKR emissions also give evidence for a recurrent pattern of solar wind interaction with Saturn's magnetosphere, suggesting a two-sector structure and associated corotating interaction regions that influence the level of auroral activity on Saturn. But there are other SKR intensifications that may be due to internal processes. This coordinated campaign is a perfect example of the many coordinated studies that have been performed by the Cassini MAPS teams in working to understand the aurora at Saturn.

Discovery of ring-ionosphere-magnetosphere interaction

Cassini MAPS instruments discovered and characterized a unique ring–ionosphere–magnetosphere interaction. INMS first observed O_2^+, O^+, and H^+ ions over the A-ring in its ion mode during SOI [Waite et al. 2005]. Further Cassini observations revealed that the ring–ionosphere–magnetosphere interaction is driven by photolytic processes, not impact processes [Farrell et al. 2017]. Specifically, the Sun-facing side of the main rings are a source of photo-dissociated neutrals that get ionized to form a relatively low energy exo-ionosphere. This exo-ionosphere cannot directly access the shadowed/unlit side of the rings: the ring particles represent obstacles to their transport. Thus, the plasma density on the unlit side is modulated by ring density, being lowest where the ring obstruction is the highest in the central B-ring. Local maxima are expected where the local ring particle density is low, such as across the Cassini Division. There is little evidence of impact-generated plasma like that which was predicted during the Voyager era. Cassini observation suggested that there is a current system driven by the rings–magnetosphere interaction. While the plasma on field lines over the rings would be corotating, the particles and associated photo-dissociated gas of the rings would be moving in Keplerian motion, creating drag on the plasma. This drag creates an associated change in plasma speed. Beyond the synchronous point, the plasma is slowed by the Keplerian-moving particles and gas, creating a radially outward directed electric field in order to maintain the new sub-corotation speed. This new electric field drives an outward current that then acts to form a magnetohydrodynamic JxB force to balance the plasma-ring drag force. Inward of the synchronous point, the corotating plasma is accelerated by the ring drag force, creating an inward radial electric field and current that forms a JxB force to offset the acceleration. At the edges of the rings, these cross-ring currents become a field-aligned parallel

current that closes down to the ionosphere along connecting magnetic field lines at the outer edge of the A-ring near L = 2.25 and inner edge of the D-ring near L ~1.11. The rings thus behave as an electrical generator in the plasma, driving currents from the ring surfaces along magnetic field lines down to the ionosphere.

Discovery of heavy positive and negative ions in Titan's ionosphere

This is one of the major surprises of the Cassini mission—the high level of chemical complexity observed in Titan's ionosphere. The first in situ ion composition measurements of Titan's ionosphere were made by the INMS in its ion mode and showed a complex composition [Cravens et al. 2006]. From the earliest close encounters Cassini Plasma Spectrometer (CAPS) detected heavy negatively charged ions with mass/charge up to 13,800 amu/q. In addition, heavy positive ions up to ~350 amu/q [Crary et al. 2009] and as high as 1000 amu/q [Coates et al. 2010] were also detected. An unexpected level of chemical complexity was seen in the neutrals as well [Waite et al. 2007]. The existence of negative ions was completely unexpected at the altitudes sampled by Cassini.

Dust–plasma interactions

The discovery of the dense neutral water vapor jets at Enceladus resulted in a continuous, detailed examination of all aspects of the Enceladus plume and the extended effects on the magnetosphere. A major result of this examination is the detection of singly charged nanometer-size water-ice grains [Coates et al. 2009; Jones et al. 2009; Hill et al. 2012; Meier et al. 2014; Dong et al. 2015; Meier et al. 2015]. Such nanograins had been inferred to exist in various cold, tenuous geophysical and astrophysical environments, but the close Enceladus plume encounters by Cassini offered the first (and still the only) opportunity to measure and characterize the nanograins in situ.

This analysis confirms that the nanograins are largely uncharged when they emerge from the surface vents and become increasingly (mostly negatively) charged as they approach Cassini a few tenths of Enceladus radii away. The most plausible charging mechanism is electron attachment from the dense plume plasma. The non-neutrality of the nanograins observed by CAPS, n(−) >> n(+), plausibly cancels the opposite non-neutrality of the plume plasma observed by RPWS Langmuir Probe (LP). Most of the electrons missing from the plume plasma reside on the nanograins.

Discovery of nanodust between the planet and the D-ring

An exciting result of the proximal orbits during the final months of the Cassini mission was the discovery of nanograins between the planet/ionosphere and the D-ring. Understanding the implications of these particles is still a work in progress, and the first in situ measurements by RPWS of the cold ionosphere properties have just been reported [Wahlund et al. 2018]. Several other manuscripts have been submitted by MAPS instrument teams, and they all show a very strong interaction between the D-ring and the ionosphere of Saturn, causing the ionosphere to

become extremely variable with more than two orders of magnitude and trigger a dust-ionosphere layer near the equator.

Discovery of the shape of the heliosphere

Beyond the Saturn system, one of the most important contributions of Cassini to our understanding of the solar heliosphere came from the MIMI/Ion and Neutral Camera (INCA), first ever images of the global heliosphere in > 5.2 keV ENA measurements [Krimigis et al. 2009]. These images identified two striking, previously unexpected, heliospheric signatures: a) the Belt, a broad band of emission in the sky, identified as a high intensity, relatively wide ENA region that wraps around the celestial sphere in ecliptic coordinates, passing through the nose, the anti-nose (tail), and the north and south heliosphere poles; and b) the basins, identified as two extended heliosphere lobes where the ENA minima occur. In addition, INCA measurements could be used to image the shape of our heliosphere with a surprising result that it is now thought to be a sphere rather a structure with a nose and a tail, like a magnetosphere [Dialynas et al. 2018].

MIMI's images came at a time when Voyager 1 and Voyager 2 crossed the termination shock, where the supersonic solar wind presumably terminates at the shock front, at respective distances of ~94 and ~84 AU in 2004 and 2007 at +35° and −26° ecliptic latitudes [Decker et al. 2008, 2005], pinpointing both the size of the local heliosphere and the scale of the heliospheric asymmetry. After this crossing, V1 additionally unexpectedly passed through the heliopause [Krimigis et al. 2013] at a distance of ~122 AU. Due to the powerful synergy between in situ ions from V1 Low Energy Charged Particle (LECP) instrument and ENAs from INCA (in overlapping energy bands), MIMI has made key discoveries, beginning in about 2009, that altered our past notions on the formation and interactions of the heliosphere, and led to a number of surprises concerning the physics that governs this enormous system and also provided insights on the plasma processes at ~100 AU that were substantially at variance with previous theories and models.

Assessment of Overall DWG Science

The Cassini MAPS DWG was successful in carrying out a robust and complete science investigation over the seven-year cruise and more than thirteen years in orbit at Saturn (the nominal mission plus extensions). The Cassini mission addressed each of the nominal and extended mission science objectives. As is typical in scientific investigation, the process of answering questions typically creates new unanticipated questions. This was certainly the case for the Cassini mission and MAPS science, in particular. Cassini was able to make advances in these unanticipated areas due to the capabilities of the Cassini spacecraft and the ability to plan robust and exciting extended mission designs. Although there are certainly questions that are left for future mission to answer (see section entitled Open Questions for Saturn System Science), all of the MAPS science objectives were addressed and advances were made. In the section entitled MAPS DWG Science Assessment, Table MAPS-1 indicates that all MAPS key science objectives were completed except for the determination of Saturn's internal rotation rate. Although tremendous advances have been made to address this determination, as outlined in the Key Open Questions,

the relationship of the SKR to the true rotation period of Saturn is still under investigation. For this reason, this science objective is marked as partially completed.

Key Open Questions

- Internal rotation rate of Saturn.
- Rotational modulation in axisymmetric configuration.
- How are mass and magnetic flux transported in the middle and outer magnetosphere?
- Solar wind control of the Saturnian magnetosphere.
- Why do neutral particles dominate the Saturnian magnetosphere in contrast to Jupiter?
- Very limited plasma measurements in auroral acceleration and source region of related SKR.
- Understanding the Enceladus plume-magnetosphere interaction. Crossing too fast for better time resolution. Limited plasma measurements.
- Composition of the negative ions at Titan and > 100 amu positive ions.

KEY OBJECTIVES FOR MAPS DWG

The scientific goals of the MAPS DWG were, simply stated, to seek to understand as much about Saturn's magnetosphere, ionosphere, moon interaction, and plasma physics as possible. The key science objectives are listed below.

Characterize the vector fields as a function of position and time.

- **MC1b:** Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.
  - Investigate what controls the interplay between the Dungey and Vasyliunas cycles.
  - Study the solar cycle dependence of the magnetospheric dynamics.
  - Investigate magnetospheric structure: variations in force balance.
  - Investigate non-static and other variant radiation belt features.
- **MN1a:** Determine the dynamics of Saturn's magnetotail.
  - Study thoroughly the plasma sheet in Saturn's magnetotail.

- Investigate the relation between solar wind compression events and magnetotail dynamics.
- Investigate the plasma sheet thickness and scale height as functions of radial distance and local time.
- Statistically characterize magnetotail variations, especially those associated with plasmoids, and correlate them with changes in the inner magnetosphere.
- Critically evaluate the Dungey and Vasyliunas cycles in light of the new observations, especially those of flow speeds.

Characterize Saturn's interaction with the magnetosphere.

- **MN1b:** Conduct in situ studies of Saturn's ionosphere and inner radiation belt.
  - Investigate the effects on aurora of solar wind and seasons.
  - Are there UV satellite footprints on Saturn? (like at Jupiter)
  - Is there a seasonal variation in auroral activity?
  - Investigate solar wind–ionosphere–magnetosphere coupling through the auroral regions.
  - Investigate whether there are UV satellite footprints on Saturn and whether there are Region 1 currents connecting the ionosphere and the magnetopause.
  - Investigate the composition of Saturn's ionosphere.
  - Study whether there is a significant polar outflow from Saturn's high latitude ionosphere and whether the outflow exhibits seasonal or solar cycle variation.
  - Determine whether there is a radiation belt between the D-ring inner edge and the atmosphere.
- **MN2a:** Determine the coupling between Saturn's rings and ionosphere.
  - Study how field-aligned currents are coupled to the rings and satellites.
  - Explore the dust dynamics in the proximity region.
  - Investigate the mid-plane of Saturn's D-ring.
  - Determine the grain composition in the proximity region.
  - Investigate the possible interaction of lightning with the inner magnetosphere and the rings.
  - Investigate coupling between E-ring and the Enceladus neutral and plasma tori.

Characterize the absolute energy spectra, composition, and angular distribution of energetic charged particles and plasma, including plasma wave phenomena, as a function of position and time.

- **M_AO2:** Determine current systems, composition, sources, and sinks of magnetosphere-charged particles.
- **M_AO3:** Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.

Determine the rotational, seasonal, solar cycle, and secular variations of SKR and its relation to magnetic field oscillations.

- **M_AO1:** Determine the configuration of the nearly axially symmetric magnetic field and its relation to the modulation of SKR.
- **MN1c:** Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the SKR periods are imposed from close to the planet (3–5 R_S) out to the deep tail.
  - Determine what controls the SKR periods and whether there is a solar cycle and/or seasonal variation.
  - Investigate the coupling mechanism between the SKR periods and the internal rotation rate.
  - Study whether the ionosphere and/or thermosphere is differentially rotating.
  - Determine which hemispherical SKR period dominates other periodicities in the magnetosphere and whether this varies with time.

Investigate satellite–magnetosphere interactions.

- **M_AO5:** Investigate interactions of Titan's atmosphere and exosphere with the surrounding plasma.
- **M_AO4:** Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.
- **MC1a:** Determine the temporal variability of Enceladus' plumes.
  - Investigate temporal variations in Enceladus gas production and plume composition, on the scale of seasons and solar cycle.
  - Study plume neutral gas composition.
  - Investigate the physics of the dusty plasma environment.
  - Determine how the magnetosphere reacts to changes in (plume?) gas production rates by studying Enceladus' auroral footprint.
  - Study variability in dust-to-gas mass ratio.

- **MC2a:** Observe seasonal variation of Titan's ionosphere from one solstice to the next.
  - Study how intensity variations of energetic ions and electrons affect the energy deposition in the atmosphere, and the degree of ionization at different depths.
  - Investigate how the energy input from energetic particles varies when Titan resides in the plasma sheet or magnetosheath.

Cruise science and Jupiter objectives.

- **J_AO3:** Explore the dusk side of Jupiter's magnetosphere and intermediate regions of the magnetotail unvisited by previous spacecraft.
- **J_AO4:** Obtain the first high-resolution images of the Io torus.
- **C_AO1:** Extend the sensitivity of composition measurements of interstellar ions by approximately three orders of magnitude.
- **C_AO2:** Investigate the behavior of the solar wind during solar minimum, for comparison with earlier Galileo and Ulysses measurements.
- **C_AO4:** Extend studies of interplanetary dust to the orbit of Saturn.
- **S_AO4:** Study the diurnal variations and magnetic control of the ionosphere of Saturn.

MAPS DWG Science Assessment

Table MAPS-1. MAPS Science Assessment. AO and TM Objectives are paired with MAPS science objectives.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

MAPS Science Objectives	AO and TM Science Objectives	MAPS Science Assessment	Comments
Characterize the vector fields			
Seasonal and solar cycle variations	MC1b		
Magnetotail configuration and dynamics	MN1a		
High-order magnetic moments of Saturn	M_AO1, MN1c		
Saturn's interaction with the magnetosphere			
Magnetospheric convection	MN1b		
Aurora and satellite footprints	MN1b		
Plasma loss into the magnetotail	MC1a, MN1a		
Ionospheric convection	MN1b, S_AO4		
Composition of ionosphere/thermosphere	MN1b, MN2a		
Particle distributions			
Plasma sources and sinks	M_AO2		

Table MAPS-1. MAPS Science Assessment. AO and TM Objectives are paired with MAPS science objectives.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

MAPS Science Objectives	AO and TM Science Objectives	MAPS Science Assessment	Comments
Plasma kinetics	M_AO3		
Radiation belts	M_AO3, MC1b, MN1b		
Wave-particle interactions	M_AO3		
Periodicities			
Saturn's magnetic field and its relation to the modulation of SKR	M_AO1, MN1c		
Solar cycle/seasonal variation of SKR periods	MN1c		
SKR periods and Saturn's internal rotation rate	MN1c		Rotation rate is still not known
Differential rotation of the ionosphere and/or thermosphere	MN1c		
Satellite/ring magnetosphere interactions			
Titan's interaction with the surrounding plasma	M_AO4, M_AO5, MC2a		
Interaction of the Enceladus plume with the magnetosphere	M_AO2, M_AO3, MC1a, MN2a		
Ring-magnetosphere interaction	M_AO3, MN2a		
Cruise science & other science			
Jupiter's magnetotail, Io Torus	J_AO3, J_AO4		In spite of no-cruise science decision by Project Management
Interstellar particles	C_AO1		
Solar wind from Earth to Saturn	C_AO2		
Interplanetary dust studies of Saturn	C_AO4		

MAPS DWG Magnetosphere Science Results

Titan Science

Instruments on the Cassini Orbiter carried out extensive measurements of the upper atmosphere and ionosphere of Titan as well as its interaction with Saturn's magnetosphere. Over the course of the Cassini mission, the spacecraft performed 127 flybys of Titan. The flybys, varying in trajectory and closest approach altitude, served as gravity assists to change Cassini's trajectory, but also to bring our understanding of the moon's environment to an unprecedented level.

Titan's upper atmosphere and its interaction with the surrounding plasma

- **M_AO5:** Investigate interactions of Titan's atmosphere and exosphere with the surrounding plasma.

- **M_AO4:** Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.
- **MC2a:** Observe seasonal variation of Titan's ionosphere from one solstice to the next.

TITAN'S NEUTRAL ATMOSPHERE

The first neutral measurements made by MAPS instruments were made during the TA pass. These measurements were made in order to characterize the initial ionospheric density and thereby assess safe altitudes for future flybys.

Observations of neutral densities (mainly N_2) have allowed us to make inferences into the thermal structure of Titan's upper atmosphere [cf. Müeller-Wodarg et al. 2008, 2006a; Cui et al. 2009, 2008; Magee et al. 2009; Westlake et al. 2011; Snowden et al. 2013]. The average thermospheric temperature derived from Ion and Neutral Mass Spectrometer (INMS) data is approximately 150 K, which is in good agreement with pre-Cassini estimates [Müeller-Wodarg 2003, 2000; Müeller-Wodarg and Yelle 2002]. However, the temperature of Titan's thermosphere exhibits a high degree of variability that was not predicted prior to Cassini, see for example, Müeller-Wodarg [2003, 2000; Müeller-Wodarg and Yelle 2002]. Pre-Cassini models calculated day–night variations on the order of 10–15 K. Cassini has observed temperature variations much larger than this over the course of a single Titan day, even when observing the same region of atmosphere at a similar local time. The variations in temperature are not correlated with solar input, indicating there are additional heating/cooling mechanisms with magnitudes that are similar to solar insulation. The short-timescales associated with the large variations in temperature has led some to postulate that the magnetosphere may provide sporadic and localized inputs [Westlake et al. 2011] or internal gravity waves may be depositing significant energy into the upper atmosphere [Müeller-Wodarg et al. 2006b; Snowden et al. 2013]. Atmospheric escape may also significantly alter the temperature of the upper thermosphere [Tucker et al. 2013] as can spatial and temporal variation of minor species that are strong sources of radiative cooling such as hydrogen cyanide (HCN) and CH_4.

Prior to the arrival of Cassini at Saturn, modeling of the production of energetic neutral atoms (ENAs) began as a preparation for the first observations.

The INCA instrument had the capability of remotely measuring the exosphere of Titan, an ambient neutral population too tenuous to be measured by in situ mass spectrometers. Prior to the arrival of Cassini at Saturn, modeling of the production of energetic neutral atoms (ENAs) began as a preparation for the first observations. Amsif et al. [1997] developed a model that included the inner and outer exosphere, as well as the five major species contained in Titan's atmosphere, namely, H, H_2, N, N_2, and CH_4. The ENA production was modeled using a proton spectrum from the Voyager flyby. Taking into account the production from both the inner and outer exosphere (estimated using a Chamberlain model), they predicted that Cassini would be able to image the

exosphere out to at least five Titan radii. Dandouras and Amsif [1999] analyzed the production of synthetic ENA images while taking into account the same exospheric model from Amsif et al. [1997], but included the geometry of the interaction region and the expected ENA trajectories. They concluded that the INCA instrument would be able to provide information regarding the ion fluxes and spectra, as well as the magnetic field environment in the vicinity of Titan, based on a shadowing effect produced by the presence of the moon itself.

Combining data from the INCA and the INMS instruments, Dandouras et al. [2008] calculated profiles of the main exospheric species that revealed the non-thermal nature of their distributions. They also found that the ENA emissions from the interaction region get absorbed below an altitude of about 1000 km, where energetic ions deposit their energy. In terms of the extension of the atmosphere, they were able to measure it up to an altitude of 40,000 km.

Using data from SOI to 2007, Brandt et al. [2012] studied the exospheric composition of Titan. For this, 36-minute accumulation time hydrogen data from the INCA detector when observing Titan without the magnetosphere behind it were analyzed. Combining these observations with a model for the production of ENAs, they found that the molecular hydrogen exosphere of Titan extends to a distance of about 50,000 km (almost 20 Titan radii) confirming the lower limit of 5 Titan radii obtained by Amsif et al. [1997]. Taking into account the profiles obtained and the fact that ENAs have direct access to Titan's atmosphere, they estimated a precipitating energy flux from ENAs of 5×10^6 keV/(cm^2 s), a number comparable to previous estimates of precipitating energetic ions [Sittler et al. 2009a] and solar extreme ultraviolet (EUV) [Tobiska 2004].

TITAN'S IONOSPHERE

Voyager measurements, both in situ of the magnetotail and radio occultation of the main ionosphere, showed the existence of an ionosphere at Titan [Neubauer et al. 1984; Bird et al. 1997]. Subsequent theoretical modeling suggested that the ionospheric composition could be quite complex, largely due to the presence of hydrocarbons associated with dissociation and ionization of methane [Nagy and Cravens 1998; Keller et al. 1998, 1992; Fox and Yelle 1997]. But the series of Cassini measurements by the MAPS instruments quantified the ionospheric densities and the extent of the ionosphere.

The main structure of Titan's ionosphere emerged after a few flybys [Ågren et al. 2009, 2007; Robertson et al. 2009] and it became clear that solar EUV radiation dominated the ionization of Titan's upper atmosphere, and varied with the long-term EUV output from the Sun [Edberg et al. 2013a; Madanian et al. 2016; Shebanits et al. 2017] (Figure MAPS-1). Energetic particle precipitation from the magnetosphere is important on the nightside of Titan, but only occasionally makes a significant difference on the dayside [Edberg et al. 2013b]. A most surprising find was the importance of the ionosphere for the production of complex organic chemistry and aerosol particles (dust) below about 1100-km altitude, see for example, Coates et al. [2011, 2007]; Wahlund et al. [2009]; Vuitton et al. [2009]; Ågren et al. [2012]; Lavvas et al. [2013]; Shebanits et al. [2016; 2013], where the Langmuir probe provided a measure of the detailed amounts of organic ions and charged

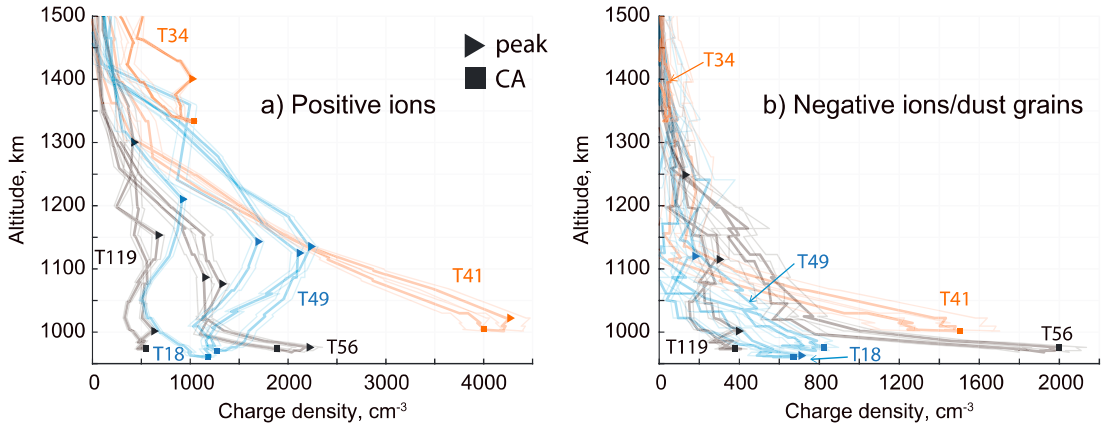

Figure MAPS-1. Examples from six flybys of Titan of altitude profiles of the positive ion and negative ion/aerosol number densities as derived from the RPWS Langmuir probe measurements [Shebanits et al. 2017]. Note the dominance of charged aerosol particles below 1100 km. Dayside flybys are colored in orange, terminator in blue, and nightside in black; the triangles mark the peaks and the squares mark the closest-approach (CA) maxima.

aerosol particles. The mechanism starts with EUV producing an N_2^+ ion that then reacts primarily with methane, with subsequently more complex C-H-N chemistry and aerosol formation [Lavvas et al. 2013].

The major ion species produced in the ionosphere is N_2^+, since N_2 is the major neutral species. However, chemical considerations told us that the main ion species at mass 28 is not N_2^+ but $HCNH^+$, so another ion species, CH_3^+, was used to almost directly deduce ion production rates [Richard et al. 2015a, 2015b; Vigren et al. 2015; Sagnières et al. 2015]. The rapid chemical reaction of N_2^+ with CH_4 produces CH_3^+ (mass 15). The ionization rate of CH_4 can be deduced by the measured CH_4^+ ions at mass 16 [Richard et al. 2015a, 2015b].

Sources of ionization deep on the nightside were also studied by Cassini. Globally, solar radiation accounts for 90% of total ionization, but precipitation of energetic electrons and ions leading to ionization is obviously locally important on the nightside [Ågren et al. 2007; Cravens et al. 2009a, 2008a, 2008b; Vigren et al. 2015; Snowden and Yelle 2014a, 2014b; Edberg et al. 2013a, 2013b; Robertson et al. 2009; Galand et al. 2014]. As on Venus and Mars, the two possible sources of the nightside ionosphere are local/direct ionization from precipitation (i.e., a diffuse aurora) and transport of plasma from the dayside. Evidence for the precipitation source is provided by INMS measurements of primary or almost primary ion species (CH_3^+, CH_4^+, CH_5^+, …), which have short chemical lifetimes and could only be produced locally and also by MIMI data which provided in situ data to understand the upstream conditions at Titan's orbit as well as the energy deposition by energetic ions in the atmosphere. Cassini data from the T5 and T18 flybys has been used to study the energy deposition by energetic ions as well as the energetic protons [Cravens et al. 2008a, 2008b; Cui et al. 2009; Smith et al. 2009].

Modeling combined with Cassini data determined that the precipitation ionization source depends on magnetic topology and on the location of Titan in Saturn's magnetosphere. Incident

magnetospheric electron fluxes and the associated nightside ionosphere were more robust when Titan was located in the plasma sheet region as opposed to the magnetic lobes of Saturn's magnetosphere [Richard et al. 2015a; Rymer et al. 2009a] and that ionization rates can vary by up to 80% from one location to another due to finite gyro radius effects [Regoli et al. 2016].

The chemistry of Titan's upper atmosphere and ionosphere is complex due to the presence of a large number of organic species extending up to high mass numbers. The neutral and ion chemistry is linked together [Waite et al. 2007]. The INMS has played a key role in improving our understanding of this chemistry. Photodissociation and photoionization of N_2 and CH_4 form ion and neutral species that are very reactive and that initiate a series of reactions that produce increasing larger species, up to aerosol-sized particles [Waite et al. 2007]. Primary N_2^+ ions react with CH_4 to produce CH_3^+, which again reacts with CH_4 to produce $C_2H_5^+$. $C_2H_5^+$ reacts with HCN to produce the very abundant species $HCNH^+$. Reactions of $C_2H_5^+$ and $HCNH^+$ with C_2H_2, C_2H_4, and C_4H_2 drive a chain of reactions leading to families of $C_nH_m^+$ species, including protonated benzene ($C_6H_7^+$), and up to masses exceeding 99 Da [Anicich and McEwan 1997; Cravens et al. 2006; Vuitton et al. 2009, 2007, 2006; Westlake et al. 2014; Cui et al. 2009; Mandt et al. 2012]. See Figure MAPS-2.

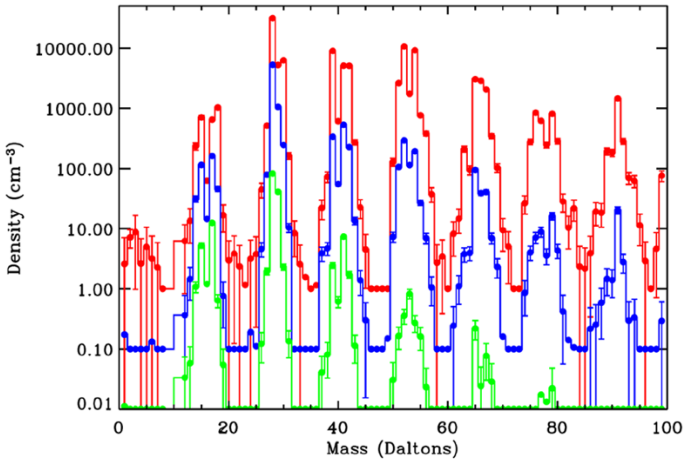

Figure MAPS-2. Shown are the first INMS measurements of ion densities versus Mass number at three different altitudes for the T5 nightside ionosphere [Cravens et al. 2006]. *Red*: 1027–1200 km. *Blue*: 1200–1400 km. *Green*: 1400–1600 km. Chemical complexity increases with decreasing altitude.

Titan's ionosphere consists of positive and negative ions, some of which have masses of up to and possibly beyond thousands of Da [Waite et al. 2007; Coates et al. 2007; Crary et al. 2009]. The study of Vuitton et al. [2007] identified over 100 ions in the INMS spectrum including several N-bearing species such as protonated ammonia (NH_4^+), $CH_2NH_2^+$, and CH_3CNH^+. Titan's atmosphere is a reducing atmosphere (little or no oxygen species are present) and as such the ionization will flow from species whose parent neutral molecules have low proton affinities (PAs) to those whose parent neutral molecules have greater PAs.

Measurements made by CAPS and INMS between altitudes of 950 to 1400 km were responsible for one of the major surprises of the Cassini mission, the high level of chemical

complexity observed in Titan's ionosphere. From the earliest close encounters electron spectrometer (ELS) detected heavy negatively charged ions with mass/charge up to 13,800 amu/q. In addition, heavy positive ions up to ~350 amu/q [Crary et al. 2009] and as high as 1000 amu/q [Coates et al. 2010] were detected by Ion Beam Spectrometer (IBS) (Figure MAPS-3). An unexpected level of chemical complexity was seen in the neutrals as well [Waite et al. 2007]. Before Cassini, models of Titan's chemistry had shown some complexity in the interaction of the neutral atmosphere with positive ions [Wilson and Atreya 2004]. The observations from Cassini necessitated more sophisticated modelling of the positive ion composition [Cravens et al. 2009b]. The negative ion observations by ELS were completely unexpected at the altitudes sampled by Cassini, opening up a whole new field for modeling and understanding the complex chemistry of Titan's atmosphere.

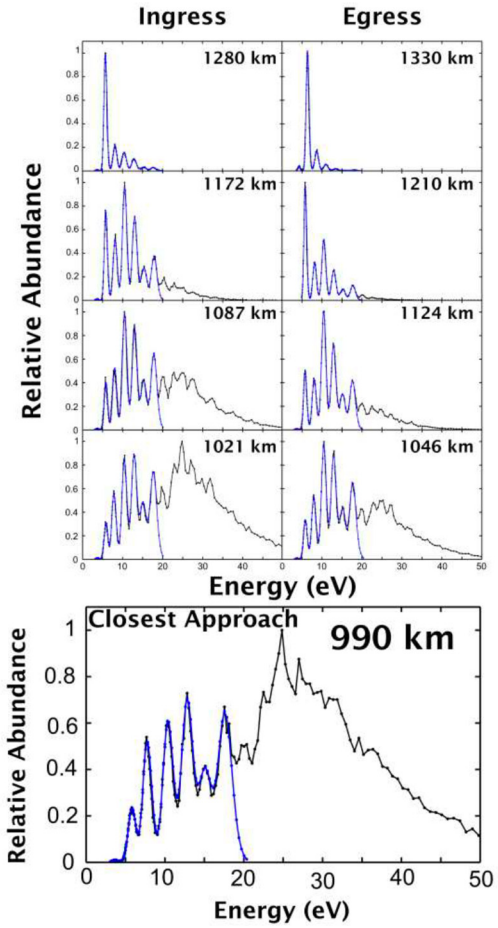

Figure MAPS-3. Shown are nine ion mass spectra obtained by the CAPS-IBS instrument at various altitudes during the T26 flyby. The blue lines show the INMS data converted using the CAPS-IBS instrument response model.

Westlake et al. [2014] analyzed the T57 flyby in detail between the CAPS and INMS observations to determine the characteristics of the processes responsible for the production and

loss of the large hydrocarbons observed at Titan. The work suggested that an ion-molecule reaction pathway could be responsible for the production of the heavy ions, namely reactions that utilize abundant building blocks such as C_2H_2 and C_2H_4, which have been shown to be energetically favorable and that have already been identified as ion growth patterns for the lighter ions detected by the INMS.

An additional discovery made by the Cassini MAPS instruments is the presence of large negative ions in Titan's ionosphere. After initial discovery by CAPS, further studies have been made of the spatial distribution and density of these ions on parameters including altitude and solar zenith angle [Wellbrock et al. 2013; Desai et al. 2017]. Wellbrock et al. [2013] have shown that the highest densities of negative ions are found at lower altitudes. Moreover, the average altitudes where peak ion densities occur decrease with increasing ion mass. In addition, the maximum altitudes at which ions from a specific mass group are observed (the reference altitude) decrease with increasing mass group. The highest mass negative ions were observed during the T16 encounter. A recent analysis of this data shows that polar winter is where the heaviest negative ions are seen [Wellbrock et al. 2019]. This helps to constrain the chemical processes at work to produce these large ions. The relativity low-mass negative ions were identified as CN^-, C_3N^-, and C_5N^- in the first chemical models used to describe the negative ions seen at these altitudes [Vuitton et al. 2009].

While some progress has been made on formation of higher mass ions, this topic is still under study. The geometric configuration of heavy ions is relatively unconstrained, and chains, rings or even fullerenes may be possible. Sittler et al. [2009a, 2009b] have suggested that the latter may trap and transport oxygen to the surface although there are as yet no observations that confirm this hypothesis. Agglomeration of large molecules caused by charging [Michael et al. 2011] or chemical processes [Lavvas et al. 2013] have been suggested as potential mechanisms to produce the large negative ions. However recent work by Desai et al. [2017] shows that chains of negative ions at intermediate masses may provide another pathway for heavy ion formation. Heavy negative and positive ions may also link up to form embryo aerosols of both negative and positive charge [Coates et al. 2007; Crary et al. 2009].

Desai et al. [2017] used observations of negative ions by CAPS/ELS to show mass peaks where unsaturated carbon-chain negative ions such as CN^-/C_2H^-, C_3N^-/C_4H^-, C_5N^-/C_6H^-, etc., might exist. Higher mass ions ~117 ± 3 amu/q and 154 ± 8 amu/q could be longer negative carbon chains with 10 or 12 or more carbon atoms in saturated aromatic versions. Thus, negative ions exist at masses where INMS cannot measure positive ions, which makes the two instruments not only complementary in their measurements but make them highly dependent on each other if we are going to have deeper insight into the composition of Titan's ionosphere. A second example of INMS/CAPS interdependence are IBS observations of heavy positive ions above 1000 amu/q [Crary et al. 2009] which complements INMS measurements that are limited to $m/q \leq 100$ amu/q.

TITAN'S MAGNETOSPHERIC INTERACTION

All the Cassini MAPS instruments have provided data, that with associated modeling, has increased our understanding of Titan's plasma interaction with Saturn's magnetosphere and, rarely, with the solar wind plasma. Titan's interaction with the magnetosphere of Saturn results in the formation of an induced magnetosphere around Titan. The virtual absence of an intrinsic field at Titan makes this interaction mainly atmospheric as fields and charged particles from Saturn or the Sun impinge on the moon's chemically complex atmosphere, exosphere and ionosphere. Atmospheric interactions are common elsewhere in the solar system with Mars and Venus as their most typical examples. In these cases, as well as in Titan's, charged particles from its atmosphere (originating from photoionization, charge exchange and electron impact) become electromagnetically coupled to those carried by the plasma winds that flow past it [Bertucci et al. 2011].

The Cassini/RPWS sensors have mapped the interaction region—for example, Modolo et al. [2007a, 2007b]—proved the existence of cold ionospheric flows from Titan—for example, Edberg et al. [2011, 2010]—as well as more energetic ion pick-up [Modolo et al. 2007b] (Figure MAPS-4), and studied how these processes change when Titan enters the magnetosheath [Bertucci et al. 2008; Garnier et al. 2009]. Titan's ionosphere also acts as a conductive medium where electric currents generated in the induced magnetosphere close [Rosenqvist et al. 2009; Ågren et al. 2011]. The escape rate through the cold plasma was determined to be a few kg/s (10^{25} ions/s), which is considered small compared to the exosphere escape rates.

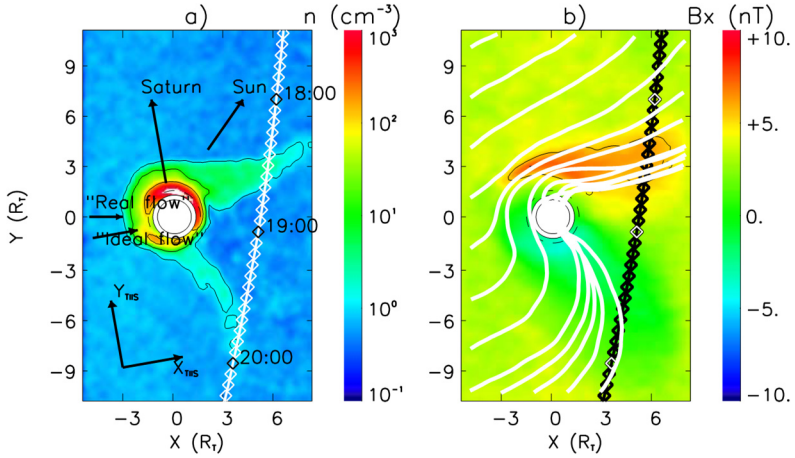

Figure MAPS-4. The induced magnetosphere of Titan as measured and modelled during the T9 flyby through the tail [Modolo et al. 2007b].

Many of the individual encounters with Titan have been studied. In joint studies of the TA flyby a comparison between MAG and RPWS-data was done by Wahlund et al. [2005] and a comparison between Cassini and Voyager data using both plasma spectrometer (PLS) and magnetic field data by Hartle et al. [2006a, 2006b]. Magnetic field and PLS electron data from flybys TA, TB, and T3 [Neubauer et al. 2006] showed a draping boundary as the outer boundary of strong magnetic field draping. In addition, the shape of the tail was found to be similar to a delta wing in aerodynamics.

It was shown that the long travel time of frozen-in magnetic field lines into the lower ionosphere of Titan led to the observation of old or fossil field lines compared with their times of arrival in front of Titan. This concept was later called memory effect by Bertucci et al. [2008] in a paper discussing Titan encounter T32 which occurred for the first time in the Saturnian magnetosheath but also contained old Saturnian magnetospheric field as a memory effect, see also Ma et al. [2009]. A special study of the magnetotails has investigated the tails by wake flybys with closest approach (CA) distances > 2.5 R_T in the whole set of flybys TA-T84 [Simon et al. 2014]. The resulting eight flybys confirmed the delta wing structure found in Neubauer et al. [2006] leading to a thickness of the wing of ±3 R_T.

The interaction between Titan and the corotating Saturnian plasma forms an induced magnetosphere with an elongated Alfven-wing-style magnetotail. During the first mid-tail flyby T9, Cassini plasma and magnetic field instruments detected in one tail lobe a magnetic flux tube connected with ionosphere and filled with cold ionospheric plasma. This magnetic structure indicates that Titan's ionosphere appears to be escaping along field lines down the tail, leading to particle loss from the atmosphere [Wei et al. 2007].

The first opportunity to study the induced tail at medium distances occurred at T9 [Bertucci et al. 2007]. This data analysis led to a number of modelling papers which helped to disentangle the detailed plasma and magnetic field characteristics [Kallio et al. 2007; Wei et al. 2007; Ma et al. 2007] of the complex magnetotail. All the early papers also led to the conclusion that an internal magnetic field of Titan was at most very small. Using the magnetic field observations on flyby orbits very close to Titan, Wei et al. [2010] found an upper limit on the moment of 0.78 nT × R_{Ti}^3 improving the Voyager 1 upper limit by a factor of five.

One most remarkable features revealed by Cassini MAG instrument was that Titan's induced magnetosphere is formed by layers of different polarity of the external magnetic field that allow to reconstruct the history of the moon's magnetic environment. Indeed, in the same way as older sediments lay beneath more recent deposits in geology, the magnetic fields fossilized in the deep layers of Titan's induced magnetosphere provide information about the orientation of the field Titan was exposed up to three hours before the encounter with Cassini [Bertucci et al. 2008]. This magnetic memory of Titan is significantly longer than at Venus and Mars and is a result of the capacity of Titan plasma to remove momentum form the external plasma. A further study of the ionosphere of Titan with its embedded magnetic field on the nightside ionosphere was published by Cravens et al. [2009a]. During the interaction between Titan's ionosphere and its ambient plasma, Cassini observations find that the lower ionosphere of Titan is often magnetized, with large scale magnetic fields and some structures resemble magnetic flux ropes. These flux ropes are either starting to form or maturely formed, with their axial orientations in agreement with the formation mechanism [Wei et al. 2010].

This magnetic memory of Titan is significantly longer than at Venus and Mars and is a result of the capacity of Titan plasma to remove momentum form the external plasma.

Titan's orbit is typically located inside Saturn's magnetosphere, but could occasionally move outside it into the magnetosheath or even into the solar wind. T96 was the first encounter presumably occurring in the supersonic solar wind and the observed structures at Titan's unique example of interaction with the supersonic solar wind were similar to structures found at Mars and Venus (an induced magnetospheric boundary and a collisional bow shock) [Bertucci et al. 2015]. Omidi et al. [2017] made simulations which showed that a deformed bow shock could form that would encompass both Titan and Saturn's magnetosphere.

To understand the internal magnetic moments of Titan, we use the radial component of Cassini magnetometer observations near Titan surface (from 950 km to 1100 km) is used to calculate the permanent dipole moment. The upper limit to Titan's permanent dipole moment is 1.25 nT × R_{Ti}^3, using the observations during the southern summer season of Saturn (April 2005 to March 2009). This weak internal field indicates the interior of Titan may not contain a liquid core sufficiently electrically conductive for a magnetic dynamo to be generated inside Titan or even for the simple amplification of the external magnetic field [Wei et al. 2010]. For the signs of the calculated internal field components, the g11 and h11 component, corresponding with the Titan-to-Saturn direction and the corotation direction, respectively, are in agreement with the signs of the averaged ambient field around Titan during the observation period. This indicates that these estimated internal moments may be due to the penetration of the ambient field into the interior of Titan, generating induced fields. After Saturn's equinox, August 2009, the ambient of field of Titan changes sign in the Titan-to-Saturn direction and the corotation direction, as Titan moved from below Saturn's current sheet to above it. Thus, we compare the calculated internal moments using the observations before and after Saturn's equinox, and find that the g11 and h11 moment change sign in agreement with the sign of Titan's ambient field.

The Cassini/CAPS instrument measured pick-up ions in the form of beams of CH_4^+ and N_2^+ that can be explained theoretically as the result of kinetic interactions between Titan and the magnetosphere [Hartle and Killen 2006; Hartle and Sittler 2007; Hartle et al. 2011]. It is no surprise that beam composition is consistent with the composition Titan's exosphere and atmosphere which is dominated by N_2 (98.4%) and CH_4 (1.4%) [cf. Waite et al. 2005].

Sittler et al. [2010] observed nearly field aligned outflows from the topside ionosphere during the T9 flyby and estimated the loss of methane ions due to pick-up from the exosphere at ~5 × 10^{22} mol/s [Sittler et al. 2009a]. The outflows serve ultimately as a sink from Titan's atmosphere of roughly ~5 × 10^{24} mol/s. Later, Coates et al. [2012] observed similar amounts of ionospheric outflows during the T9, T63, and T75 flybys. The theoretical cause of these outflows was originally discussed in Hartle et al. [2008]. It is produced by a field-aligned polarization electric field E_{pol} ~−$1/n_e e \nabla_{||} P_e$ so that above the ionospheric density peak the outward acceleration is > 10 times the force of gravity for m/q ~28 amu/q ions. (Note: the ionospheric electron temperature T_e ~1000° K is much greater than the ionospheric ion temperature T_{ION} < 180° K, which gives rise to charge separation and hence the dipolar electric field.) Sittler et al. [2010] found that the resulting ion outflow speeds were ~7 km/s with T_{ION} ~50,000° K. Therefore both significant accelerations and heating must have occurred at altitudes above 5000 km. Later, using electron observations, Coates et al. [2015] measured the total potential

drop of this electric field to be ~0.2 μV/m to heights ~15,000 km, which is sufficient to accelerate methane ions to the observed speeds ~5–6 km/s. Future 3-D hybrid simulations similar to that done by Lipatov et al. [2014, 2012, 2011] will be required to understand the heating, for example, due to wave-particle interactions, of ions to the observed high temperatures. In addition to the outflows, Sittler et al. [2010] also found evidence of Alfven waves during the T9 flyby with transverse velocity and magnetic field fluctuations that were anti-correlated with time and thus consistent with field-aligned propagation of these waves.

One other surprising observation that affects Titan atmospheric chemistry was CAPS' discovery of kilovolt oxygen ions with inflows ranging up to ~1023 O^+/s [Hartle et al. 2006a, 2006b] arriving from the magnetosphere at the exobase of Titan's atmosphere. Its likely origins are Enceladus and the rings, see Johnson et al. [2005]; Cassidy and Johnson [2010]. Oxygen combined with the complex chemical makeup of the ionosphere is most likely the source of CO in the atmosphere [Hörst et al. 2008; Krasnopolsky 2012]. The influx of O^+ into the atmosphere, where it undoubtedly affects Titan's already complex chemistry, is one more unusual and interesting aspect of Saturn's magnetosphere in which it acts as a conduit for the chemistry of one moon (Enceladus plumes) to affect the chemistry of another.

The peak ionospheric density at Titan was found to be dependent on solar cycle variations by Edberg et al. [2013a]. RPWS measurements of the electron density in the ionospheric peak region made during 2012 (T83–T88) showed significant increases compared to previous averages. These measurements suggest that a solar cycle variation caused by the rise of EUV fluxes during solar maximum. The study uses a power law to estimate the peak electron density at the subsolar point of Titan during solar maximum conditions and find it to be about 6500 cm^{-3}, i.e., 85–160% more than had been previously measured during the entire Cassini mission.

TITAN'S ATMOSPHERIC LOSS

Both CAPS and the INMS have provided crucial data for estimating processes that contribute to atmospheric loss. The review article by Johnson et al. [2009] highlights mechanisms and estimates of loss. They are primarily H_2 thermal (or Jeans) escape, CH_4 destruction/precipitation, N_2/CH_4 sputtering, ion pick-up causing ionospheric outflows, CH_4 hydrodynamic outflow [Yelle et al. 2008], and CH_4 plus H_2 hydrodynamic outflow [Strobel 2008].

Waite et al. [2005] presented the first observations of H_2, CH_4 and N_2 altitude profiles extending above the exobase to ~1400 km. There is a break in the altitude profiles above the exobase that is consistent with atmospheric escape. Cui et al. [2008] and Bell et al. [2009] estimated H_2 escape to be ~10^{10} amu/q/cm^2/s locally, and ~1.6×10^{28} amu/q/s globally (integrated over the entire surface area of the atmosphere). Sittler et al. [2010] reported that during the T9 and T18 flybys H^+ and H_2^+ ions were present in the flow of plasma moving towards Titan. The ions also happened to be moving perpendicular to the local magnetic field, leading Sittler et al. [2010] to conclude that they were seeing pick-up ions from Titan's hydrogen corona which can extend to ~20 Titan radii (i.e., out to the Hill sphere).

The primary chemical losses occur when methane is dissociated and ionized by photochemical reactions initiated by solar UV and particle impact. Further reactions with neutrals and ions then make heavier hydrocarbons and nitriles, which can eventually grow into aerosols that precipitate to Titan's surface. Sittler et al. [2009a], using an analogy to molecular clouds and planetary nebulas, suggested that negative chains of carbon atoms form and eventually fold into fullerenes, implying that the same might be going on at Titan. They then estimated precipitation to the surface to be ~2.7 × 10^{-14} kg/m^2/s at 950 km altitude and a global rate of ~4 × 10^{27} amu/q/s. This mass loss rate appears to dominate all other present day atmospheric loss mechanisms [e.g., Johnson et al. 2009] and, because it is large, in order to maintain a steady state methane concentration would require upward diffusion of methane, presumably from a source of methane from Titan's surface.

Sittler et al. [2009a] estimated the loss rate due to pick-up ions to be between ~5 × 10^{22} ions/s and ~10^{24} amu/q/s, which is much smaller than the lower bound given by Johnson et al. [2009] of ~10^{26} amu/q/s possibly due to the inclusion of scavenging down Titan's ion tail, see for example, Sillanpää et al. [2006]; Hartle et al. [2006b]. Escape caused by ionospheric outflows are ~5 × 10^{24} mol/s or ~10^{26} amu/q/s [Sittler et al. 2010; Coates et al. 2012] which may be included in the Johnson et al. [2009] estimate. The escape fluxes caused by sputtering, hot atomic recoils and charge transfer by ENAs also cause heating of the thermosphere and corona [De LaHaye et al. 2007a, 2007b]. Adding all these terms Johnson et al. [2009] find a total escape rate of ~0.32 to ~3.8 × 10^{28} amu/q/s.

Recent work highlights the need to reanalyze INMS data using detailed models of sputtering and energy deposition in the upper atmosphere in order to understand the energy distribution of neutral molecules in the exosphere region. Snowden and Yelle [2014a, 2014b] used Fourier's Law to extract energy deposition rates in the upper atmosphere from INMS data. They determined that precipitation of magnetospheric ions observed by CAPS is too small to explain the observed temperature variations and escape rates. They suggest that gravity waves produced in the lower atmosphere could produce the variability, but a source for the waves has not been identified.

Tucker et al. [2016] showed that using the Louisville Theorem approach, with a non-thermal energy distribution at the exobase, can lead to incorrect estimations of the upper atmospheric thermal structure and, consequently, escape rates due to collisions in the transitional region. Furthermore, such corona fits obtain different exobase energy distributions for N_2 and CH_4 density distributions, which is suggestive of different heating mechanisms occurring between species. Therefore, ion/pick-up fluxes and spectra extracted from CAPS data and model development of gas-kinetic models are needed for detailed simulations of the ion-neutral interaction. Such models can consider the ion - neutral interaction at the microscopic level, and include the production of hot recoil molecules.

The final topic is hydrodynamic loss proposed by Yelle et al. [2008] and Strobel [2008]. By using CH_4 and N_2 ingress altitude profiles with methane diffusing through atmospheric N_2, and then using the ^{40}Ar density profiles, they were able to separate the molecular and eddy diffusivities, which then required an upward methane flux ~4–5 × 10^{10} amu/q/cm^2/s and globally

~4.5 × 10^{28} amu/q/s. This estimate is close to the chemical destruction/precipitation of methane to heavier molecules and aerosols. The model by Strobel [2008] called slow wind argues that solar UV penetrates below the ionosphere where it is deposited. This excess heat is then conducted upward to higher altitudes to drive the hydrodynamic slow wind. But, in order to meet the upward flux required by Yelle et al. [2008] this heat must be transported above the exobase where there are no collisions to conduct the heat, which is its major weakness. Direct Simulation Monte Carlo (DSMC) simulations by Tucker and Johnson [2009] did not show any enhancement of the methane escape rate significantly greater than the Jeans escape rate ~3 × 10^{22} amu/q/s. Therefore, it is highly unlikely that Titan is currently undergoing hydrodynamic escape of CH_4. Tucker et al. [2013] showed that H_2 escape cools the background gas resulting in non-isothermal density profiles without requiring a significant escape rate. Volkov et al. [2011a, 2011b] examined the hydrodynamic escape problem in detail using DSMC simulations. They found that above a Jeans parameter of 6 at the exobase the thermal escape rate is enhanced towards the analytical Jeans rate only by a factor of 1.4–1.7. This is in contrast to Strobel [2008] which predicts a CH_4 escape rate orders of magnitude larger than the Jeans rates, due to an overestimation of heat conduction in the transitional region.

Icy Satellite Science

Interaction of the Enceladus plume with the magnetosphere

- **M_AO2:** Determine current systems, composition, sources, and sinks of magnetosphere charged particles.
- **M_AO3:** Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.
- **MC1a:** Determine the temporal variability of Enceladus' plumes.
  - Investigate temporal variations in Enceladus gas production and plume composition, on the scale of seasons and solar cycle.
  - Study plume neutral gas composition.
  - Investigate the physics of the dusty plasma environment.
  - Determine how the magnetosphere reacts to changes in (plume?) gas production rates by studying Enceladus' auroral footprint.
  - Study variability in dust-to-gas mass ratio.
- **MN2a:** Determine the coupling between Saturn's rings and ionosphere.
  - Study how field aligned currents are coupled to the rings and satellites.
  - Explore the dust dynamics in the proximity region.
  - Investigate the mid-plane of Saturn's D-ring.

- Determine the grain composition in the proximity region.
- Investigate the possible interaction of lightning with the inner magnetosphere and the rings.
- Investigate Coupling Between E-ring and the Enceladus neutral and plasma tori.

The initial Cassini MAPS teams began planning for Enceladus encounters as if Enceladus was just another small icy satellite albeit of some additional interest due to the fact that it was embedded in the E-ring. All this changed with discovery of an atmospheric plume at Enceladus by the magnetometer team [Dougherty et al. 2006] on February 17, 2005. With later confirmation by subsequent measurements by many Cassini instruments on later flybys Enceladus quickly became one of the most important objects in the Saturnian system. The main question to answer, "Does Enceladus have liquid water beneath the surface?", because the answer could be the major determining factor if life could exist there.

With the discovery of a thin neutral atmosphere by the magnetic signature of an electrodynamic interaction, all the other Cassini MAPS teams began to reexamine their previous data and to also plan new observing strategies for future encounters.

In 2005, and far from Enceladus, CAPS/Ion Mass Spectrometer (IMS) measured pick-up water group ions (O^+, OH^+, H_2O^+ and H_3O^+ or, collectively, W^+) throughout Saturn's inner magnetosphere [Young et al. 2005; Sittler et al. 2006a, 2006b, 2005; Tokar et al. 2008]. The source of these ions is charge exchange collisions that scatter water group neutrals, replacing a fraction of the co-rotating core distribution with a new and slower-moving ion population without changing the total ion content. The newly-created ions are moving near the local Keplerian speed, which is slower than the co-rotation speed, and hence are picked-up by Saturn's magnetic field. IMS detected these water-group ions within their source region, the Enceladus torus, thus providing the first measurements of W^+ ions throughout their toroidal source region and far from Enceladus. High ion count rates in IMS were observed at the ion pick-up energies, with largest signals near the Enceladus and Dione orbits.

Although encounters with Enceladus later in the mission would be at much closer distances, CAPS was still able to detect indications of a strong interaction between Enceladus and magnetospheric plasma … .

Striking observations were also obtained with IMS during the close encounters of Cassini with Enceladus. On the same encounter where MAG made its discovery, the spacecraft flew within 175 km of Enceladus, and passed through its surrounding cloud of neutrals and plasma. Although encounters with Enceladus later in the mission would be at much closer distances, CAPS was still able to detect indications of a strong interaction between Enceladus and magnetospheric plasma [Tokar et al. 2006]. Originally detected by the Hubble space telescope, Enceladus was known to sit in a cloud of neutral OH forming a torus around Saturn. The cloud detected by CAPS extends from about 3 to 8 R_S with maximum concentration of ~10^3 cm^{-3} inferred to exist near the orbit of

Enceladus (3.95 R_S). The OH cloud is produced by dissociation of H_2O, and although the peak concentration suggested that the largest source of water molecules was in the region near the orbit of Enceladus, the nature of this source was unknown. IMS measurements during the 2005 encounter established a strong perturbation of the plasma flow caused by Enceladus, and perhaps most importantly, the presence of W^+ ions. This population had been detected earlier during SOI [Young et al. 2005].

Later in the mission, during closer encounters with Enceladus, CAPS obtained in situ measurements of W^+ ions freshly produced in the dense Enceladus plume. The dominant species there are light ions (H^+, H_2^+), W^+ ions, and single water cluster ions, ($H_2O \times H_2O^+$). All were observed close to, and nearly due south, of Enceladus. The ions have kinetic energies in the IMS frame roughly equal to ions that are at rest with respect to Enceladus and rammed into the CAPS sensors at the spacecraft speed. This is the signature of freshly produced ions in the plume due, e.g., to charge exchange interactions of incoming magnetospheric ions with neutral plume gas. Figure MAPS-5 shows an example of these ions detected by IMS during the E3 encounter only 52 km from Enceladus. The high count rates close to the ion ram energies in CAPS (denoted by vertical arrows) are clearly visible. Further details of these data are discussed in Tokar et al. [2009].

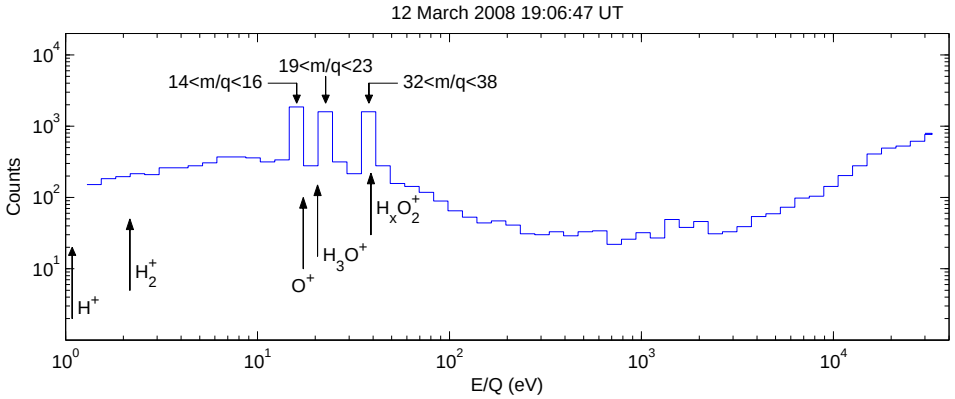

Figure MAPS-5. Individual ion counting rates versus energy per charge measured by IMS anode 5 within the plume during the March 12, 2008 (E3) flyby of Enceladus. Figure from Tokar et al. [2009].

The E7 encounter on November 2, 2009 provided additional observations of the plume stagnation region as Cassini passed directly through the Enceladus plume. The IMS detector sensitive to rammed ions observed stagnation and fresh ions at the ion ram energies. The strong interaction region within the plume is clearly visible in the CAPS IMS data as are the water group ions near 10 eV that are at rest in the Enceladus frame.

The E7 encounter also exhibited the close correspondence between IMS observations of ion slowing and the observed entry into the dense water vapor plume measured by INMS. The data suggest that magnetospheric plasma enters the dense plume leading to charge exchange with plume water vapor followed by subsequent pick-up into the corotating flow. The signature of this process is very sharp on the Saturn-ward side of the plume as the new ions are picked-up and gyrate away from Saturn. The transition out of the plume opposite Saturn for E7 is more extended

due to a number of factors—for example, ion drift velocity and variable ion gyro radii for the various masses created. Note that the IMS observed ion flow speed from the count distributions in the ram direction imply speeds as low as a few km/s in the Enceladus frame.

RPWS results from the E8 flyby reported observations of whistler mode auroral hiss emissions produced by magnetic field-aligned electron beams [Gurnett et al. 2011b]. A ray path analysis of the funnel emission shows the hiss source region within a few moon radii of the Enceladus surface. Figure MAPS-6 is adapted from Gurnett et al. [2011b] Figure 2, and shows the auroral hiss funnel from the E8 flyby in the top panel and the nearly field-aligned electron beams from the CAPS ELS instrument in the second panel. The magnetometer observations of the field-aligned currents which accelerate the electron beams are shown in the bottom panel. The ramp-like signature of the southward current is associated with a shear-mode Alfven wave excited by the moon-plasma interaction. Parallel electric fields, often associated with the Alfven wave, are believed to be accelerated by these waves along magnetic field lines that map to the Enceladus footprint in Saturn's aurora [Gurnett and Pryor 2012]. Sulaiman et al. [2018] showed evidence of currents

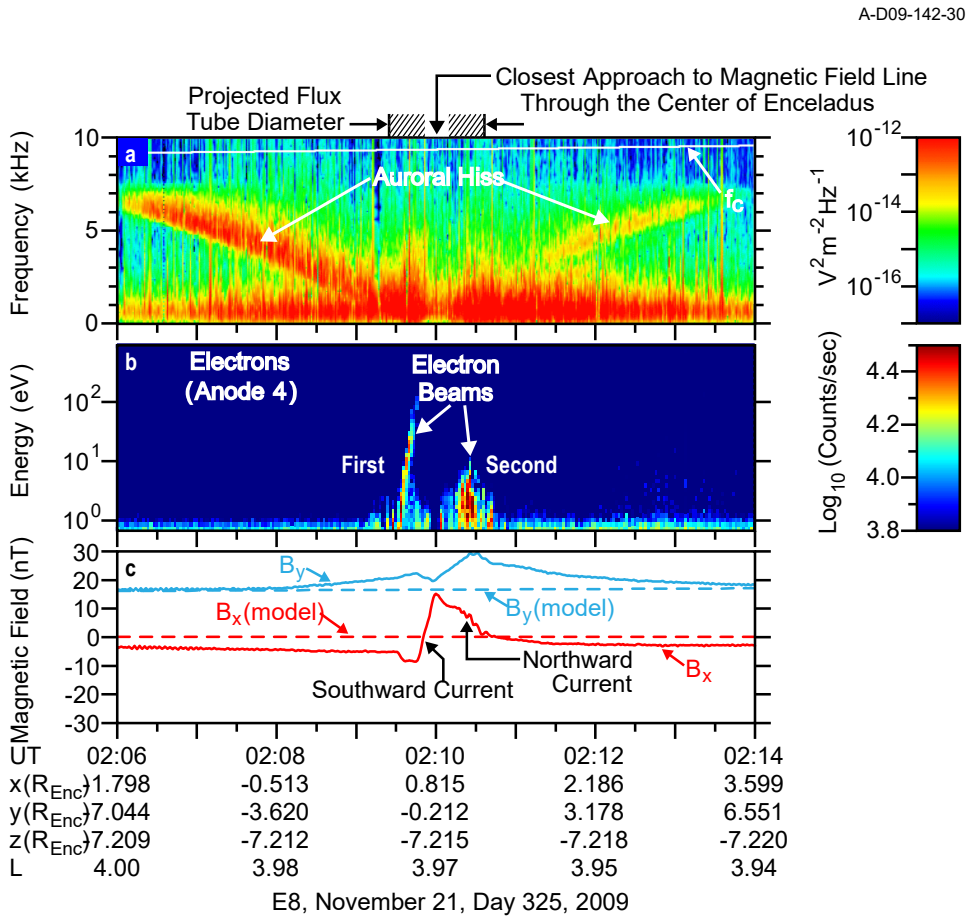

Figure MAPS-6. The auroral hiss funnel from the E8 flyby in the top panel and the nearly field-aligned electron beams from the CAPS ELS instrument in the second panel. Figure from Gurnett et al. [2011a].

between Enceladus and Saturn in the form of very low frequency (VLF) saucers generated by electron beams from Saturn's ionosphere on the Enceladus flux tube.

In addition to the dense neutral water vapor measured by INMS and the resulting cold plasma measured by CAPS and RPWS-LP, the south-polar plume of Enceladus was also found by CAPS and INMS to carry singly charged nanometer-size water-ice grains [Coates et al. 2009; Farrell et al. 2009; Jones et al. 2009; Hill et al. 2012; Morooka et al. 2011; Meier et al. 2015, 2014; Dong et al. 2015]. Such nanograins had been inferred to exist in various cold, tenuous geophysical and astrophysical environments, but the close Enceladus plume encounters by Cassini offered the first (and still the only) opportunity to measure and characterize the nanograins in situ. Before the CAPS shutdown in June 2012 there were three close Enceladus encounters that provided the CAPS ram pointing required to measure these high mass-per-charge particles—E3 on March 12, 2008, E5 on October 9, 2008, and E7 on November 2, 2009. The detailed analysis was reported by Hill et al. [2012]. RPWS data was used by Farrell et al. [2009] to present high-time resolution spectral evidence from the E3 flyby of small water-ice grain impacts on the electric antennas in the vicinity of Enceladus and a sudden, large drop in the electron density in the same region, a density depletion that they attribute to the absorption of electrons by sub-millimeter-sized icy particles. Morooka et al. [2011] presented Langmuir Probe observations to provide evidence for the presence of dusty plasma in the Enceladus plume region. The data show large increases in the ion and electron densities just south of the equatorial plane in the plume region for four Enceladus flybys in 2008, but there is a two order of magnitude difference in these plasma densities with $n_e/n_i < 0.01$. This plasma signature is attributed to electron absorption by dust grains in the plume, which subsequently become negatively charged. Data shows the strong drop in the ne/ni density ratio in this same region where the presence of dust grains had been previously determined [Farrell et al. 2009]. The density profiles of these micron size dust grains was measured by the CDA and RPWS instruments [Ye et al. 2014a]. Additionally, RPWS measurements show almost Keplerian ion speeds measured by the Langmuir Probe which are well below the plasma corotation speed, reaching a minimum below Keplerian speeds in the plume region. The interaction between the cold plasma and the negatively charged small dust grains is believed to cause this slowing of the plasma that moves with Enceladus, explaining the lack of a plasma wake behind the moon.

The presence of dust grains inferred by the ion-electron density difference led to a number of research results. Ye et al. [2014b] discovered that, after a dust grain impacted the RPWS electric antennas, a dust ringing effect was observed by the RPWS wideband receiver, characterized as periodic plasma oscillations. The frequency of these oscillations was shown to be consistent with the local electron plasma frequency, providing a measurement of the electron density. Densities derived from this method in the Enceladus plume region were found to be consistent with electron densities derived by the Langmuir Probe for four consecutive Enceladus flybys in 2008. Shafiq et al. [2011] presented Langmuir Probe observations of the E3 flyby to derive estimates of the dusty plasma parameters and found that the dust density would vary depending on the grain size. The submicron-sized dust grains dominate in the plume region with densities of 10^2 cm^{-3}. The micrometer-sized and larger sized grains are estimated to have densities of only 6.3×10^{-5} cm^{-3}.

Analysis by the CAPS team confirms that the nanograins are largely uncharged when they emerge from the surface vents, and become increasingly (mostly negatively) charged as they approach Cassini a few tenths of Enceladus radii away. The charged nanograin density versus distance from the surface source is shown in Figure MAPS-7, from Hill et al. [2012]. The dashed line shows the r^{-2} dependence that would be expected if the grains were already charged when they emerged from the source. The most plausible charging mechanism is electron attachment from the dense plume plasma. The non-neutrality of the nanograins observed by CAPS, n(−) >> n(+), plausibly cancels the opposite non-neutrality of the plume plasma observed by RPWS-LP. Most of the electrons missing from the plume plasma reside on the nanograins.

This dynamic atmospheric plume was shown by the Imaging team to be due to geyser activity on the southern hemisphere of Enceladus. The electrodynamic interaction involves southern and northern Alfvén wings such that the atmospheric influence not only shows up in the southern, but also the northern wing, hemispheric coupling [Saur et al. 2007]. Using these concepts and magnetic field observations of flybys E0, E1, E2, and neutral density measurements at E2 the time variability of the plumes was investigated [Saur et al. 2008]. Subsequent modelling based on analytical theory clearly showed that the magnetometer results required the presence of negatively charged dust particles [Simon et al. 2011]. The paper also proves the presence of the hemispheric coupling currents required by Saur et al. [2007]. The interaction was later modelled numerically in detail using a hybrid (fluid electron) kinetic code including charged dust particles [Kriegel et al. 2011]. As a unique feature at Enceladus dust–plasma interactions play an important role to explain the observations.

Further modeling has been applied to a spherical obstacle in a plasma flow to show the effect of the moon and local pick-up separately [Jia et al. 2010a]. With this model, we have refined the plume geometry with E2 data [Jia et al. 2010b] and constrained the outgassing rate of the Enceladus plume with data from the nine early flybys [Jia et al. 2010c, 2010d].

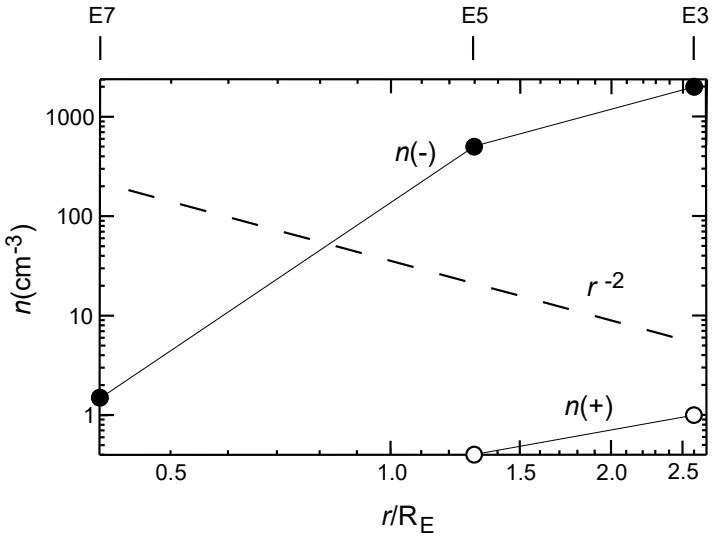

Figure MAPS-7. Total charged nanograin number density within the CAPS E/q range versus distance from the south-pole source vent.

Plume brightness is found to be varying by a factor of a few around the apocenter of Enceladus orbit, using visual images. In contrast, when we plot our deduced outgassing rate against time, we have found 50% variation in gas production rate during the first nine passes E0–E8. The magnetometer could not confirm this postulation with local interaction data. Then, the field perturbation perpendicular to both the direction of magnetospheric flow, and to the magnetic field has been studied with our multi-fluid code, to illustrate the effect of charged dust in creating such a field perturbation [Jia et al. 2011].

Beyond the plasma interaction physics that has been explored by the Cassini/MAPS team, extensive measurements by the INMS team has contributed to characterization of the neutral species in the plume, the plume distribution and to questions about the internal ocean.

The first close flyby of Enceladus with a ram pointing orientation for INMS occurred during the E2 encounter on the July 14, 2005 when Cassini passed with 168.2 km of the flank of Enceladus. The presence of water vapor emanating from the south polar cap was noted over 4000 km before the encounter. A day later on July 15, 2005, the first INMS measurements of the plume's composition were made in the plume's outer edge, and revealed that the plume consists predominantly of water vapor, with small amounts of carbon dioxide, methane, a species of mass 28 (carbon dioxide and molecular nitrogen were suggested), and trace quantities of acetylene and propane.

The next major milestone for INMS occurred during the E5 flyby that occurred at a much higher relative velocity of ~18 km/s, approached from the Northern hemisphere and fly out along the south polar axis. This produced the highest signal to noise mass spectra of Enceladus of the entire mission due to the long outbound duration in the plume. The integrated mass spectra, reproduced from Waite et al. [2009] Figure 1, shows a much more complex spectrum extending out to the limits of the INMS mass range (99 u) (Figure MAPS-8).

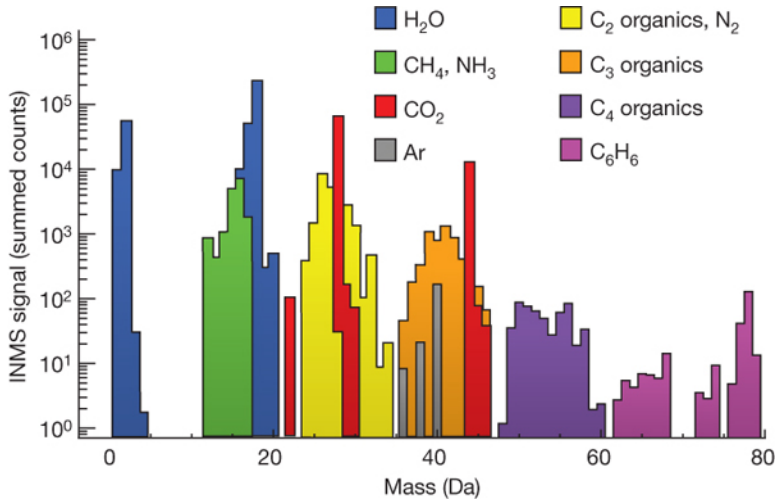

Figure MAPS-8. A complex spectrum extending out to the limits of the INMS mass range (99 u). Figure from Waite et al. [2009] Figure 1.

A mass deconvolution of the E5 integrated mass spectra indicates a host of complex organic compounds, as well as, the compounds previously cited on flyby E2: water, carbon dioxide, methane, mass 28, ammonia, acetylene, and propane. Of particular note was that water seems to be converted into molecular hydrogen and some other compounds abundance altered due to the high flyby speed. This conversion was interpreted and later verified [Walker et al. 2015] as due to raw titanium vapor from ice grain impacts reacting with water to form TiO and TiO_2 and leaving behind the H_2. The serendipitous side effect of this reaction allowed the INMS team to determine the D/H ratio in water from Enceladus, which was found to be similar to comet Halley ($2.9\ (+1.5/-0.7) \times 10^{-4}$) suggesting that Enceladus had never come into chemical equilibrium with the protoplanetary nebula of Saturn otherwise the ratio would have been much closer to the protoplanetary value of 2×10^{-5}.

The INMS data obtained during the E14, E17, and E18 flybys, all at relative flyby speeds of 7–8 km/s and all along or in parallel tracks near the Baghdad tiger stripe, provide a consistent and repeatable depiction of the mass spectra at relative speeds low enough that fragmentation effects are minimized. The spectra above 50 u (not shown) were near the noise level and further reinforce the point that the relative speeds above 8 km/s can lead to significant fragmentation of heavy organics buried in ice grains that complicate the interpretation of the mass spectra from E3 (~14 km/s) and E5 (~18 km/s). One can mass deconvolve the combined spectra from the slower flybys (E14, E17, and E18) (see Figure MAPS-9). The detailed analysis of this data set is the subject of a paper in preparation by Magee et al. [2018].

During six encounters between 2008 and 2013, the Cassini INMS made in situ measurements deep within the Enceladus plumes. Throughout each encounter, those measurements showed density variations that reflected the nature of the source, particularly of the high-velocity jets. Since

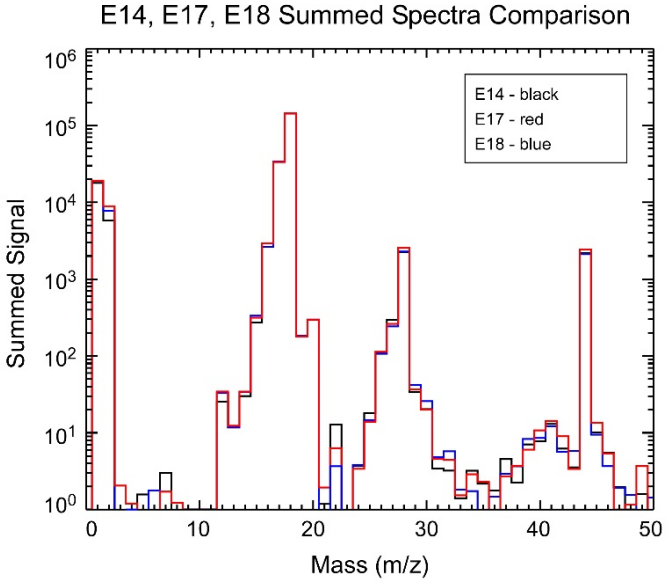

Figure MAPS-9. Overlaid mass spectra for flybys E14, E17, and E18. Note the consistency of the spectra.

the dominant constituent of the vapor, H_2O, interacted with the walls of the INMS inlet, changes in the external vapor density are tracked by using more-volatile species that responded promptly to those changes. To understand the plumes requires examination of each of the three components of Enceladus ejecta, fast and dense jets, slower diffuse gas, and ice grains.

The vapor plumes show variability that was first reported by Hedman et al. [2013]. A comparison of data from the last three encounters, E14, E17, and E18, are consistent with the VIMS observation of variability in jet production and a slower, more diffuse gas flux from the four sulci or tiger stripes. Teolis et al. [2017] used data from all INMS and Ultraviolet Imaging Spectrograph (UVIS) encounters to constrain a time-dependent and high-resolution model of the plumes.

During the final low-altitude flybys of Enceladus, the most abundant, non-sticky species in the plume, CO_2 at 44 u, was sampled at a higher rate, to enable higher-resolution measurements of local density variations along Cassini's trajectory, achieving resolution of 0.25 s temporal and 1.9 km spatial. As shown in Figure MAPS-10, CO_2 data from E17 clearly resolved density variations, indicative of gas jets, along Cassini's trajectory. Hurley et al. [2015] suggested on the basis of Monte Carlo models that the plume source may be continuously distributed, albeit variable, along the tiger stripes. These models included one lower-velocity component for the tiger stripes and a second, higher-velocity component for the jets. The complete plume three-dimensional structure is difficult to uniquely constrain solely on the basis of the few INMS flybys as multiple combinations of jet pointing directions and intensities can fit the data, and temporal variability further increases the potential solutions.

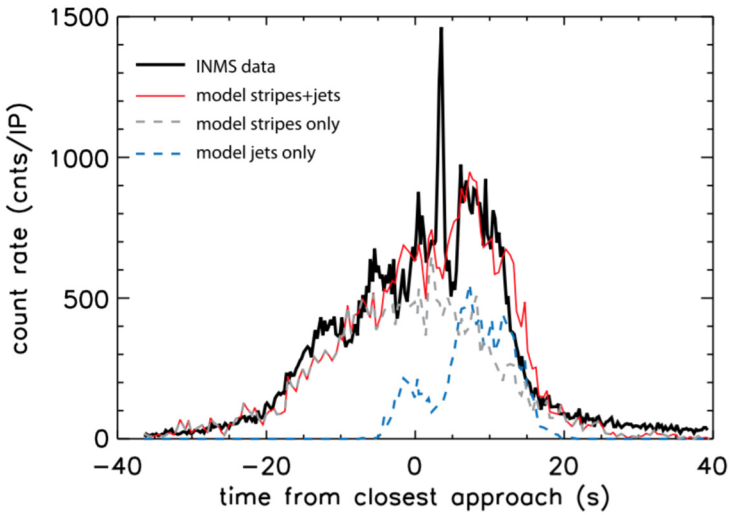

Figure MAPS-10. INMS measurements of mass 44 u species during the E17 flyby are shown in black. Model [Hurley et al. 2015] predictions using constant emission along the tiger stripes at 500 m/s and 270 K (gray dashed line) are selected to match the rise and fall on the outskirts of the plume. The jet model using Mach 4 (1500 m/s and 270 K) are included (blue dashed line) to reproduce the overall enhancement near closest approach. The sum of the two models, shown in red, reproduces the overall structure of the plume, but misses some of the fine structure.

During Cassini's close (99, 74, 74 km) E14, E17, and E18 flybys through the Enceladus gas/dust plume on October 1, 2011, March 27, 2012, and April 14, 2012, the INMS measured in situ the detailed spatial structure of the neutral gas along the trajectories. These encounters were the first to fly close enough to the plume sources with the required pointing and sufficient data acquisition rate, to enable resolution of individual gas jets within the broad plume by INMS. During these flybys two INMS objectives were to: 1) constrain the locations, magnitudes and gas velocity from the plume surface sources; and 2) extrapolate the three-dimensional structure of the plume, including the diffuse plume and individual major jets. Since these flybys, the INMS team have carried out detailed plume modeling, combining the along-track densities measured at different times/dates by INMS, with and occultation, surface temperature, and imaging data from UVIS, Composite Infrared Spectrometer (CIRS) and ISS. The goals were to constrain the physics of the jet sources, that is, the nozzle dimension and gas thermodynamic properties including temperature, density, flow and expansion rate, and provide necessary inputs for future modeling of the plume interaction with the Saturn system, that is, the E-ring and magnetospheric sources and mass loading.

The results of our studies are now published in the papers by Perry et al. [2015] and Teolis et al. [2017]. Teolis et al. [2017] describes a detailed comparison of several plume source scenarios. The findings indicate that a time variable source, consisting of: 1) a source continuously (but non-uniformly) distributed along the tiger stripes; and 2) sharp gas jets as inferred from ISS data [Porco et al. 2014], provide the best fit to the INMS and UVIS data.

In the curtain and jet cases, the model suggests that a gas source with a Mach number distribution, containing a slow (with thermal velocity, Mach 0) isotropic emission, and a super-sonic (high velocity) component, was required to fit the broad distribution, and the fine structure, respectively, observed in the UVIS/INMS data. The fits use a 4-point Mach number distribution ranging from zero (gas at rest) to 16 (the fast component), as necessary to best fit the shapes of the features in the INMS and UVIS data. The curtain model considered three cases: 1) a uniform emission along the tiger stripes; 2) emission correlated to the tiger stripe temperature from CIRS data (Figure MAPS-11); and 3) emission optimized to fit the INMS and UVIS data. For jets, the model considered two cases: 1) jets with equal intensities; and 2) jet intensity optimized to fit the data. The optimized models typically give multiple solutions, corresponding to reductions/enhancements in different combinations of jets, or different vapor source distributions along the tiger stripes. Figures MAPS-26–MAPS-30 show the averages over these solution 'families' to compare and contrast the quality of the fits in the cases of continuous distributed emission and of discrete gas jets. It is clear on the basis of the plots, that neither the thermal plume cases, nor the cases of uniform curtains or jets, provide very good fits to the data. Both optimized curtains and jets yield rough agreement with the data but, as shown in the plots, some features of the data are better matched by the jets. The models could not fit all of the INMS and UVIS data simultaneously with a unique model solution. Therefore, given the curtain and [Porco et al. 2014], jets as a modeling constraint, an assumption of time variability of plume source distribution and/or individual jets between the Cassini flybys, is required to fit the data. The changes over time of the individual jets appears to be chaotic, exhibiting no obvious correlation to the Enceladus mean anomaly, as seen (for the plume as a whole) in VIMS data [Hedman et al. 2013].

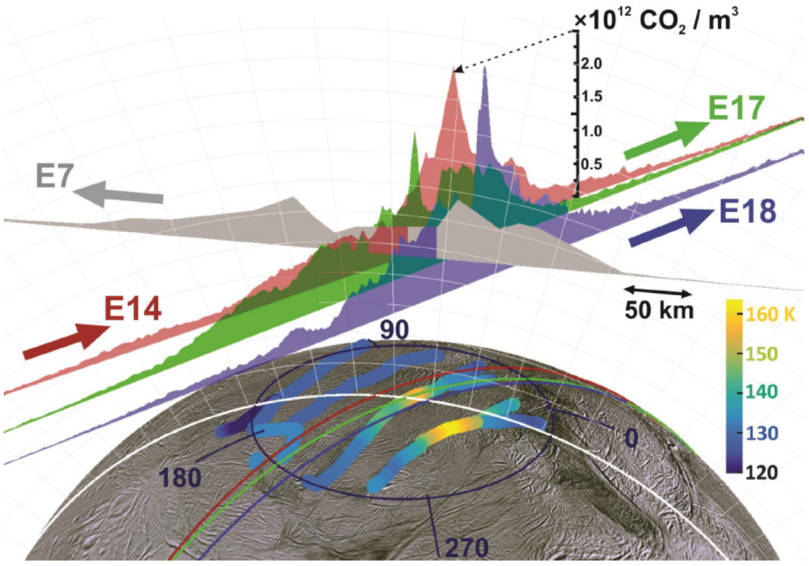

Figure MAPS-11. To scale 3-D representation of the E14, E17, E18 and also (lower resolution) E7 INMS data, with vertical areas representing (in linear scale) the density, and the flat base of the areas corresponding to the Cassini trajectories. Lines across the surface are the ground tracks. The Tiger stripes are colored according to the temperature estimated by CIRS. Figure from Teolis et al. [2017].

Table MAPS-2 shows the major species composition of Enceladus' plume gas and the volume mixing ratios reproduced from Waite et al. [2017] Table 1.

Table MAPS-2. The major species composition of Enceladus' plume gas. Volume mixing ratios are derived from Cassini INMS measurements [Waite et al. 2017].

Constituent	Mixing Ratio (%)
H_2O	96 to 99
CO_2	0.3 to 0.8
CH_4	0.1 to 0.3
NH_3	0.4 to 1.3
H_2	0.4 to 1.4

Ring Science

Ring-magnetosphere-ionosphere interaction

- **MN2a:** Determine the coupling between Saturn's rings and ionosphere.
  - Study how field aligned currents are coupled to the rings and satellites.
  - Explore the dust dynamics in the proximity region.
  - Investigate the mid-plane of Saturn's D-ring.
  - Determine the grain composition in the proximity region.

  - Investigate the possible interaction of lightning with the inner magnetosphere and the rings.
  - Investigate Coupling Between E-ring and the Enceladus neutral and plasma tori.
- **M_AO2:** Determine current systems, composition, sources, and sinks of magnetosphere charged particles.
- **M_AO3:** Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.

The Cassini mission brought about a profound new view the interaction of the amazing Saturnian main ring system with the magnetospheric space environment. During the Voyager era, it was presumed that meteors continually bombarded the rings. The spokes were thought to represent a stunning visual manifestation of these intense impacts. The associated impact-ionized vapor plume then delivered ring water and oxygen ions along connecting magnetic field lines to the ionosphere. These water ions were thought to chemically disrupt the ionosphere hydrogen cycle and deplete the ionosphere locally of electrons. It was also thought that these ring-generated ions possibly modify the color of the cloud tops. In this view, the rings were considered a source of quasi-energetic plasma delivering heavy ions to the exobase above the cloud-tops. Figure MAPS-12 shows the predicted impact-generated plasma flux from the rings, with peak densities over the dense portion of the central B-ring [Wilson and Waite 1989]. Voyager, unfortunately, did not actually fly over the rings and thus confirmation of this impact-driven ring plasma source could only be inferred.

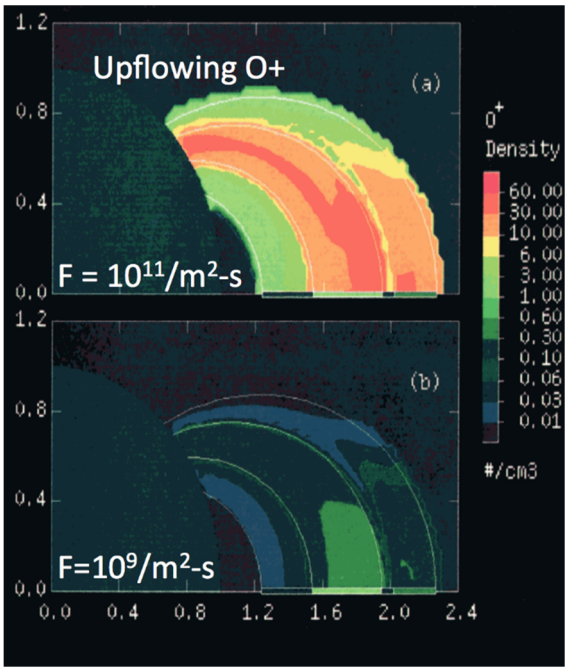

Figure MAPS-12. Wilson and Waite Impact-Driven Ring Plasma Model [Wilson and Waite 1989].

Cassini's orbit provided several important periods during which measurements were made of the rings and their interaction with the magnetosphere and ionosphere. First measurements of this important system began with Cassini's very first passage through the magnetosphere during SOI. During this period, Cassini crossed the ring plane in a gap between the F-ring and G-ring and also flew directly across magnetic field lines that connect back down to the main rings. The RPWS instrument thus obtained unique direct measurements of the plasma environment across the main A-ring, B-ring, and C-ring [Gurnett et al. 2005; Wang et al. 2006]. Near the very end of the mission, Cassini again was able to make measurements while crossing these flux tubes, this time by many instruments. After SOI, during the first few years of the mission, Cassini made a number of inclined and equatorial crossings of the E-ring, particularly near the orbit of Enceladus. Later, Cassini shifted to high inclination orbits and crossed the E-ring multiple times in 2016, providing opportunities to compare the vertical dust density profiles to those measured before equinox [Kurth et al. 2006; Ye et al. 2016a].

During Cassini's SOI on July 1, 2004, the spacecraft passed over the B-ring, A-ring, F-ring, and the Cassini division before descending (inside the G-ring) through the ring plane. The trajectory provided the first in situ plasma measurements over Saturn's main rings, complementing data obtained by the Voyager 2 plasma science instrument outside the main rings. During SOI, data form the MAPS instruments presented a new view of the plasma environment over the main rings. Data from RPWS [Gurnett et al. 2005] shows the plasma density as derived from the narrow-banded upper hybrid waves, electron plasma oscillations, and high frequency edge of the auroral hiss (see Figure MAPS-13). From the same RPWS measurements, Wang et al. [2006] were able

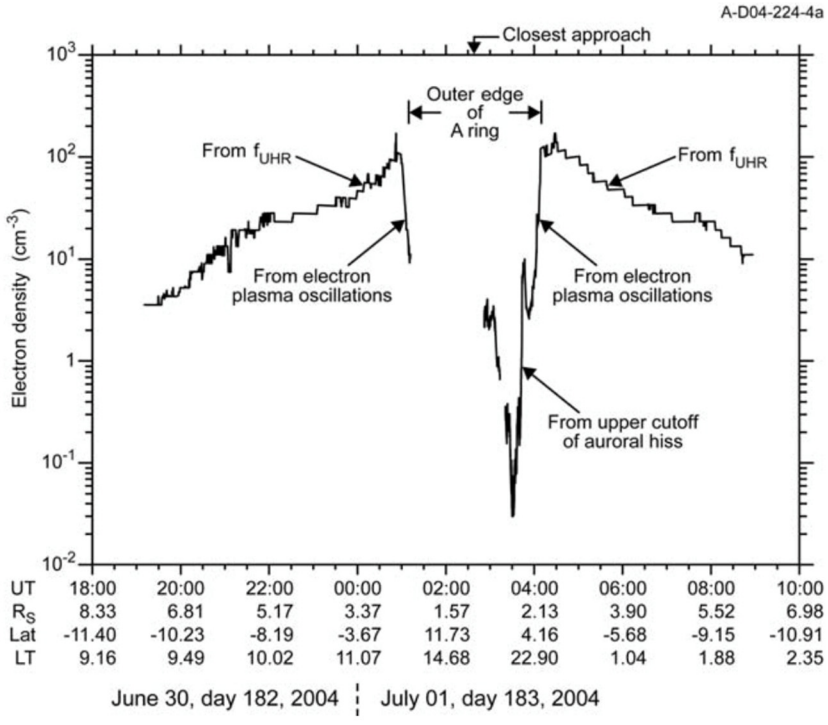

Figure MAPS-13. The electron density over the main rings as derived by the plasma waves detected by RPWS. See Gurnett et al. [2005] for more details.

to provide information on the micron sized dust at the inbound and outbound ring plane crossings before and after SOI.

This RPWS electron density profile was unexpected and almost diametrically opposite to what would have been predicted from an impact-driven ring plasma system, where the maximum in plasma density is expected in the central B-ring. There are two stunning features to this profile. First, immediately adjacent to the dense A-ring, there is an electron density maximum at over 100 electrons/cm^3 , with the high density region (>10/cm^3) extending out to beyond L = 5. It would later be found [Persoon et al. 2015, 2009] that this high density region is a plasma torus created by ionization and pick-up of new ions born in the Enceladus plume and a seasonal contribution from photo-ionized neutrals originating from the rings themselves. Second, the region over the main rings is devoid of plasma, with an electron density drop of near 10000 from the outer edge of the A-ring to values of 0.04 electrons/cm^3 at 1.76 R_S over the central portion of the B-ring [Xin et al. 2006; Farrell et al. 2017]. This void region has been identified as a ring plasma cavity (RPC) with its lowest density near the synchronous location. The profile of electron density over the main rings varied inversely with ring optical depth, with the lowest plasma densities observed over the central dense B-ring and a local maxima sense when passing over field lines connected to the Cassini Division. (In Figure MAPS-13, this Cassini Division plasma maxima is seen near 03:45 spacecraft event time (SCET) with the local peak near 10/cm^3.)

During the same period (SOI) CAPS IMS observed an enhanced ion flux (compared to background outside the rings) outside of the main rings and in the vicinity of the F-ring and G-ring as Cassini crossed the ring plane during orbit insertion on July 1, 2004. Near the edge of the main rings the IMS ion flux as a function of energy per charge provided strong evidence for the presence of O_2^+. Analysis led to the conclusion that the enhanced ion flux between the F-ring and G-ring consisted of the water group ions O^+, OH^+, and H_2O^+ (the other water group ion H_3O^+ could not be identified) coming from Enceladus with an admixture of O_2^+, predominantly from the extended ring O_2 atmosphere. The O_2^+ component appeared to be dominant at SOI and was later found to vary with season [Elrod et al. 2014, 2012] due to the changing orientation of the ring plane relative to the solar UV flux (Figure MAPS-14).

Near the edge of the main rings the IMS ion flux as a function of energy per charge provided strong evidence for the presence of O_2^+.

RPWS observations confirm the model of Tseng et al. [2013a] that the ring-ionosphere-magnetosphere interaction is driven by photolytic processes, not impact processes [Farrell et al. 2017]. Specifically, the Sun-facing side of the main rings are a source of photo-dissociated neutrals that then get ionized to form a relatively low energy exo-ionosphere. This exo-ionosphere cannot directly access the shadowed/unlit side of the rings: the ring particles represent obstacles to their transport. Thus, the plasma density on the unlit side is modulated by ring density, being lowest where the ring obstruction is the highest, (in the central B-ring). Local maxima are expected where the local ring particle density is low, like across the Cassini Division. There is little evidence of impact-generated plasma like that predicted during the Voyager era.

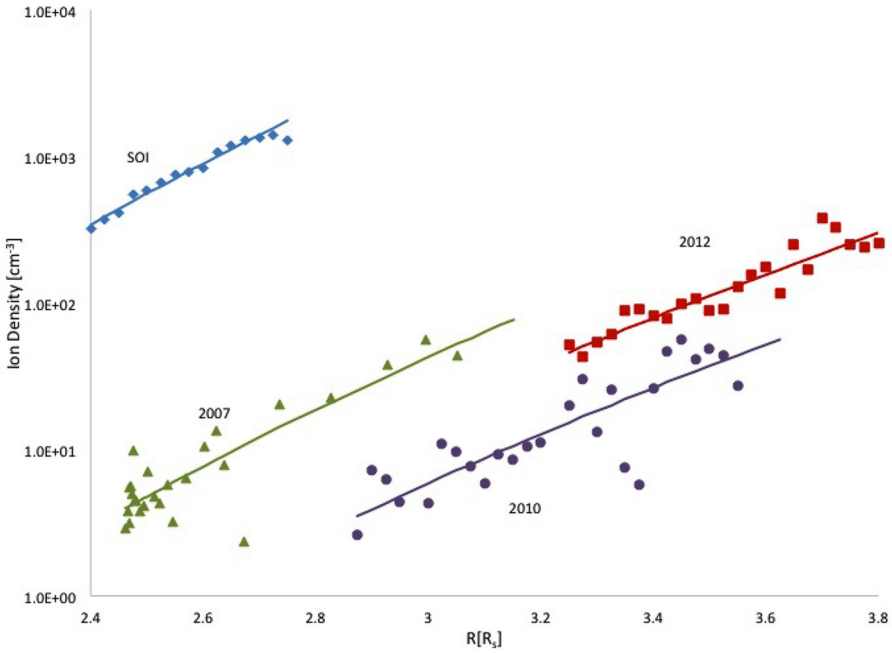

Figure MAPS-14. Ion densities extracted from CAPS IMS data at SOI in 2004, and inferred for subsequent years by modelling. The modeling indicates the seasonal dependence of ring plasma. This region contains ions formed from neutrals scattered out of the ring atmosphere as well as ions formed from neutrals in the Enceladus torus. SOI was dominated by O_2^+ and the later years by water group ions. Figure from Elrod et al. [2014].

The seasonal dependence observed and modeled using CAPS data confirmed that the O_2^+ ionization source was indeed solar UV acting on oxygen in the ring atmosphere as predicted by Tseng et al. [2010]. Seasonally varying oxygen was subsequently observed at much larger radii by the MIMI instrument, confirming that oxygen originating in the rings can be scattered throughout the inner magnetosphere and, consequently, also into Saturn's atmosphere. This likely accounts for oxygen observed in Saturn's thermosphere. Subsequent modeling [Tseng et al. 2013a] shows that model calculations based on the CAPS data were in reasonable agreement with that data.

Laboratory data showed that radiation decomposition of ice would lead to the production of roughly twice as much H_2 as O_2, thereby maintaining the near stoichiometry of irradiated ice grains —for example, Brown et al. [1982]. Indeed CAPS measurements have shown that the Saturnian magnetosphere is permeated with H_2^+ and H^+ from a variety of sources (Titan, the Enceladus torus, and Saturn's atmosphere), including the ring atmosphere [Tseng et al. 2013b, 2011]. Since H_2 is much lighter than O_2 it has a proportionately larger neutral scale height, and can also be easily scattered throughout the magnetosphere by the heavier molecules. Ionization of the H_2 component of the extended ring atmosphere, and the pick-up of H_2^+ formed by this process, was shown by Tseng et al. [2011] to be an important component of magnetospheric H_2^+ detected by CAPS [Thomsen et al. 2010].

Surprisingly, the IMS ion densities observed between the outer edge of the main rings and Mimas and populated by ionization of neutrals from the ring atmosphere and the Enceladus torus,

exhibited an unexpected radial dependence [Elrod et al. 2014, 2012]. Not only did the plasma detected by CAPS in this region exhibit a seasonal dependence, with the O_2^+ component dominated by the water products from the Enceladus torus at Equinox, but the observed radial dependence suggested that an ion loss process other that electron-ion recombination, charge exchange or diffusion was acting [Elrod et al. 2014; Tseng et al. 2013a]. Since the CAPS ion densities and the RPWS electron densities differed, particularly at SOI, the observed radial dependence of the CAPS ion data was subsequently determined to be due quenching of the ions on nano-grains. These grains, a fraction of which were negatively charged, were presumed to be emitted from the edge of the main rings and present in the tenuous F-ring and G-ring, acted as ion sinks [Johnson et al. 2017]. That this process was occurring in this region of the magnetosphere was subsequently confirmed by the RPWS instrument during the F-ring orbits when, unfortunately, the CAPS instrument was turned off.

IMS observed ion fluxes over the main rings consistent with the presence of atomic and molecular oxygen ions [Young et al. 2005]. CAPS IMS observations over the main rings detected both O^+ and O_2^+ at densities of a few per cm^3 using the IMS time-of-flight (TOF) sensor (Figure MAPS-15) [Tokar et al. 2005; Elrod et al. 2012]. Further analysis by Elrod et al. [2012] shows much higher densities of O^+ when CAPS was over the outer edge of the B-ring and again when CAPS was over the inner edge of the A-ring.

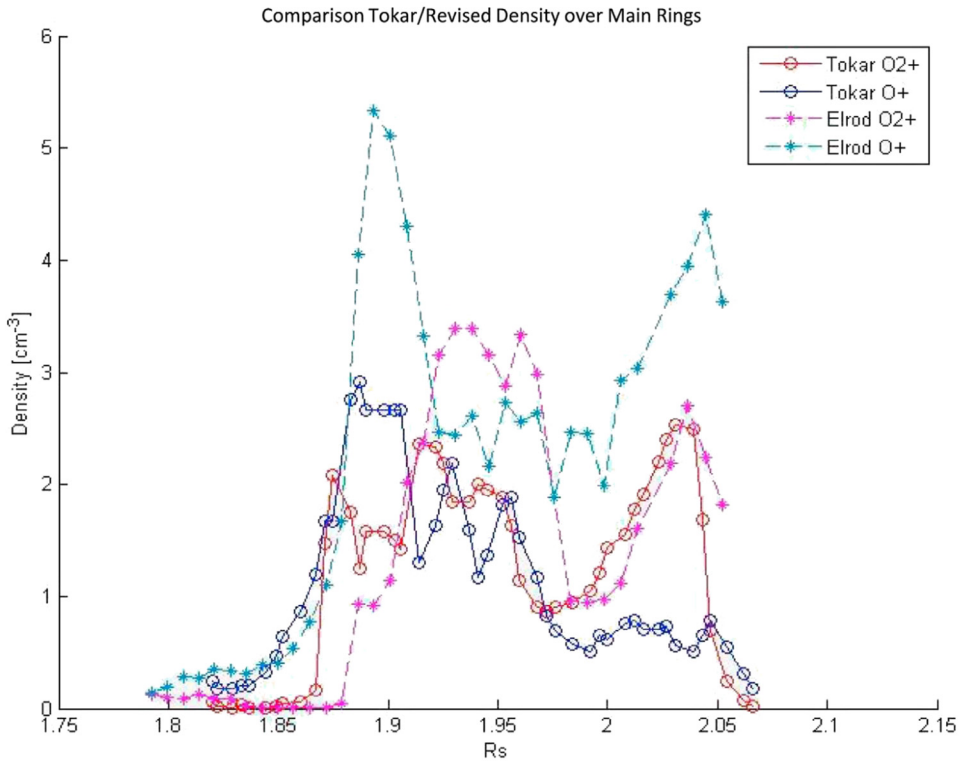

Figure MAPS-15. Densities of O^+ and O_2^+ obtained from IMS data over the main rings as a function of radial distance from Saturn in R_S. Data from Tokar et al. [2005] and re-analyzed by Elrod et al. [2012].

The IMS data suggested the presence of a ring atmosphere that was predominantly O_2 rather than H_2O and much more robust than predicted. Since the energetic ion density in this region is highly depleted due to absorption by ring particles, for example, Cooper et al. [2017], the CAPS team proposed that the atmosphere was produced by UV-induced decomposition of ice on the ring particles [Johnson et al. 2006]. Such a neutral atmosphere would have a scale height confining it close to the ring plane. Because ions were detected well above the ring plane, this also led to the prediction that ion-neutral scattering would produce both a ring ionosphere with a much larger scale height, and a neutral oxygen cloud that permeated Saturn's magnetosphere [Johnson et al. 2006; Luhman et al. 2006; Bouhram et al. 2006]. Following ionization, pick-up and scattering of the neutrals from this atmosphere was shown to populate the magnetosphere with oxygen atoms and molecules which are eventually ionized far from the main rings [Johnson et al. 2006]. Molecular oxygen ions in were eventually discovered in the inner magnetosphere as well [Martens et al. 2008]. This has been subsequently confirmed by additional data and modeling.

Interestingly, the INMS instrument also observed only water-group ions in the F-ring. Unlike the neutrals, the ion densities were not symmetrical with respect to the equatorial plane, varying in both total density and the relative fractions within the water group. The predominance of O^+ versus the other water-group ions indicates that there may be a source of O^+ other than as a byproduct of water. One possibility is that CH_4^+ contributes a fraction of the 16 u ions. The lack of O_2^+, which INMS observed during Cassini's insertion into orbit about Saturn, is likely due to the INMS energy limit: at the F-ring speeds, O_2^+ exceeds the INMS limit for ions. The lack of H_2^+ is surprising and not yet explained. As with neutrals, noise prevents INMS measurement of H^+ at 1 u.

In addition to the ion and electron plasma population detected in the vicinity of the ring, the INMS instruments was able to detect the neutral parent molecules. INMS found two neutrals with remarkable consistency during the F-ring passes: H_2 and a species at 28 u (Figure MAPS-16). The scale height, or the half-width-half-max of the INMS counts, for both of these species was approximately 3,000 km, or 0.05 Saturn radii (R_S). This parameter and the total counts were nearly identical in each pass.

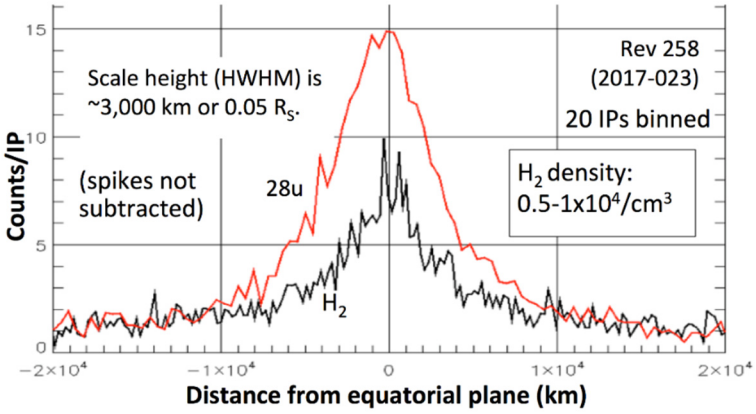

Figure MAPS-16. The major neutrals measured by INMS in the F-ring. Twenty measurements (integration periods or IPs) were binned for this plot.

Although H_2 was expected in this area of the rings, models and Earth-based observations predicted a larger scale height for H_2 from Saturn's atmosphere, and the narrow distribution of the observed H_2 suggests that it is more liked to originate in the rings. The lack of variability indicates a stable ring atmosphere. Atomic hydrogen is not measured by INMS due to instrumental noise at 1 u.

CH_4 (16 u) and CO_2 (44 u) are the only other measured species. They both have a count rate that is approximately 20% of the H_2 rate. CH_4 is confirmed by the presence of 15 u counts at the correct electron impact dissociative ionization ratio, the amount produced from CH_4 in the INMS ionization chamber. CO_2 is not a common dissociation product and may be a native species. It exists on the surface of several icy moons. Count rates for both CH_4 and CO_2 are depressed due to dissociation and they may be more abundant than indicated by the measurements. There are small amounts of 26 u and 27 u, which are expected products from ionization of C_2H_4, one possibility for the 28 u measurements. However, the count rates for these two cracking products are lower than expected if the entire 28 u signal was produced by C_2H_4. This deficiency implies that another species such as CO may contribute to the 28 u signal.

Several expected neutrals are missing, most notably H_2O and O_2. Since water is temporarily adsorbed onto the walls of the INMS inlet, H_2O counts are suppressed and delayed. Combined with the radiation background, which increases after passing through the equatorial plane, INMS would not detect low densities of H_2O, particularly after some loss due to high-velocity dissociation. Models show that O_2 could be abundant, but that densities decrease a factor of 1,000 approaching the location of Cassini's trajectory; moreover, much of the O_2 would be lost due to dissociation.

The observation suggested that there is a current system driven by the rings-magnetosphere interaction, with the electron beams and currents near the synchronous point … possibly being part of the current closure system.

In addition to the surprising neutral and plasma composition and the existence of a unique ring ionosphere, Cassini instruments were also able to the study the current systems that connects the rings, the ring ionosphere, Saturn's magnetosphere, and Saturn's own ionosphere. Xin et al. [2006] reported a strong auroral hiss signal detected at the deepest depletion of the electrons within the RPC near 1.76 R_S. The whistler-mode auroral hiss emission is a classic signature of the presence of energetic field aligned electron beams, in this case flowing outward from the rings along field lines connecting to the ionosphere. They reported that the RPC environment had a stunning similarity to plasma cavities found in polar auroral regions, usually associated with field aligned currents that drive the aurora. The observation suggested that there is a current system driven by the rings-magnetosphere interaction, with the electron beams and currents near the synchronous point at 1.76 R_S possibly being part of the current closure system.

Figure MAPS-17 illustrates the concept of this new ring current system presented in Xin et al. [2006]. While the plasma on field lines over the rings would be corotating, the particles and associated photo-dissociated gas of the rings would be moving in Keplerian motion, creating drag

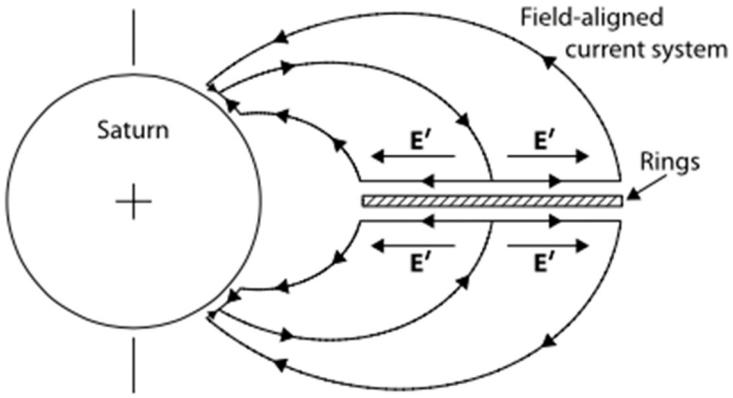

Figure MAPS-17. The proposed large-scale current system that would be induced in Saturn's magnetosphere by the interaction of the rings (including any associated gas) with the corotating magnetospheric plasma. Figure from Xin et al. [2006].

on the plasma. This drag creates an associated change in plasma speed, ΔV. Beyond the synchronous point, the plasma is slowed by the Keplerian-moving particles and gas, creating an outward radially-directed E-field in order to maintain the new sub-corotation speed E′ = ΔV × B. This new E-field drives an outward current, J, which acts to then form a magnetohydrodynamic J × B force to balance the plasma-ring drag force. Inward of the synchronous point, the corotating plasma is accelerated by the ring drag force, creating an inward radial E-field and current that forms a J × B force to offset the acceleration. At the edges of the rings, these cross-ring currents become field-aligned parallel current that close down to the ionosphere along connecting magnetic field lines at the outer edge of the A-ring near L = 2.25 and inner edge of the D-ring near L ~1.11. The rings thus behave as an electrical generator in the plasma, driving currents from the ring surfaces along magnetic field lines down to the ionosphere.

While detailed analysis of the proximal orbits is still ongoing, Wahlund et al. [2018] reported on a very strong Saturnian ionosphere D-ring electrical connection, which would represent the current closure of the Xin et al. [2006] model at the inner radial edge of the main rings. Using the RPWS Langmuir Probe, they found that Cassini passed through a cold, dense electron region during proximal perigee, which has been interpreted to be entry into the Saturnian ionosphere.

At higher altitude proximal perigee passes, like orbit 277, Cassini passed through the inner edge of the D-ring (also immersed in the outer edge of the ionosphere). In these cases, the electron density had a distinct bite-out or decrease near the equator which is believed to be due to the presence of D-ring particulates that have absorbed the local ionospheric plasma. The RPWS instrument also detected micron-sized dust grain impacts revealing the presence of these D-ring particulates. The complex dusty plasma interactions remain a subject of considerable study even after the end of the mission [Ye et al. 2018].

An additional surprise during the proximal orbits was that the MIMI/INCA and Charge-Energy-Mass Spectrometer (CHEMS) instruments, that were designed to measure energetic particles, were detecting signatures of D-ring dust falling into Saturn's equatorial atmosphere. These particles

are of 1–3 nm size, much smaller than what is detected by the CDA instrument designed to measure dust. The dust is reaching the atmosphere within 4 h and provides a continuous influx of about 5 kg/s from the rings into the atmosphere [Hsu et al. 2018; Mitchell et al. 2018].

The ionosphere of Saturn and its connection to the ring ionosphere system is still a work in progress. First in situ measurements by RPWS of the cold ionosphere properties have just been reported [Wahlund et al. 2018]. Several other manuscripts have been submitted, and they all show a very strong interaction between the D-ring and the ionosphere of Saturn, causing the ionosphere to become extremely variable with more than two orders of magnitude and trigger a dust-ionosphere layer near the equator.

Magnetosphere Science

Seasonal and solar cycle variations

- **MC1b:** Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.
  - Investigate what controls the interplay between the Dungey and Vasyliunas cycles?
  - Study the solar cycle dependence of the magnetospheric dynamics.
  - Investigate magnetospheric structure: variations in force balance.
  - Investigate non-static and other variant radiation belt features.

Cassini spent 13 years in Saturn's magnetosphere. This allowed the MAPS instruments aboard the spacecraft to make measurements of Saturn's magnetosphere and of the important moons such as Enceladus and Titan over more than a solar cycle and over nearly half of a Saturnian year. This allowed MAPS scientists to study the effects of both the solar cycle and the Kronian season on the magnetosphere. Many of the results of the seasonal and solar cycle variation are detailed in the section of this summary where their underlying processes are addressed. For example, see sections entitled:

- Titan's upper atmosphere and its interaction with the surrounding plasma
- Magnetotail configuration and dynamics
- Magnetospheric structure and convection
- Plasma loss into the magnetotail; Radiation belts
- Time varying modulation of SKR and associated planetary period oscillation (PPO) signals

In this section we will highlight just a few of the results related to solar cycle and seasonal effects produced by the MAPS instruments teams.

One of the most important discoveries of the Cassini mission was the identification the ring ionosphere, the ring sources of plasma and the activity of Enceladus. Many of these interesting new phenomena exhibited seasonal dependence due to the inclination of the rings relative to the activating solar UV. Amount these effects was the discovery of a seasonally-dependent source of plasma between the A-ring and Enceladus. Additionally, a seasonal dependence was observed and modeled using CAPS data that confirmed that the O_2^+ ionization source was indeed solar UV acting on oxygen in the ring atmosphere as predicted by Tseng et al. [2010]. Seasonally varying oxygen was subsequently observed at much larger radii by the MIMI instrument, confirming that oxygen originating in the rings can be scattered throughout the inner magnetosphere and, consequently, also into Saturn's atmosphere. Surprisingly, the IMS ion densities observed between the outer edge of the main rings and Mimas, and populated by ionization of neutrals from the ring atmosphere and the Enceladus torus, exhibited an unexpected radial dependence [Elrod et al. 2014, 2012]. Not only did the plasma detected by CAPS in this region exhibit a seasonal dependence, with the O_2^+ component dominated by the water products from the Enceladus torus at Equinox, but the observed radial dependence suggested that an ion loss process other that electron-ion recombination, charge exchange or diffusion was acting [Elrod et al. 2014; Tseng et al. 2013a].

As outlined in the section entitled Time varying modulation of SKR and associated PPO signals, many aspects of Saturn's magnetosphere are modulated at the assumed rotation period as approximated by the SKR signal. Extensive studies of the SKR period as well as associated auroral activity have shown a mark dependence on the Saturnian season. The SKR spectrum was studied statistically with RPWS observations from a wide variety of Cassini's positions. Southern SKR was predominant during Saturn's southern summer up to 2010–mid 2011 (slightly after the equinox of 2009), while the northern SKR was predominant after, consistent with a seasonal control of field-aligned currents driving auroral emissions by solar illumination of Saturn's ionosphere.

The major discovery brought by RPWS was then the identification of 2 SKR periods [Kurth et al. 2008] corresponding to the 2 Kronian hemispheres, differing by ~1%. These periods were found to both vary with time in anti-correlation over yearly timescales and crossed closely after equinox, a trend which was interpreted as a seasonal driving of solar illumination [Gurnett et al. 2011a, 2010b, 2009; Lamy 2011]. These dual periods were later noticed in narrowband (NB) emissions and auroral hiss as well [Gurnett et al. 2010b; Ye et al. 2017, 2010] and more generally observed in numerous magnetospheric observables including magnetic oscillations, ENA emissions, aurorae [Mitchell et al. 2009b; Carbary et al. 2011a, 2010a; Nichols et al. 2010; Andrews et al. 2011, 2010a; Provan et al. 2011; Badman et al. 2012a, 2012b]. It is now accepted that these dual rotational modulations all originate from two rotating hemispheric systems of field-aligned currents, whose origin may be atmospheric vortices [Jia et al. 2012].

Clearly related to the variation in aurora and the SKR signal, the PPO current were found to have similar seasonal dependence. MAG data comparing high-latitude data sets from 2006/2007 and 2008 in Saturn's late southern summer to a third interval of high-latitude data was obtained in 2012/2013 during northern spring [Bradley et al. 2018]. The PPO currents were found to be of similar form but somewhat weaker than in 2008, while the sub-corotation currents exhibited strong

opposite seasonal asymmetries in the north and south polar regions, indicative of weak polar ionospheric conductivity in the winter polar cap. Investigation of the current signatures observed on the F-ring and proximal orbits spanning northern summer solstice at the end of the Cassini mission are currently ongoing [Hunt et al. 2018a].

Thus far we have outlined several seasonal variations at Saturn. Most of these have been related to either the ring plane inclination or to current system. The CAPS instrument measurements of the in situ plasma do not show such a strong variation. In fact, on the time scale of months to years, most of Saturn's magnetospheric plasma does not exhibit strong variability, less than a factor of three [Wilson et al. 2017], in spite of the fact that the Enceladus plume source does appear to vary on the scale of several months [Smith et al. 2010]. In the very inner magnetosphere, just outside the main rings, heavy ion densities (O_2^+ and W^+) show a seasonal dependence, as could be expected for a ring source that depends on the solar illumination angle [Elrod et al. 2014, 2012]. Utilizing many measurements by the RPWS instrument in the inner magnetosphere, Persoon et al. [2013, 2009] were able to develop an empirical plasma density model for the Saturnian system.

Beyond the seasonal dependence, there was an expectation that the solar cycle would have effects on Saturn's magnetosphere. The strength of this dependence would depend on the overall capability of the solar wind to feed energy into and drive the magnetosphere. Sections entitled Magnetotail configuration and dynamics, Magnetospheric structure and convection, Plasma loss into the magnetotail, and Time varying modulation of SKR and associated PPO signals address how efficient the solar wind is at influencing the global magnetosphere and therefore many results related to solar cycle can be found in studies highlighted in those sections.

Above in the previous paragraphs, we outline the dependence of the SKR on seasonal effects. The SKR also exhibit solar cycle effects. [Kimura et al. 2013] investigated the very long-term (six years of measurements) variations of northern and southern SKR spectra, separated by polarization. This study confirms the prominent role of solar wind pressure over one solar cycle, and additionally identified a seasonal dependence of the SKR activity, with a maximum in summer.

Saturn is often placed in between Earth (solar wind driven) and Jupiter (internally driven) in terms of its magnetospheric dynamics, but this is an overly-simplistic picture. Much work has been done to characterize the structure of the solar wind upstream of the planet. Jackman et al. [2004] analyzed several solar rotations worth of upstream interplanetary magnetic field (IMF) data while Cassini was approaching Saturn, and Jackman et al. [2005a] followed up with an analysis of the solar wind excursion on Cassini's long first capture orbit. Overall it was found that during the declining phase of the solar cycle, the IMF is structured into a very clear pattern of two compressions per solar rotation separated by rarefactions. This structuring is very useful because it helps to predict

Saturn is often placed in between Earth (solar wind driven) and Jupiter (internally driven) in terms of its magnetospheric dynamics, but this is an overly-simplistic picture.

the phasing of intermittent driving of the magnetosphere by the solar wind. Jackman et al. [2004] developed an empirical formula to calculate how much open flux is generated through dayside reconnection, dependent on the IMF direction, the solar wind velocity, and assuming a certain length of a predicted reconnection x-line at the dayside magnetopause. This formula has since been widely used by many other authors, in particular to compare to auroral images which seem to indicate addition and removal of flux, for example, Badman et al. [2012a, 2005]. The solar wind conditions at Saturn (and Jupiter) spanning all stages of the solar cycle were summarized in Jackman and Arridge [2011a]. Reconnection voltages were predicted to be slightly lower at solar minimum than solar maximum, while increased photoionization of the Enceladus torus at solar maximum can lead to a more plasma dominated system at this stage of the solar cycle.

In addition to the MAG results, MIMI also discovered that energetic particles with oscillations at the solar wind period (~26 d) likely display solar cycle variations. This solar wind periodicity was discerned during solar minimum (i.e., 2008–2010) when the solar wind structure was not disrupted by solar activity. The solar wind periodicity was first recognized in the energetic electrons [Carbary et al. 2009a], but was perhaps even stronger in the energetic ions [Carbary et al. 2013]. Because solar activity varied with the ~22-year solar cycle, the appearance of this 26-day periodicity itself should vary with the solar cycle.

The solar cycle is also evident in MIMI/LEMMS measurements of Saturn's radiation belts. The very energetic protons (E > 1 MeV) that form Saturn's ionic radiation belts were found to be modulated with the solar cycle, which provided clues that they might derive from CRAND from Saturn's atmosphere [Roussos et al. 2011]. As at Earth, the cosmic rays causing CRAND at Saturn are themselves modulated by the solar cycle, and LEMMS detected this for the first time using observations over many years. The ring current boundary, deduced from LEMMS observations, also appears to fluctuate in response to solar energetic particle (SEP) events, which are themselves conditioned according to the solar cycle [Roussos et al. 2014].

The section entitled Radiation belts outlines the MAPS contribution to our understanding of the radiation environment at Saturn. The MIMI measurements achieved a comprehensive description of the radiation belts of Saturn during approximately 200 orbits which crossed into the radiation belts, allowing us to understand and quantify their average structure, but also to monitor time variations, despite the single point measurements. Studies by Christon et al. [2014a, 2014b, 2013] provide the most detailed characterization of trace energetic ions and their charge states at an outer planet, showing how their origin may be connected to the planet's rings, the activity of Enceladus and seasonal or solar cycle effects.

Finally, a recent study by Roussos et al. [2018c] uses a novel technique to overcome the lack of an upstream solar wind monitor at Saturn. Cassini MIMI/LEMMS observations of SEP and Galactic Cosmic Ray (GCR) transients, that are both linked to energetic processes in the heliosphere such as Interplanetary Coronal Mass Ejections (ICMEs) and Corotating Interaction Regions (CIRs), are used to trace enhanced solar wind conditions at Saturn's distance. A survey of the MIMI/LEMMS dataset between 2004 and 2016 resulted in the identification of 46 SEP events. Most events last more than two weeks and have their lowest occurrence rate around the extended

solar minimum between 2008 and 2010, suggesting that they are associated to ICMEs rather than CIRs, which are the main source of activity during the declining phase and the minimum of the solar cycle. Also, 17 time periods (> 50 days each) are identified where GCRs show a clear solar periodicity (~13 or 26 days). The 13-day period that derives from two CIRs per solar rotation dominates over the 26-day period in only one of the 17 cases catalogued. This interval belongs to the second half of 2008 when expansions of Saturn's electron radiation belts were previously reported to show a similar periodicity. That observation not only links the variability of Saturn's electron belts to solar wind processes, but also indicates that the source of the observed periodicity in GCRs may be local. In this case, GCR measurements can be used to provide the phase of CIRs at Saturn. The survey results also suggest that magnetospheric convection induced by solar wind disturbances associated with SEPs is a necessary driver for the formation of transient radiation belts that were observed throughout Saturn's magnetosphere on several occasions during 2005 and on day 105 of 2012. Also, an enhanced solar wind perturbation period that is connected to an SEP of day 332/2013 was the definite source of a strong magnetospheric compression (enhanced SKR and low frequency extension (LFE) were also detected at this time) which led to open flux loading in the magnetotail. This event lists can a guide to better constrain or identify the arrival times of interplanetary shocks or solar wind compressions for single case studies or statistical investigations on how Saturn and its moons (particularly Titan) respond to extreme solar wind conditions or on the transport of SEPs and GCRs in the heliosphere.

Magnetotail configuration and dynamics

- **MN1a:** Determine the dynamics of Saturn's magnetotail.
  - Study thoroughly the plasma sheet in Saturn's magnetotail.
  - Investigate the relation between solar wind compression events and magnetotail dynamics.
  - Investigate the plasma sheet thickness and scale height as functions of radial distance and local time.
  - Statistically characterize magnetotail variations, especially those associated with plasmoids, and correlate them with changes in the inner magnetosphere.
  - Critically evaluate the Dungey and Vasyliunas cycles in light of the new observations, especially those of flow speeds.

Measurements made by Cassini in the magnetotail, have allowed MAPS team members to study the dynamic nature of this region of the magnetosphere. Studies include characterizing reconnection, the observation and characterization of plasmoid-like structures, observation of dipolarization events, describing the warping of Saturn's current sheet and studying the response of the magnetosphere to the solar wind.

Since the outer magnetosphere is very dynamic, it is very challenging to describe its average properties. Still, the continuous in situ measurements by CHEMS and LEMMS and the remote

monitoring by INCA have provided unique insights into that region. A detailed study of the outer magnetosphere's average structure is given by Krimigis et al. [2007]; Sergis et al. [2009], which highlight the distinct day-night asymmetry in the vertical extent of the ring current (or plasma sheet). INCA images have been used to determine the most active sites for dipolarization (or large-scale injection events) in the outer magnetosphere being in the post-midnight sector of the magnetosphere [Mitchell et al. 2009b, 2005; Carbary et al. 2008a]. They have revealed the wavy structure of the magnetodisk [Carbary et al. 2016, 2015, 2008b; Carbary 2013] and links to auroral emissions. Energetic electrons have been used to identify an unexpected source of high energy electrons, seen as quasi-periodic pulsations with a period of about 65 minutes. These events are seen globally, they can accelerate electrons to the MeV range instantly and have been linked to reconnection, auroral transients, and similar periodic observations in magnetic field and plasma wave data [Roussos et al. 2016b; Palmaerts et al. 2016a, 2016b; Carbary et al. 2016]. The magnetospheric topology (e.g., open versus closed field lines or the cusp) has been discussed in the context of MIMI observations—for example, Gurnett et al. [2010b]; Arridge et al. [2016a], while MIMI data have been central in the study and interpretation of reconnection/dipolarization events, in combination with other datasets—for example, Badman et al. [2016, 2013]; Jackman et al. [2015, 2008]; Masters et al. [2010]. CHEMS observations also revealed outer magnetosphere asymmetries in the fractional abundance of solar wind-originating ions penetrating into the magnetosphere of Saturn [Allen et al. 2018]. These asymmetries indicate that solar wind He^{++} particles may be entering the magnetosphere due to a combination of Dungey-type reconnection as well as Kelvin-Helmholtz (K-H) instabilities [Allen et al. 2018].

Cassini MAG measurements (often in concert with plasma measurements) have been used to characterize the tail in terms of distinguishing the lobe and plasma sheet regions and exploring how they change with distance from the planet. The current sheet is found to be warped out of the equatorial plane [Arridge et al. 2008a], with a characteristic hinging distance of ~25 R_S. This warping made a significant impact in Saturn's southern hemisphere summer in 2006 when Cassini executed its deepest tail orbits, first in the equatorial plane (below the hinged current sheet) and later at higher latitudes (close to the hinged current sheet). The current sheet has also been found to flap, or oscillate vertically with a period close to the ~10 hours linked to the mysterious planetary periodicities. Jackman and Arridge [2011b] performed a statistical study of Saturn's lobes and plasma sheet during 2006, developing numerical definitions for these regions, and deriving the falloff of the field strength in the lobes with radial distance. They found that the near magnetotail of Saturn is similar to that of Jupiter and Earth (when scaled to a common distance). Unlike at Earth, we do not have spacecraft coverage of the asymptotic tail region, but rather have likely only covered the part of the tail where the magnetopause boundary is still flaring outward and where the lobe field strength is falling off before reaching a steady asymptotic level. We do not know the exact length of Saturn's tail, but can consider arguments first made by Dungey [1965] for the Earth where length was estimated by time for open field lines to be dragged over the poles before ultimately sinking in toward the center of the tail before reconnection (giving ~1000 R_E). Milan et al. [2005] examined the case at Saturn where the polar cap refresh time (i.e., the time for magnetic flux to be cycled through dayside to nightside reconnection) is expected to be many days—for example, Jackman et al. [2004], compared to a much shorter (~10–11 hours) planetary rotation period. This may be expected to twist the lobes of the tail

and Milan argued each turn of a twisted lobe could be ~900 R_S long. They theorized that Saturn is a last-in-first-out system in which recently opened field lines are the first to be closed by reconnection in the tail, due to this twist. This implies that Saturn's tail lobes contain a core of old open field lines that can be stretched to incredible lengths (>15000 R_S).

Saturn's magnetosphere is observed to undergo dramatic, explosive energy release events. The first indication of such behavior was on the outbound pass of SOI where Bunce et al. [2005] reported an episode of solar wind compression-induced tail reconnection, with dipolarizing field and injection of hot plasma. The products of reconnection tailward of the x-line (plasmoids and travelling compression regions, TCRs), were first observed with the Cassini magnetometer by Jackman et al. [2007]. They are identified primarily by a bipolar deflection in the north-south component of the field, with northward turnings implying reconnection products tailward of the x-line and southward turnings implying dipolarizations planetward of the x-line. Multi-instrument views of reconnection events reveal changes in the flow pattern from azimuthal to tailward and local heating of the plasma, for example, Jackman et al. [2008]. It is sometimes observed that northward turnings are not purely bipolar but instead have an extended interval where the field remains northward. This has been interpreted as the Kronian equivalent of the post-plasmoid plasma sheet [Jackman et al. 2011], which represents an interval where previously open flux is being closed by reconnection.

Over the years, catalogues of reconnection events were built up from by-eye surveys and basic automation involving simple background thresholding of the magnetic field and searching for significant deflections above or below these thresholds. Surveys covering the deepest tail orbits of 2006 revealed a significant imbalance between the rate of mass loss inferred from plasmoid release and the rate of mass loading from the moon Enceladus, which has been termed the mass budget problem [Jackman et al. 2014]. More sophisticated automated event searches have returned surveys of > 2000 events from tail orbits during 2006, 2009, and 2010, and Smith et al. [2016] revealed that the rate of observed reconnection events peaked post-midnight, with a highly variable radial location of the reconnection x-line, with an average ranging from 20–30 R_S from the planet. To date only one study has identified the x-line region itself [Arridge et al. 2016b], while more recently Smith et al. [2018a] presented a series of very short duration reconnection-related inward and outward flows in quick succession on the dusk flank. Their interpretation was that over a 7-hour interval investigated, reconnection sites had formed both tailward and planetward of the spacecraft, showing that reconnection can operate on small spatial/temporal scales. A second case study showed an event during which the reconnection site was inferred to retreat tailward, resulting in progressively hotter, dipolarizing material reaching Cassini.

The properties of dipolarizations planetward of the x-line give us another view of the impact of reconnection on the magnetosphere. Jackman et al. [2013] published a case study which showed rapid acceleration of newly-reconnected field lines back toward the planet. The transition from a radially stretched to dipolar field configuration can cause a current which usually flows across the tail to divert into the ionosphere, potentially leading to bright, distinct spots of auroral emission. Jackman et al. [2015] further showed that dipolarization of the field can be accompanied by ion flows at speeds of up to 1500 km/s toward the planet following tail reconnection, representing a significant departure

from the slower, sub-corotational flow typically seen in the tail. A reconnection event that starts at a small x-line can have a big impact on the magnetosphere as a whole.

Dipolarizations themselves have also been shown to have a dramatic effect on the local plasma: Smith et al. [2018b] investigated dipolarizations as identified from southward deflections of the magnetic field and found they were clustered preferentially post-midnight. The analysis of the accompanying CAPS data showed that the dipolarizing material was systematically hotter and less dense than the ambient plasma sheet. This density depletion and heating was found to be much more variable post-midnight, suggesting a more variable reconnection site.

By analyzing Cassini's MAG and CAPS data, Yao et al. [2017a] revealed that there are two fundamentally different drivers of dipolarization (i.e., magnetic reconnection and electrical current re-distribution) at Saturn, similarly to what is found in the terrestrial magnetotail.

Beyond reconnection and dipolarizations, several studies have been done of larger scale reconfigurations of the magnetotail. Some of this work is reported in a series of papers by Jackman and coauthors. Jackman et al. [2009a] revealed evidence of plasmoid-like magnetic structures and other phenomena indicative of the Saturnian equivalent of terrestrial substorms. In general, there was a good correlation between the timing of reconnection events and enhancements in the auroral SKR emission. Eight of nine reconnection events studied occur at SKR phases where the SKR power would be expected to be rising with time. Thus, while the recurrence rate of substorm-like events at Saturn is likely much longer than the planetary rotation timescale, the events are favored to occur at a particular phase of the rotation. Three examples were found in which the SKR spectrum extended to lower frequencies than usual. These low frequency extension SKR events were labeled LFEs and were interpreted as an expansion of the auroral particle acceleration region to higher altitudes (lower radio frequency) along magnetic field lines as a direct consequence of an increase in the magnetosphere-ionosphere current density driven by substorm-like events. Saturnian substorms are likely a much more prevalent phenomenon than this small number of observations suggests, but the statistics in this study were hampered by viewing geometries, primary the small amount of time that Cassini spent in the deep magnetotail near the nominal current sheet location. Many examples of LFEs are observed by Cassini from a wide set of vantage points, but the spacecraft is only in the right position to observe the corresponding magnetic signature (if any) a fraction of the time.

In general, there was a good correlation between the timing of reconnection events and enhancements in the auroral SKR emission.

Jackman et al. [2010] also explored the dynamic response of Saturn's magnetotail to an episode of solar wind compression that took place while Cassini was sampling Saturn's nightside equatorial magnetosphere in 2006. Following an initial increase in solar wind dynamic pressure, the magnetosphere was compressed and became more streamlined, with an elevated lobe field strength as external pressure compressed the tail. Then, assuming a favorable IMF direction (for

at least part of the interval, as seems entirely plausible), dayside reconnection may have been ongoing, leading to an increase in the amount of open flux inside the magnetosphere, flaring of the magnetotail, and continued elevated lobe field strength. Because of the longer time scales involved at Saturn for loading of the tail with open flux, it can take several days for the tail to be inflated to a point where reconnection is likely to occur, and this study suggested that the time scale observed in this case was of order ~6–7 days. No strong evidence for magnetotail reconnection events during this loading phase were detected, however, toward the end of this period a sharp decrease in lobe field strength and what appears to be significant current sheet deflection toward the equator from its previously hinged position was observed. Several days later the current sheet was displaced southward from its previously hinged position, and magnetic signatures consistent with the passage of a plasmoid were observed. These field signatures are closely correlated with intense radio emission, evidenced by low-frequency extensions (LFEs) of radio emission, corresponding to radio sources detected at higher altitudes. All of the above features are believed to be a common consequence of the impact of a solar wind compression on Saturn's magnetosphere.

Additional evidence for significant dynamical effects attributable to solar wind variability has been reported by the CAPS team. CAPS observations from SOI outbound, in the pre-dawn tail, showed sudden energization of plasma associated with a field dipolarization, which was interpreted as evidence of a solar wind compression-related tail collapse via magnetic reconnection. Under conditions of high solar wind dynamic pressure, the magnetotail appears to enter a state of sustained lobe reconnection, resulting in a more Dungey-like configuration [Thomsen et al. 2015a]. In the inner magnetosphere, there is no apparent relation between the depth of electron penetration and solar wind properties [Thomsen et al. 2016], although the energization of ions in a large-scale standing wave might be caused by a solar wind pressure impulse [Thomsen et al. 2017a].

Jackman et al. [2015] presented a rare observation of strong planetward flow following a reconnection episode in Saturn's tail from August of 2006, when the Cassini spacecraft was sampling the region near 32 R_S and 22 h local time (LT). Cassini observed a strong northward-to-southward turning of the magnetic field, which is interpreted as the signature of dipolarization of the field as seen by the spacecraft planetward of the reconnection X-line. This event was accompanied by very rapid (up to ~1500 km s^{-1}) thermal plasma flow toward the planet. At energies above 28 keV, energetic hydrogen and oxygen ion flow bursts were observed to stream planetward from a reconnection site downtail of the spacecraft. Meanwhile, a strong field-aligned beam of energetic hydrogen was also observed to stream tailward, likely from an ionospheric source. SKR radio emissions enhancements similar to ones previously associated with plasmoid formation and release were detected slightly more than an hour after the observation of the dipolarization. The reconnection episode as inferred from the planetward directional flow duration lasts on the order of ~1.5 h, a significant fraction of a planetary rotation. The continuing presence of energetic O^+ ions throughout the event demonstrates that this must be a case of long-lasting Vasyliunas-type reconnection occurring beyond 32 R_S in the premidnight region, perhaps indicating quasi-steady reconnection of the type. Because of the persistent presence of O^+, we find little evidence for lobe involvement in the reconnection.

Kimura et al. [2013] investigated the very long-term (six years of measurements) variations of northern and southern SKR spectra, separated by polarization. This study confirms the prominent role of solar wind pressure over one solar cycle, and additionally identified a seasonal dependence of the SKR activity, with a maximum in summer.

Felici et al. [2016] presented a case study of data from Saturn's magnetotail, when Cassini was located at ~22 hour Local Time at 36 R_S from Saturn that suggests for the first time that a low-energy ionospheric outflow event has been detected at planets other than Earth. During several entries into the magnetotail lobe, tailward flowing cold electrons and a cold ion beam were observed directly adjacent to the plasma sheet and extending deeper into the lobe. The electrons and ions appear to be dispersed, dropping to lower energies with time. The composition of both the plasma sheet and lobe ions show very low fluxes (sometimes zero within measurement error) of water group ions. The magnetic field has a swept-forward configuration which is atypical for this region, and the total magnetic field strength is larger than expected at this distance from the planet. Ultraviolet auroral observations show a dawn brightening, SKR is enhanced and extends down to lower frequencies, and upstream heliospheric models suggest that the magnetosphere is being compressed by a region of high solar wind ram pressure. This event is interpreted as the observation of ionospheric outflow in Saturn's magnetotail, with the active atmospheric regions most likely the main auroral oval.

The majority of the previously discussed studies involved periods where Saturn's magnetosphere encountered a high density solar wind. The study by Kinrade et al. [2017] discusses observations during a period that Saturn's magnetosphere was in a rarified solar wind region. During this period on June 14, 2014 (day 165), the Hubble Space Telescope observed an unusual auroral morphology, where for 2 h, the Saturn's far ultraviolet (FUV) aurora faded almost entirely, with the exception of a distinct emission spot at high latitude. The spot remained fixed in local time between 10 and 15 LT and moved poleward to a minimum colatitude of ~4°. Interestingly, the spot constituted the entirety of the northern auroral emission, with no emissions present at any other local time, including Saturn's characteristic dawn arc, the complete absence of which is rarely observed. Solar wind parameters from propagation models, together with a Cassini magnetopause bow shock crossing, indicate that Saturn's magnetosphere in an expanded magnetosphere configuration during the interval, suggesting it was likely embedded in a rarefaction region. The spot was possibly sustained by reconnection either poleward of the cusp or at low latitudes under a strong component of interplanetary magnetic field transverse to the solar wind flow. The subsequent poleward motion could then arise from either reconfiguration of successive open field lines across the polar cap or convection of newly opened field lines. The spot's fixed LT position may be attributed to the negative IMF BY conditions incident at the time, combined with increased subcorotation of open flux toward higher latitudes. The emission intensity was also possibly enhanced by a sector of upward PPO current rotating through the region. These observations show conclusively that the mechanisms producing noon auroral spots and the main oval auroras (i.e., the dawn arc) are distinct, since in this case the cusp spot occurred without the arc. These observations also suggest that reconnection can occur in an expanded magnetosphere, in agreement with the cusp observations of Arridge et al. [2016a], who found evidence of reconnection under a range of upstream solar wind conditions.

Magnetospheric structure and convection

- **MN1b:** Conduct in situ studies of Saturn's ionosphere and inner radiation belt.
  - Investigate the effects on aurora of solar wind and seasons.
  - Are there UV satellite footprints on Saturn? (like at Jupiter)
  - Is there a seasonal variation in auroral activity?
  - Investigate solar wind - ionosphere - magnetosphere coupling through the auroral regions.
  - Investigate whether there are UV satellite footprints on Saturn and whether there are Region 1 currents connecting the ionosphere and the magnetopause.
  - Investigate the composition of Saturn's ionosphere.
  - Study whether there is a significant polar outflow from Saturn's high latitude ionosphere and whether the outflow exhibits seasonal or solar cycle variation.
  - Determine whether there is a radiation belt between the D-ring inner edge and the atmosphere.

Understanding the structure of the magnetosphere and the convection systems within the magnetosphere are clearly two of the most important goals of the MAPS investigation. Each MAPS instrument team and the IDS teams have contributed extensively to the study of this aspect of Saturn and have published extensive literature. In this summary document it is only possible to summarize a small fraction of the work done by the MAPS instruments. We refer the interested read to the individual MAPS instrument team reports and the published literature for a more complete coverage of the extensive contribution of Cassini to understanding Saturn's magnetospheric structure.

The Cassini spacecraft crossed the bow shock of Saturn for the first time at 09:45 UT on June 27, 2004, at a radial distance of 49.2 R_S from Saturn. After the initial crossing, the large apoapsis orbits by the Cassini spacecraft around Saturn over many years enabled hundreds of bow shock crossings. This allowed for thorough analyses of the three-dimensional shape, a capability to predict the location of the boundary and to investigating the microphysics of high Mach number shocks. Studying the global shape, location, and dynamics of the bow shock offers important insights into the physics governing its formation and the magnetosphere's response to solar wind dynamics.

Studying the global shape, location, and dynamics of the bow shock offers important insights into the physics governing its formation and the magnetosphere's response to solar wind dynamics.

A number of authors have used the Cassini data to develop models of the average shape of Saturn's bow shock as well as the response of this surface to changes in the dynamic pressure of the upstream solar wind. Masters et al. [2008] and Went et al. [2011] developed an exhaustive semi-empirical model of Saturn's dayside bow shock. The average three-dimensional shape of the boundary was constructed and equations relating the response of the subsolar point to variations in solar wind dynamic pressure derived. Achilleos et al. [2006] presented magnetic field signatures of some of the earliest crossings in the mission. Their results showed clearly defined overshoot and foot signatures that are typical of quasi-perpendicular shocks. This is by virtue of the Parker spiral structure of the IMF at 10 AU, where the magnetic fields met the bow shock with very large azimuthal components.

In addition, a number of studies have investigated the properties of the bow shocks themselves at Saturn [Masters et al. 2017, 2013a, 2013b; Sulaiman et al. 2015; Sundberg et al. 2017], and the particles and regions associated with the bow shock, including hot flow anomalies [Masters et al. 2009], superthermal electrons [Masters et al. 2016], and upstream whistler mode waves [Sulaiman et al. 2017] occurred during a period of high solar wind pressure that caused Saturn's bow shock to be pushed inside Titan's orbit, exposing the moon and its ionosphere to the solar wind. Omidi et al. [2017] using electromagnetic hybrid (kinetic ions and fluid electrons) simulations and Cassini observations, showed a formation of a single deformed bow shock for the Titan-Saturn system. Sulaiman et al. [2016] characterized Saturn's bow shock using the largest sample of crossings to date. They showed Saturn's dayside bow shock was in the quasi-perpendicular configuration for a large majority of the time. The bow shock was found to exhibit characteristics akin to both terrestrial and astrophysical regimes. Clarke et al. [2010a] investigated 35 Cassini orbits on which the spacecraft crossed Saturn's magnetopause and bow shock during 2004–2007, and concluded that the bow shock and magnetopause oscillate approximately in phase, within a phase uncertainty of about ±25°. The typical amplitude is 1–2 R_S and the period is significantly organized by the phase of the interior magnetic field oscillations, with a period near that of planetary rotation. Saturn's (dayside) bow shocks are predominantly quasi-perpendicular by virtue of the Parker spiral at 10 AU.

The Cassini spacecraft has shown that Saturn's bow shock can occasionally reach a high-Mach number typical of astrophysical shocks. In this regime Cassini has provided the first in situ evidence for suprathermal electron acceleration under quasi-parallel upstream magnetic conditions [Masters et al. 2016]. Masters et al. [2013b, 2011a] explore several different aspects of Saturn's shock structure. They investigated the Mach number dependence of electron heating across a bow shock. Their work presented a positive correlation between the electron temperature increase across the shock and kinetic energy of an incident proton, where electron heating accounts for ~3%–~7% [Masters et al. 2011a]. In addition, they compared observations of overshoots between Mercury's and Saturn's bow shocks, both of which represent drastically different Mach numbers in parameter space. They showed, on average, the overshoots at Saturn's bow shock were much higher than those observed at Mercury's. This supported the larger role of particle dynamics at higher Mach numbers [Masters et al. 2013b]. In addition, Sulaiman et al. [2015] showed evidence for cyclic reformation controlled by specular ion reflection occurring at the predicted time scale of

~0.3 τ c, where τ c is the ion gyroperiod. In addition, they experimentally revealed the relationship between reformation and alfvenic Mach number (Figure MAPS-18).

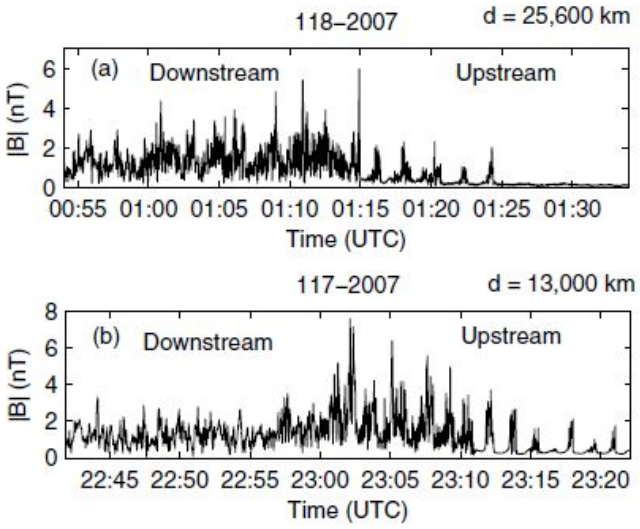

Figure MAPS-18. The panels are two examples of magnetic field plots showing quasi-perpendicular bow shock crossings with re-formation cycles occurring upstream of the shock. Figure adapted from Sulaiman et al. [2015] Figure 2.

Collisionless shock waves are also known to be efficient particle accelerators. It is widely believed that a large proportion of cosmic rays originate from energetic charged particles accelerated at collisionless shocks associated with supernova explosions in our galaxy. Masters et al. [2013a] confirmed, for the first time, electron acceleration up to relativistic energies at an unusually strong Saturn bow shock under a quasi-perpendicular configuration. This contradicted previous knowledge purporting a magnetic dependence on this phenomenon. Further works by Masters et al. [2016] and Masters et al. [2017] provided the full picture of suprathermal electrons at Saturn's bow shock. They showed results that are consistent with the theory in which the "injection" of thermal electrons into an acceleration process is possible for all magnetic field configurations at high Mach numbers.

Long-term sampling of Saturn's magnetosheath by Cassini afforded the most complete coverage of this intermediary region between the unshocked solar wind and Saturn's magnetosphere. A relatively high Alfvén Mach number solar wind and a polar-flattened magnetosphere make Saturn's magnetosheath both physically and geometrically distinct from the Earth's. Fast rotating gas giants, such as Saturn, are bulged along the equator and flattened along the poles owing to their embedded plasma disks and for this reason, Sulaiman et al. [2014] showed that the magnetic structure of Saturn's magnetosheath significantly deviated from axisymmetry. Their results showed large northward/southward components in the magnetic field despite the prevailing Parker spiral configuration being largely in the equatorial plane.

Using CAPS and other MAPS data, Sergis et al. [2013] investigated the properties of the magnetosheath. At energies of a few keV the magnetosheath is comprised of shocked solar wind plasma, while at energies above a few keV there is a strong presence of water group ions forming localized structures that are being convected downstream in the plasma flow. Under average magnetic field conditions in the magnetosheath, the kinetic properties of these hot water group ions can enable escape upstream from the bow shock. To help future scientists access the CAPS data to study the magnetosheath, Thomsen et al. [2017a] provides a comprehensive survey of intervals in which the observed magnetosheath flow was encompassed within the plasma analyzer field of view, and for which the computed numerical moments are accurate. The data extend over eight years from 2004 day 299 to 2012 day 151. The magnetosheath population is characterized by ion energies between ~100 eV and ~2 keV and electrons up to about 100 eV. The solar wind is best identified in the electrons, which have energies generally below 10 eV.

Saturn's magnetopause marks the boundary between the impinging solar wind and the region of space dominated by Saturn's intrinsic magnetic field. The magnetopause presents an obstacle to the solar wind. Cassini MAPS instruments have made extensive measurements of crossing of the magnetopause and have allowed us to examine the ways in which energy can be transferred in to and out of near-Saturn space. Understanding this is crucial for revealing the dynamics of the coupled planetary system of magnetosphere, moons, rings, and atmosphere.

A good understanding of the geometry of the magnetopause, and how its position changes with the pressure of the solar wind, is important for characterizing the distant dayside magnetosphere and in developing a three-dimensional global model of the magnetospheric magnetic field. Arridge et al. [2006] used early measurements of the magnetopause from Cassini/MAG, combined with measurements from Voyager 1/2 and Pioneer 11, to develop a new model of Saturn's magnetopause. This new model revealed that Saturn's magnetosphere was more compressible than previously thought: more compressible than Earth's magnetosphere, but less than Jupiter. This was confirmed and enhanced in further studies using larger datasets from Cassini/MAG [Kanani et al. 2010; Pilkington et al. 2015]. In a study by Achilleos et al. [2008], the MAG team analyzed some of the early orbits and the points along those orbits where the spacecraft crossed the magnetopause. By analyzing the distribution of the magnetopause crossings, it was concluded that the size of the magnetosphere was certainly being controlled by the dynamic pressure of the solar wind upstream of the planet, but that there was also evidence for an additional influence, probably due to a process internal to the magnetosphere. The system preferentially spent most of the time in one of two states, characterized by subsolar magnetopause distances near ~22 and ~27 Saturn radii.

A study some years later [Pilkington et al. 2015] built upon this work by constructing an up-to-date empirical model of Saturn's magnetopause. The work found that one could not satisfactorily fit these crossings in their entirety by assuming a system whose size responded only to solar wind pressure. By separating the crossings into subsets based on additional plasma data from the MIMI instrument, the study demonstrated that Saturn's magnetosphere plausibly made transitions between states which were plasma-light and plasma-loaded.

Magnetic reconnection is a fundamental process that can operate at a current sheet. It results in the release of energy stored in the local magnetic field, leading to acceleration of charged particles and allowing the direct transfer of mass and energy across an otherwise closed boundary. While evidence for the known operation of reconnection at Saturn's magnetopause has been sparse, MAG observations have formed the basis of important assessments that have broad implications. The first such assessment demonstrated that conditions at the magnetopause boundary of Saturn's magnetosphere are dramatically unlike those at Earth's magnetopause. As a result, reconnection at Saturn's magnetopause should be more restricted to regions where magnetic field lines adjacent to the boundary are locally anti-parallel to each other [Masters et al. 2012a]. This Cassini result began a shift in how we think about the solar wind-magnetosphere interaction at Saturn, with implications for other magnetized planets.

MAG data has also shown that when reconnection operates at Saturn's magnetopause it likely does so at a speed that is far slower than that associated with reconnection in environments closer to the Sun, for example, the solar corona, the solar wind, Earth's magnetopause, Earth's magnetotail [Masters et al. 2014]. The reason for this is the way that solar wind properties change as the plasma moves away from the Sun. The Alfvén speed, which dictates the speed of reconnection, drops with heliocentric distance, producing a relatively slow reconnection process at Saturn's magnetopause and consistent with the lack of evidence for rapid boundary later response discussed above. This result directly contributed to further work that showed that driving of Saturn's magnetosphere by global magnetopause reconnection is rarely strong enough to compete with the internal driving of the system that results from the combination of fast planetary rotation and plasma production due to the plumes of Enceladus [Masters 2015].

Magnetic reconnection at Earth has been proposed to occur only at the magnetopause and in the nightside magnetotail. At Saturn and Jupiter, internal sources are additional drivers for magnetospheric dynamics, and it is usually believed that internal sources could drive magnetic reconnection in the nightside inner magnetosphere. However, Guo et al. [2018] report in situ evidence of active magnetic reconnection process in the dayside of Saturn's magnetodisc at ~2 R_S away from Saturn's magnetopause. This study would directly support drizzle magnetic reconnection picture proposed by Delamere et al. [2015], and is also consistent with the rotating reconnection site picture proposed by Yao et al. [2017b].

The other important mechanism by which solar wind energy can enter a planetary magnetosphere is via a viscous-like interaction. This is underpinned by another fundamental process: Growth of the K-H instability. Where there are large plasma flow shears across a magnetopause this instability can lead to the evolution of small boundary perturbations in to gentle waves and eventually in to large, rolled-up vortices. The first evidence for magnetopause surface waves from Cassini came in the form of normal to the boundary determined from magnetic field observations that exhibited an oscillation in a preferred direction from one magnetopause crossing to the next [Masters et al. 2009]. The direction of wave propagation (direction of boundary normal oscillation) was controlled by the local direction of the magnetic field inside the boundary, consistent with K-H-driven waves. After this first observation, extensive continued studies of the K-H waves at magnetopause crossings has shown that such waves are ubiquitous [Masters et al. 2012b].

In addition to understanding reconnection and the K-H interaction at lower latitudes, it is important to understand how the magnetic cusps play a role in energy and particle transfer between the solar wind and the magnetosphere. At Earth, the solar wind is the primary energy source which can drive dynamical processes, and it is also a primary source of plasma. Before Cassini's arrival it was not clear what role the solar wind played in driving the magnetosphere, and so understanding the coupling between the solar wind and the magnetosphere, characterizing the phenomena of the distant dayside/flank planetary environment, was an important goal. This included studying viscous and magnetic reconnection processes at the magnetopause. Flux transfer events are a signature of dayside magnetic reconnection at Earth, Mercury and Jupiter, and consist of a rope of magnetic flux and plasma peeling away from the magnetopause. Jasinksi et al. [2016] presented an example of a flux transfer event at Saturn (the only one) and showed that this single event made a fairly small contribution (< 10%) to the magnetic flux transport budget, although it was not clear how typical this event was, and if they are more prevalent at locations on the magnetopause not sampled by Cassini.

… it is important to understand how the magnetic cusps play a role in energy and particle transfer between the solar wind and the magnetosphere.

At higher latitudes, a region known as the cusp maps to a very wide region of the magnetopause and so is ideal for remote monitoring of the magnetopause for reconnection signatures, revealing coupling between the solar wind and the magnetosphere. Cassini's inclined orbits during 2007/2008 and 2013/2014 were ideal to study this coupling process in plasma (CAPS) and the magnetic field (MAG). Some of the early inclined orbits in early 2007 showed evidence of solar wind plasma gaining entry into the magnetosphere [Arridge et al. 2016a]. This work showed evidence for movement of the cusp region in phase with magnetospheric (so-called planetary-period) oscillations, indicating the presence of current systems in the magnetosphere. It was also found that magnetopause reconnection was possible under both compressed and expanded magnetospheric conditions [Jasinski et al. 2016; Arridge et al. 2016a] and that the reconnection process could proceed in an unsteady fashion and at various locations on the magnetopause [Jasinski et al. 2016, 2014; Arridge et al. 2016a]. During SOI, the CAPS instrument showed that at latitudes above the extended plasma sheet/ring current there is a region that is largely devoid of plasma, known as the magnetospheric lobe [Young et al. 2005]. The lobe is commonly seen in the magnetotail, for example, Thomsen et al. [2015a], as the plasma sheet rocks and flaps up and down. Lobe field lines are thought to be connected by magnetopause reconnection into the solar wind and have thus lost their magnetospheric contents. At low altitudes, the lobe maps into the polar cap. The polar cap boundary is identified based on a sharp drop in ELS electron fluxes and corresponding signatures in other data sets (Figure MAPS-19), for example, Jinks et al. [2014]. A survey of polar cap boundary crossings showed that the main upward field-aligned currents associated with the aurorae reside equatorward of the open-closed boundary [Jinks et al. 2014].

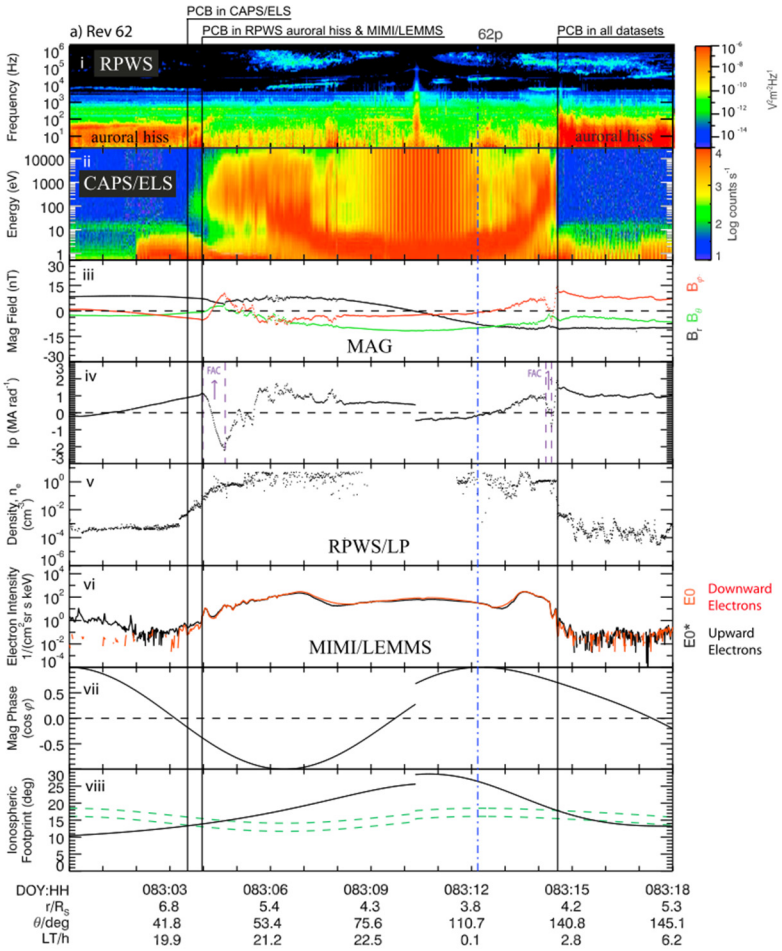

Figure MAPS-19. Polar cap boundary as seen in several different Cassini data sets. The sharp change in the ELS electron spectrum is the most definitive signature. The polar cap is largely devoid of electrons (counts below ~20 eV are due to spacecraft photoelectrons). Figure from Jinks et al. [2014].

Near noon, open magnetic field lines (which will ultimately become the lobe/polar cap) are filled with incoming magnetosheath plasma, which penetrates down to low altitudes. CAPS observations of this region, known as the cusp, demonstrate that the process of reconnection occurs at Saturn's magnetopause, with indications that the reconnection is pulsed [Jasinski et al. 2014]. The first reported cusp observation was associated with the arrival of a solar wind shock front, which compressed the magnetosphere and probably provided more favorable conditions for magnetopause reconnection [Jasinski et al. 2014]. Evidence for both bursty and more continuous reconnection is observed at different cusp events, and the locations of the reconnection site vary along the subsolar magnetopause. Magnetic reconnection and plasma injection into the cusp can occur for a variety of upstream conditions [Jasinski et al. 2017, 2016; Arridge et al. 2016a].

Saturn's magnetosphere is an example of a rapidly rotating system dominated over much of its extent by a large magnetodisk of rotating plasma, this material falling further behind corotation with the planet as we go to larger distances from the planet. Because the system is so large,

centrifugal force becomes very effective at keeping the cold plasma confined as this near-equatorial disk. In order to develop a first-principles model of Saturn's magnetodisk region, Achilleos et al. [2010a] adapted a model of field and plasma developed for the Jovian system by Caudal [1986], using plasma data available at that time to constrain the model's boundary conditions. This model was successfully used to explain the observed response of the planet's magnetospheric field to changes in system size. We were also able to compare the model contributions to the total magnetodisk current associated with the various forces on the plasma (centrifugal force and pressure gradient force) for both the Kronian and Jovian magnetodisk systems. A follow-up study by Achilleos et al. [2010b] explored particularly the influence of global changes in the energetic particle population on Saturn's magnetodisk structure. This model was also used in a study by Sorba et al. [2017], who developed theoretical compressibility curves showing how the magnetodisk size responds to changes in solar wind pressure and internal plasma content (energetic particles). These theoretical results were in good agreement with the observational analysis of Pilkington et al. [2015] and we were also able to use the model to explain why one would expect the compressibility of the system to vary with system size. We have also had some success in using this magnetodisc model, combined with the current sheet elevation model of Arridge et al. [2011a], in order to model global, near-planetary-period oscillations in the magnetic field and plasma properties [Achilleos et al. 2014].

It has been shown that periodic variations of the plasma density peak at different rotation phases depending on radial distance in the magnetosphere. We showed that this variation arises as a consequence of the interaction between simple rotation and the expansion and contraction of the magnetosphere associated with propagating compressional disturbances [Ramer et al. 2017]. Propagating compressional disturbances also cause the magnetopause to move in and out non-sinusoidally and somewhat asymmetrically [Kivelson and Jia 2014]. The simulation also explains the dawn-dusk asymmetry of field configuration and plasma flows in Saturn's magnetosphere [Jia and Kivelson 2016].

The rotation period of Saturn's magnetosphere was found to vary with time, and changing periodicities were identified in magnetic fields, radio emissions, and charged particles [Andrews et al. 2012, 2011, 2008; Provan et al. 2014, 2013, 2011, 2009]. The plasma motion of the magnetodisk is very much affected by the oscillating magnetic field of Saturn, which is different in the two hemispheres. These planetary period oscillations strongly influence the magnetic and plasma properties of the outer magnetosphere [Andrews et al. 2010a; Provan et al. 2012] as well as the density of thermal ions [Nemeth et al. 2011; Szego et al. 2011]. The thermal plasma sheet properties are different for the different ion species. The proton sheet is smoothly modulated by the flapping of the magnetodisk while heavy ions form a narrow sheet surrounding the magnetic equator. The periodicity of the observed heavy-ion rich events was found to be close to the SKR period of the southern hemisphere.

Szego et al. [2012] observed that the ion density moments derived by Thomsen et al. [2010] from Cassini CAPS measurements exhibit peaks around zero-crossings of the magnetic field. The proton peaks are broader while the heavy ion peaks are sharper. They found that the positions of these peaks can be explained by the simple structural model of Arridge et al. [2011a]. Szego et al.

[2013] modified this simple structural model to include the dual periodicity of the magnetic field, and found an even better agreement for the positions of the ion peaks.

Using numerical ion moments, Nemeth et al. [2015] investigated the azimuthal flow velocities measured by CAPS along with their periodicities. They observed a significant positive correlation between the azimuthal plasma speed and the plasma density, both anti-correlating with the magnitude of the radial component of the magnetic field. They found that the dense plasma near the magnetic equator rotates around the planet at high speed, but the dilute plasma of higher latitudes is rotating significantly slower.

Nemeth et al. [2016] analyzed the quasi-periodic variation of several plasma parameters. The variation of the magnetic field was used to recover the position of the magnetodisk, and the position information was further used to model the variation of the density and azimuthal velocity moments of the thermal ions. This simple technique provides very good fits for all three parameters simultaneously.

Saturn's disk-like magnetosphere produces a unique and interesting current system. The magnetodisk current flows in the equatorial magnetosphere eastward around the planet extending the field lines radially outward, carried by the differential drift of ions and electrons in the plasma trapped on Saturn's magnetic field lines, which grades into the cross-tail plasma sheet current separating the lobes of the magnetic tail on the nightside. Although the existence of the ring current was first established from magnetic data acquired during the Pioneer-11 and Voyager flybys, little was known of the variability of the current, and its physical nature remained a matter of controversy, whether due to centrifugal action of the plasma mass or to the effect of plasma pressure. Data from the initial sequence of near-equatorial Cassini orbits was first used to determine the strength and radial extent of the current, showing that this varies strongly with the size of the magnetosphere dependent on the dynamic pressure of the impinging solar wind [Bunce et al. 2007]. While the inner edge of the current lies nearly unvaryingly at an equatorial radial distance of ~7 R_S, the radius of the outer edge varies between ~15 R_S when the magnetosphere is strongly compressed to ~22 R_S when it is significantly expanded, these distances typically lying a only few R_S inside the dayside magnetopause. Correspondingly, the total eastward current varies from ~9 to ~15 MA, with a magnetic dipole moment that varies between ~0.2 and ~0.6 that of the internal field of the planet. A consequence is that while the dayside and comparably-near nightside field is quasi-dipolar in form when the system is compressed, the field lines extend into an equatorial magnetodisk when it is expanded [Bunce et al. 2008]. Later, when data from the first highly inclined Cassini orbits became available, the first direct measurements of the north-south thickness of the current sheet were also made, with values being typically ~3 R_S on the dayside, while varying between ~1 and ~5 R_S on the nightside [Kellett et al. 2009].

Cassini/MAG data revealed the magnetodisc [Arridge et al. 2008b; Bunce et al. 2008] was particularly sensitive to the solar wind pressure, essentially disappearing on the dayside when the magnetosphere was compressed by the solar wind and explaining why it was not detected by Pioneer 11 or Voyagers 1/2 [Arridge et al. 2008b].

The current sheet was also found to be warped out of the equatorial plane, as expected by analogy with Earth and Jupiter, but it was also found to be deformed at noon. Effectively the current sheet had the geometry of a shallow bowl, or upturned umbrella [Arridge et al. 2008a]. Subsequently, a detailed study of data from Earth's magnetosphere has revealed a similar effect at Earth [Tsyganenko and Andreeva 2014], inspired by Cassini/MAG measurements at Saturn. Superimposed upon this global warping was a flapping motion that occurred in phased with other periodicities in Saturn's magnetosphere [Arridge et al. 2011a, 2008c] and which had a lag or delay that propagated into the outer magnetosphere. However, latitudinal effects were also shown to play an important role, connected with differing periods in the northern and southern hemispheres [Provan et al. 2012].

Small ripples were also found superimposed on this bowl-shape [Arridge et al. 2007] that are largely propagating away from Saturn, indicating a source closer to the planet, possibly produced by plasma transport in the inner/middle magnetosphere [Martin and Arridge 2017].

The presence of the current sheet, and its deformation into a bowl-shape, has important consequences for Titan's magnetic and plasma environment, and so the structure of its induced magnetosphere [Backes et al. 2005; Arridge et al. 2011b; Simon et al. 2013], as not only is the magnetic field (oriented in a different location to that found by Voyager 1), but also the bowl-shaped current sheet means that the Titan is not continuously immersed in Saturn's magnetospheric plasma.

Detailed collaborative work of the MAPS teams also examined the physical nature of the current [Kellett et al. 2011, 2010; Sergis et al. 2018]. It was shown that inside ~10–12 R_S the current is carried principally by the relatively unvarying population of warm (~100 eV) water plasma picked-up from the Enceladus torus, comprising principally of inertia and pressure anisotropy currents. Beyond these distances it is carried mainly by the more variable hot tenuous plasma. While, by analogy with Earth, the term ring current particles is often taken to be synonymous with hot injected plasma, this usage has thus proven to be inappropriate at Saturn, since the outwardly-transported warm water plasma is at least as significant in carrying the current.

The middle magnetosphere is the region where the so-called ring current of Saturn resides. This current likely has important components below the energy range of MIMI. But it has been found to contain energetic ions and electron below 1 MeV, with relatively high fluxes. It is populated by large scale injections in the nightside magnetosphere of Saturn, which populate the ring current with a series of rotating, energetic ion and electron bundles, called sometimes blobs due to their appearance as such in remote sensing images by MIMI/INCA. The energy density of the energetic ion population is high enough to increase the plasma beta (the ratio of total particle pressure divided by magnetic pressure) above one, therefore causing a significant stretching of the magnetic field lines. Depending on the abundance of oxygen in the energetic ion distributions, the dynamics of the current

Depending on the abundance of oxygen in the energetic ion distributions, the dynamics of the current sheet may be dominated by the presence of energetic particles.

sheet may be dominated by the presence of energetic particles. All these results are summarized in a series of studies by Sergis et al. [2017, 2013, 2011, 2010, 2009, 2007]; Krimigis et al. [2007]; Dialynas et al. [2013, 2009]; Carbary et al. [2014, 2012, 2010b, 2008b]; Kollmann et al. [2011]. All these measurements provided a most comprehensive, average description of Saturn's ring current, which can inform numerous empirical and physical models of Saturn's magnetosphere, for example, Achilleos et al. [2010a]. The time variations in the ring current have been linked to changes in the radiation belts [Roussos et al. 2018b, 2014; Kollmann et al. 2017], injections [Mitchell et al. 2016, 2015, 2009a], revealing the coupling of the system with different regions of the magnetosphere and the interplanetary space and the aurora, for example, Mitchell et al. [2009b]. The average properties of the ring current, as monitored by ENAs, have been inverted in order to probe the characteristics of Saturn's neutral gas cloud [Dialynas et al. 2013]. Meanwhile, the average distribution of the middle magnetosphere energetic particles has been studies using observations from CHEMS [Allen et al. 2018].

Many of the studies focusing of the inner magnetosphere extended into the region of the ring current, meaning that energy spectra, angular and L-shell distributions, composition, as well as asymmetries are equally well quantified for $9 < L < 15$.

In the inner and middle magnetospheres, significant work has been done to characterize not only the current systems, but also the plasma properties. In these regions the primary spatial dependence of magnetospheric properties is in the radial direction. From the first SOI pass through the magnetosphere [Young et al. 2005], several distinct magnetospheric regions could be identified: an outer region (inside the magnetopause) with extremely low density, later understood as magnetospheric lobe; then a significantly denser region with variable density and dominantly H^+, later understood as the higher-latitude manifestation of the plasma sheet/ring current; and finally, a much denser inner plasmasphere with W^+. Subsequent analyses of the SOI data [Sittler et al. 2008, 2006a, 2006b, 2005] provided quantitative estimates of the H^+, W^+, and electron plasma parameters in the inner magnetosphere and demonstrated that the plasma flow velocity is near corotation throughout the region (corotation is the azimuthal flow that results from essentially rigid rotation with the planet; it is enforced by currents flowing along the magnetic field lines between the upper atmosphere and the magnetospheric plasma). The proton and water-group temperatures were consistent with local ionization and pick-up into the corotating flow. The electrons in the inner magnetosphere consist of two populations: a cool component whose temperature tracks the proton temperature and a hotter population that increases in energy with decreasing radial distance [Young et al. 2005; Sittler et al. 2006a, 2006b; Schippers et al. 2008]. Later work [Rymer et al. 2007; Rymer 2010] showed that the cold electron component was consistent with a local pick-up source and subsequent heating via Coulomb collisions with the protons. The hot component was consistent with adiabatic transport inwards from a source in the plasma sheet/ring current region.

Calculation of the ion plasma moments (density, temperature, flow velocity) from CAPS data is complicated by incomplete and variable viewing. Nonetheless, application of a numerical computational scheme to the full data set through March 2009 enabled a survey of the properties of H^+, W^+, and H_2^+ (the third most common ion species in the magnetosphere, as revealed by CAPS time-of-flight measurements) throughout the magnetosphere [Thomsen et al. 2010]. The survey

confirmed that densities decrease and temperatures increase with radial distance inside ~20 R_S, and the W^+ density declines more rapidly than light ions. The flow velocity remains primarily in the corotational direction essentially all the way to the magnetopause, but the speed is lower than full corotation. Combined with the higher-energy measurements of MIMI, the CAPS data enabled a comprehensive survey of the total plasma pressure throughout the magnetosphere and thus an understanding of the currents that distort the dipole field within the plasma sheet and ring current region [Sergis et al. 2017, 2010]. A more recent survey of plasma moments calculated with a forward modeling approach that includes anisotropic temperatures explores both the radial and local time variations of the plasma (Figure MAPS-20), [Wilson et al. 2017].

Due to strong centrifugal forces on corotating plasma, Saturn's magnetosphere is flattened into a disk shape, especially on the night side and during times of relatively low solar wind dynamic pressure, for example, Arridge et al. [2008b, 2007]. CAPS data allow determination of the latitudinal scale heights of H^+, W^+, and H_2^+ and show that the heavy ions are more strongly confined to the equatorial plane, for example, Thomsen et al. [2010]. In the magnetotail, the magnetodisk structure is particularly prominent, with the current flowing in a relatively thin region of dense plasma separating the lobes of oppositely-directed magnetic field. The magnetodisk consists of a structured plasma sheet: a low-latitude heavy ion layer displaying narrow substructures, and a higher-latitude, smooth, broad ion layer composed dominantly of light ions (Figure MAPS-20), [Szego et al. 2011]. The density and azimuthal flow speed decline with increasing latitude [Nemeth et al. 2015] as a direct consequence of the sub-corotation of the plasma in the outer magnetosphere, for example, McAndrews et al. [2009]; Thomsen et al. [2014a, 2013]; Wilson et al. [2017]. Highest speeds occur on field lines at lowest latitudes mapping to the rapidly rotating inner regions of the plasma sheet, and the speed falls as one moves to higher latitudes, where the field lines are connected to strongly sub-corotating plasma at large radial distances.

An extremely important aspect of understanding the magnetosphere of Saturn is understanding the convection patterns and transport of plasma through and out of the magnetosphere. Saturn's magnetosphere is dominated throughout the equatorial magnetosphere by (partial) corotation with the planet. This was widely expected before the Cassini encounter, and although the expectation was not universally held, the basic result was no big surprise.

It is now clear that the dominant source of plasma for Saturn's entire equatorial magnetosphere is the inner icy satellites, in particular, the south-polar geyser plumes of Enceladus orbiting Saturn at L = 3.95, where L is the planet-centered distance normalized to Saturn's equatorial radius, $R_S \approx 60{,}300$ km [Young et al. 2005]. If tiny Enceladus is to dominate the source of Saturn's magnetospheric plasma, and hence its magnetospheric dynamics, there must be a mechanism for transporting this plasma radially from its inner-magnetospheric source to a sink in the outer magnetosphere and ultimately to the downstream solar wind. This transport mechanism is now known to be the centrifugal interchange instability.

In Saturn's magnetosphere, the centrifugal acceleration $\Omega 2/r$ is outward, and exceeds Saturn's inward gravitational acceleration beyond L ~ 2. Outward moving flux tubes release centrifugal potential energy from the system at a rate $\Omega 2/r$ per unit mass, and inward moving flux

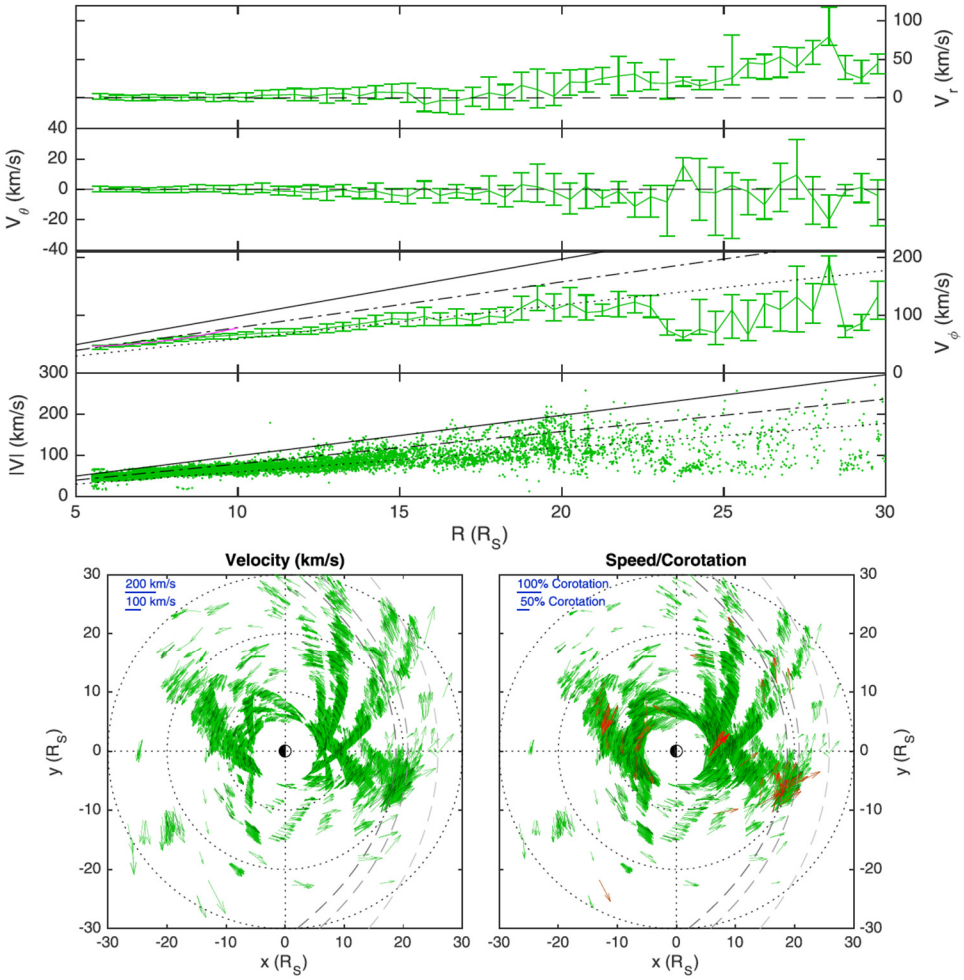

Figure MAPS-20. A recent survey of plasma moments calculated with a forward modeling approach that includes anisotropic temperatures explores both the radial and local time variations of the plasma. *Top three panels*: Radial profiles of plasma velocity components, in 0.5-Rs bins. *Fourth panel from the top*: All measured flow speeds. *Bottom left panel*: Equatorial plane projections of flow vectors with length proportional to flow speed. *Bottom right panel*: Same as the panel to the left, but with length proportional to the fraction of corotation. All data points are shown in green, while dark green shows every thirtieth data point. Figure from Wilson et al. [2017].

tubes add centrifugal potential energy to the system at the same rate per unit mass. Because of the inward density gradient of the combined plasma distribution (per unit magnetic flux), the combined flux-tube interchange process releases potential energy from the system and is therefore gravitationally unstable. The reverse would be true if the background density gradient (per unit magnetic flux) were reversed. In this sense the interchange motion is centrifugally driven. (Flux-tube interchange motions, by definition, involve no net radial transport of magnetic flux.)

It is also important to note that the azimuthal gradient and curvature drifts of the hot tenuous plasma result in plasma being injected inward by the interchange process, relative to a corotating frame of reference. This drift is prograde (eastward) for positive ions and retrograde (westward) for

negative ions and electrons. Its speed at a given distance is proportional to particle thermal energy. The injection process thus gives rise to an energy-longitude dispersion signature of the injected plasma, which has been called the smoking gun of interchange convection. This signature was repeatedly observed by CAPS on every Cassini pass through the inner magnetosphere, (L between ~5 and ~12), where the magnetic configuration is well described by an aligned dipole model [Burch et al. 2005; Hill et al. 2005; Young et al. 2005; Chen and Hill 2008; Chen et al. 2010; Rymer et al. 2009b, 2008]. An early example of this injection-dispersion signature, appropriate to this off-equatorial orbit, is shown in Figure MAPS-21 from Hill et al. [2005].

One unexpected feature of these CAPS observations was that Saturn's inflow channels (containing hot tenuous plasma) were always narrower in longitude than the neighboring outflow channels (containing cooler denser plasma), by a factor ~10 [Chen and Hill 2008; Chen et al. 2010]. All previous theoretical models of interchange convection had inflow and outflow channels of equal width, because of assumptions made for analytical convenience. Recent numerical simulations using the more flexible Rice Convection Model (RCM), driven by CAPS observational inputs [Liu et al. 2010; Liu and Hill 2012; Hill 2017, 2016; Hill et al. 2018], have clarified the reason for this apparent discrepancy between observation and theory. At Saturn (unlike at Jupiter) the source region for newly injected plasma, both from new ionization and from charge-exchange reactions with ambient neutral molecules, is broadly distributed throughout the radial range in which the resultant interchange radial transport occurs (L between ~5 and ~12).

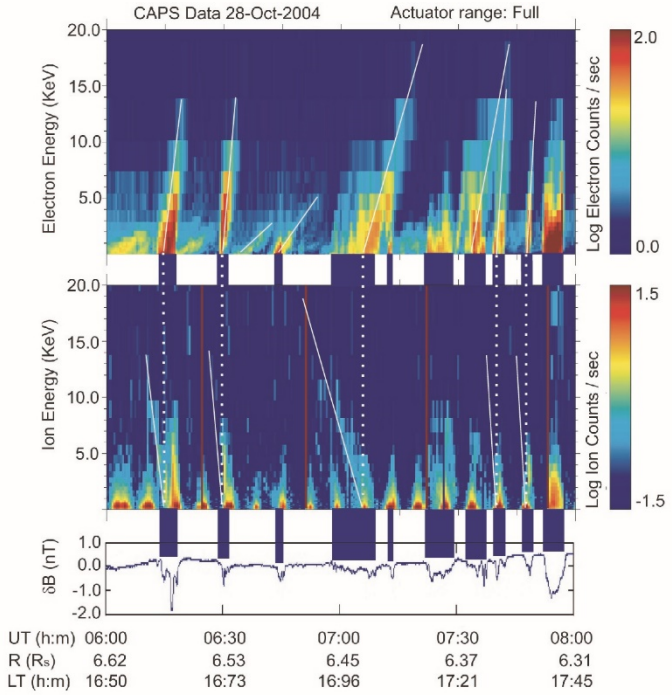

Figure MAPS-21. Early example of injection-dispersion signature, appropriate to off equatorial orbit. Linear energy-time spectrograms for electrons (*Top panel*) and positive ions (*Middle panel*) from the CAPS detectors during the second Cassini orbit of Saturn. *Bottom panel* shows simultaneous magnetic-field magnitude perturbations.

Injections at Saturn have been coarsely characterized as small and large scale. The latter would likely be accompanied by reconfigurations of the planetary magnetic field. Small-scale injections are probably confined to a small range of planetary longitudes and physically can be flux tube bundles, flow channels, or more elaborate structures. This group of injections also perturbs the magnetic field locally, for example, Andre et al. [2007, 2005], but probably at the level of a few percent of the planetary field. Andre et al. [2007] and Rymer et al. [2009b] present multi-instrument displays of interchange events in the magnetosphere of Saturn. This group of injections have been characterized as particle distributions with phase space densities that are very different from the surrounding medium in which they are observed [Mauk et al. 1998; Paranicas et al. 2016]. Mitchell et al. [2015] summarized the observational differences between small- and large-scale injections at Saturn. They found that small scale injections tended to be found inward of about 12–15 R_S, although they also found large-scale injections that could be inward of that distance. It is probably the case that small-scale injections (which are found very frequently in the data) extend in energy up to the tens of keV or so. Rymer et al. [2007] used phase space density profiles derived from CAPS data to approximate a starting radial distance of interchange injections that are observed by Cassini. Paranicas et al. [2016] approximated the inward flow speed of injections and found values comparable to the theoretical computations of Hill [2016] for $5 < L < 10$. It is believed that the radial speed of injections decreases as they approach Saturn.

Large-scale injections at Saturn have received much less attention in the literature than small scale ones. Thomsen et al. [2013] has provided a good summary of the situation. Large scale injections have been characterized by the MIMI data set. Mitchell et al. [2009b] linked some of these injections to UV data from HST and Cassini. Paranicas et al. [2010, 2007] looked at the radial range of injection remnants. Because these extend into the hundreds of keV, it is likely Paranicas was studying large-scale injections. The effects of tail collapse, plasmoid production, and related processes have been documented with the help of magnetometer data, for example, Jackman et al. [2015, 2011].

Because of their ubiquity, injections at Saturn have been used to characterize other features of the magnetosphere. Mauk et al. [2005] and Müeller et al. [2010] created azimuthal plasma flow speeds as a function of Saturn distance using MIMI injection data. Plasma flow speeds were later found using the plasma data, for example, Thomsen et al. [2010].

There are useful and well-established relationships between the local rate of plasma mass or momentum loading (through new ionization, charge exchange, or outward mass transport), on one hand, and the radial variation of the rotational lag behind rigid corotation with the planet, on the other hand. Rates of ionization, charge exchange, and net outward mass transport are difficult if not impossible to measure directly. But the corotation lag is straightforward to measure directly if one has access to reliable in situ plasma measurements. Tokar et al. [2006] reported surprisingly strong and asymmetric plasma flow perturbations during the distant and highly inclined July 2005 Cassini encounter with Enceladus. This study also concluded that plasma mass is added to Saturn's magnetosphere at a rate > ~100 kg/s in the near vicinity of Enceladus, a conclusion that was controversial at the time but was subsequently verified by many independent analyses, for example, Chen et al. [2010]. Pontius and Hill [2009] applied a similar analysis, not to the localized plasma

loading in the immediate vicinity of Enceladus, but to the much broader region 3 < ~L < ~10 where significant corotation lag was reported by Wilson et al. [2009, 2008] from their analysis of CAPS data. The study showed that the corotation lag as a fraction of the local rigid corotation speed. The data-model comparison of Pontius and Hill [2009] concludes that the plasma loading rate in this much larger volume is also > ~100 kg/s, comparable to that in the near vicinity of Enceladus.

Plasma loss into the magnetotail

- **MC1a:** Determine the temporal variability of Enceladus' plumes.
  - Investigate temporal variations in Enceladus gas production and plume composition, on the scale of seasons and solar cycle.
  - Study plume neutral gas composition.
  - Investigate the physics of the dusty plasma environment
  - Determine how the magnetosphere reacts to changes in (plume?) gas production rates by studying Enceladus' auroral footprint.
  - Study variability in dust-to-gas mass ratio.
- **MN1a:** Determine the dynamics of Saturn's magnetotail.
  - Study thoroughly the plasma sheet in Saturn's magnetotail.
  - Investigate the relation between solar wind compression events and magnetotail dynamics.
  - Investigate the plasma sheet thickness and scale height as functions of radial distance and local time.
  - Statistically characterize magnetotail variations, especially those associated with plasmoids, and correlate them with changes in the inner magnetosphere.
  - Critically evaluate the Dungey and Vasyliunas cycles in light of the new observations, especially those of flow speeds.

Enceladus, the rings, and Titan are all sources of plasma in Saturn's magnetosphere. The roughly 100 kg/s of mass being added must eventually find its way out of the inner and middle magnetosphere and into the magnetotail where it can be lost. Large-scale reconnection events that may produce plasmoids provides one potential escape route for the cool W^+ plasma that has accumulated from the interior source region. There remains some controversy as to whether this escape route is adequate to balance the interior source rate, estimated to be roughly 100 kg/s or more as noted above. It is plausible, but not yet demonstrated, that an unseen spectrum of smaller but more frequent plasmoids could contribute importantly to the escape rate.

Magnetic reconnection in the magnetotail current sheet can produce plasmoids, magnetic flux ropes (or closed magnetic loops) that are disconnected from the planet at one (or both) ends. These structures have been routinely observed in the magnetotails of Earth and Jupiter. Their detection

at Saturn by Cassini was limited by orbital geometry because the 2006 deep magnetotail passes by Cassini occurred near Saturn's northern winter solstice, when the warped magnetotail current sheet was presumably displaced well northward of Cassini's orbital plane (see Figure MAPS-22). Despite this problem, three plasmoid-like magnetic signatures were identified in the Cassini magnetometer data [Jackman et al. 2007]. Two of these events actually crossed the current sheet, where ion fluxes were sufficient to permit composition and velocity-moment information to be extracted from CAPS data. These two events were analyzed in detail by Hill et al. [2008]. The most dramatic event occurred on March 4, 2006, at a planet-centered distance of 44 R_S and at 0300 LT. Results are shown in Figure MAPS-23 and Figure MAPS-24.

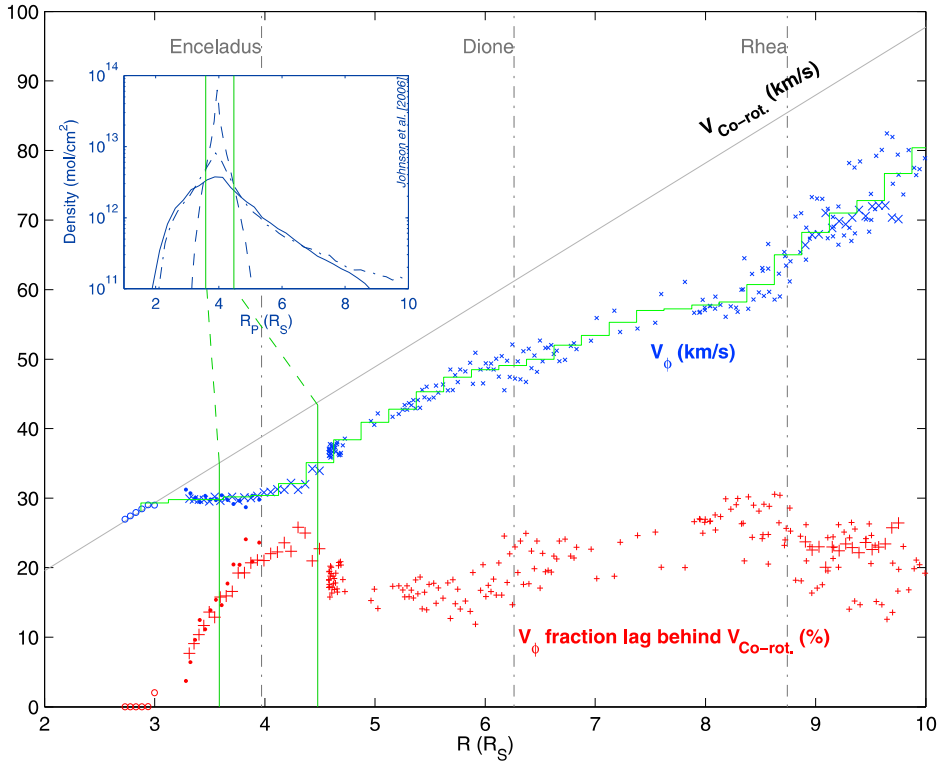

Figure MAPS-22. CAPS plasma flow measurements. Data for L > 5.5 are from forward modeling of thermalized ion velocity moments [Wilson et al. 2008]. Data for L < 5.5 are obtained from analysis of freshly picked-up charge-exchange products under the assumption of gyrotropy. Red symbols at the bottom show azimuthal speeds as a fraction of the local corotation speed. Figure from Wilson et al. [2009] Figure 4.

Early in this event, before the sharp B_θ reversal near 2300 UT, water-group ions (W^+) dominated the plasma composition, indicating a pinching off of a formerly closed flux tube containing plasma from the interior source, as in Vasyliunas-cycle reconnection. At about 23:10 UT the W^+ peak went off-scale above the energy-per-charge range of the CAPS IMS (50 V), so W^+ velocity moments became unavailable though their flux remained high. The velocity moments (based on H^+ after 23:10) indicate sub-corotational azimuthal flow throughout the event and a dramatic tailward acceleration (with Vr increasing up to ~800 km/s) late in the event. Rigid corotation at this distance would be 430 km/s in the V_Φ direction.

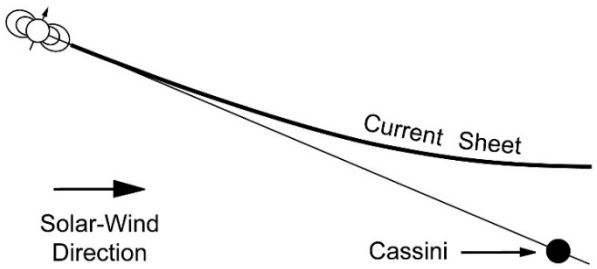

Figure MAPS-23. Orbital geometry during the deep-tail passes of Cassini. Figure from Hill et al. [2008] Figure 1.

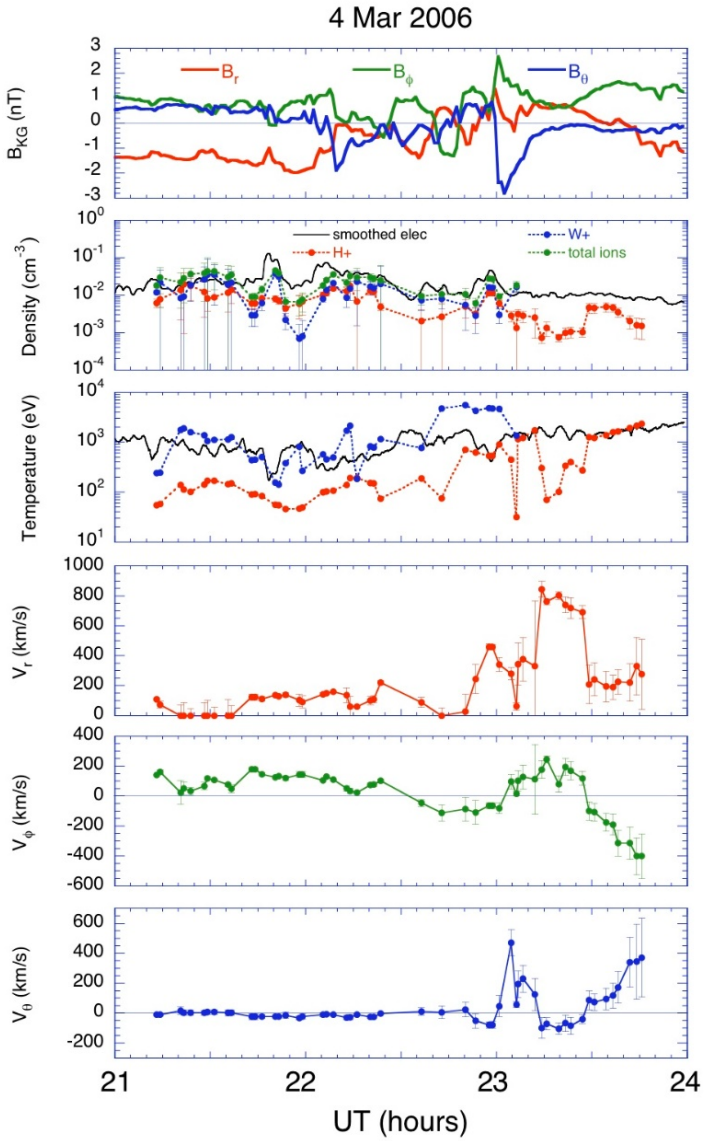

Figure MAPS-24. Magnetic field components and particle velocity moments for the plasmoid encountered by Cassini at 44 R_S near 0300 LT. Figure from Hill et al. [2008] Figure 3.

A particularly interesting feature of this event is that Cassini was in a position to see not only the plasmoid properties observed in situ by CAPS and MAG, but also the plasmoids earlier initiation closer to Saturn as observed by MIMI in ENA bursts. The viewing geometry is shown in Figure MAPS-25. The ENAs were hydrogen and oxygen atoms having speeds consistent with covering the distance from source to Cassini (~26.5 R_S) in the allotted time (~25 min). The plasmoid structure itself could also have covered the same distance in the same time interval [Hill et al. 2008].

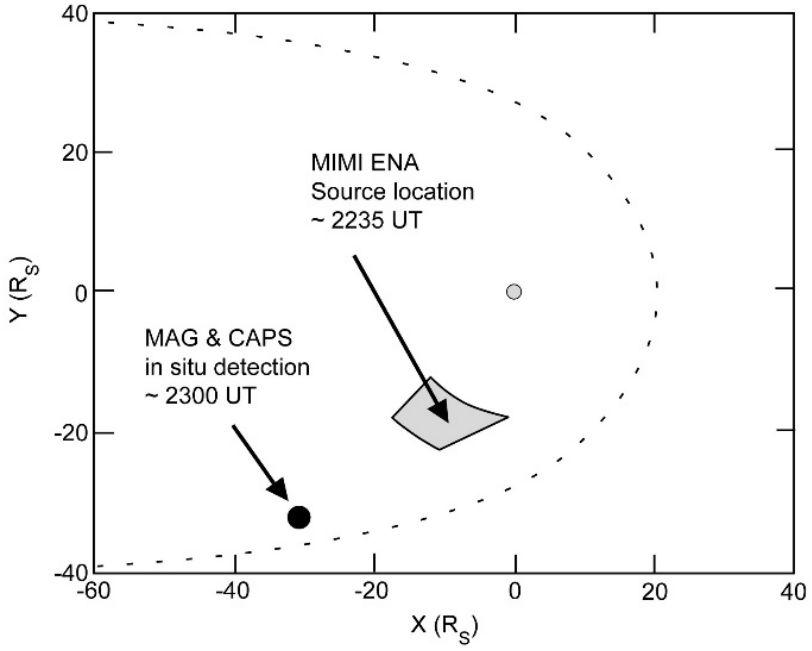

Figure MAPS-25. During the in situ CAPS and MAG plasmoid observations on March 4, 2006, Cassini was within the large dot indicated, and the ENA bursts observed from the same location ~25 min earlier were deduced to have a source within the quasi-rectangular shaded box. The dashed contour is a cartoon depiction of the typical shape and location of Saturn's magnetopause.

Magnetotail reconnection also provides a fresh source of hot, tenuous plasma to the region planetward of the reconnection site, where it produces a dipolarization signature in the magnetic field. It can also provide seed particles both for the inflow channels of the interchange cells in the inner magnetosphere, as described earlier, and for the intermittent ENA bursts observed by MIMI from the middle and outer magnetosphere, and the associated SKR bursts observed by RPWS from the footprints of the same field lines.

Theoretically, there is a clear distinction between Vasyliunas-cycle reconnection involving the pinching off of formerly closed flux tubes, containing cool dense plasma from the inner-magnetosphere source, and the more Earth-like Dungey-cycle reconnection involving the closure of formerly open flux tubes of the magnetotail lobes, containing hotter and more tenuous plasma of magnetosheath origin. The large plasmoid described above is readily explained by the Vasyliunas cycle alone. But two detailed multi-instrument event studies [Thomsen et al. 2015a, 2015b] have also found evidence of both Vasyliunas and Dungey cycles occurring either

simultaneously or sequentially. In addition, Cowley et al. [2015] estimate that based on the duration of observed plasmoid field perturbations the mass loss due to plasmoids is at least an order of magnitude smaller than necessary. Given the typically several-hour interval between plasmoid releases it has been suggested that the overall plasma structure released by such events may be at least an order of magnitude longer than the few tens of R_S lengths inferred from the magnetic data direct.

Thomsen et al. [2015b] examined a high-latitude dawnside Cassini pass from the low-density lobe region into the higher-density closed field-line region. They inferred a stripping of plasma from the outer region of closed magnetic flux tubes as those tubes cross the night side magnetosphere from dusk to dawn, attributable to Vasyliunas-cycle reconnection, together with an interval (or region) of Dungey-cycle reconnection at the high-latitude boundary between open and closed field lines.

On the other hand, Thomsen et al. [2015a] examined a deep-tail near-equatorial Cassini pass near 37 R_S near midnight LT. They found a prolonged period (~5 hours) of planet-ward plasma-sheet flow attributable to an even more prolonged period of magnetotail compression due to the passage of a recurrent solar-wind structure containing enhanced dynamic pressure. They conclude that Dungey-cycle reconnection takes precedence over Vasyliunas-cycle reconnection when the solar-wind pressure is high.

In addition, numerous reconnection-related events during the main Cassini tail exploration interval in 2006, namely planetward-travelling dipolarizations and tailward-travelling plasmoid structures, which were found to be related in timing to both the pulsing of the SKR emissions and the magnetic PPO phase [Jackman et al. 2016, 2009a]. Specifically, the events were found to be preferentially initiated during intervals when the PPO perturbations stretch the field lines radially outward from the planet and thin the plasma sheet leading to instability (see entitled Time varying modulation of SKR and associated PPO signals), especially when the two PPO systems act in this manner in concert, i.e., when they are near antiphase. Ongoing work is presently investigating dipolarization events and auroral storms during the sequence of proximal orbits observed just prior to end of mission.

Plasma composition, distribution, sources, and sinks

- **M_AO2:** Determine current systems, composition, sources, and sinks of magnetosphere charged particles.

Understanding the plasma composition, distribution, sources and sink in Saturn's magnetosphere begins with understanding the neutral gas sources. Prior to the arrival of Cassini in the Saturn system, Voyager measurements seemed to indicate that Titan was the main sources of the neutral gas in the system and therefore the main sources of plasma. However, with the discovery of the activity of Enceladus and better mass resolved measurements of the neutral and the plasma composition it became clear that Enceladus, the other icy satellites and the rings are the major source of distributed mass in the Saturn system.

Our understanding of the neutral gas distribution comes from measurements made by the INMS instrument. In 2008, the INMS investigation made in situ measurements of neutral species near Saturn's equatorial plane within 0.5 R_S of the orbit of Enceladus. After removing the large background and modeling to interpret instrumental effects, the data provide constraints on the neutral distribution and composition. These data show an azimuthal asymmetry in the neutral densities and provide measurements used to compare to simulations of neutral H_2O emitted from Enceladus (Figure MAPS-26). Far from Enceladus, the neutral water densities, at a few times 10^3 molecules/cm^3, are near the detection limit of INMS. Near Enceladus, but outside of the plumes and north of the equatorial plane, the INMS detects particles within 5,000 km of Enceladus, with the density increasing to approximately 10^5 molecules/cm^3 at the equatorial plane.

INMS observes inner-magnetosphere neutrals with a mass of 28 u that have unexpectedly high densities, no apparent source, and no clear molecular identification. With densities as high as 30% of the neutral-water density, the candidate molecules, N_2 and CO, should be abundant in the Enceladus emissions, but multiple observational approaches show that neither molecule comprises more than 3% of the H_2O density.

Although RPWS cannot distinguish the species of ions in the magnetosphere, measurements of the electron density in the inner magnetosphere show that adjacent to the dense A-ring there is an electron density maximum at over 100 electrons/cm^3, with the high density region (> 10/cm^3)

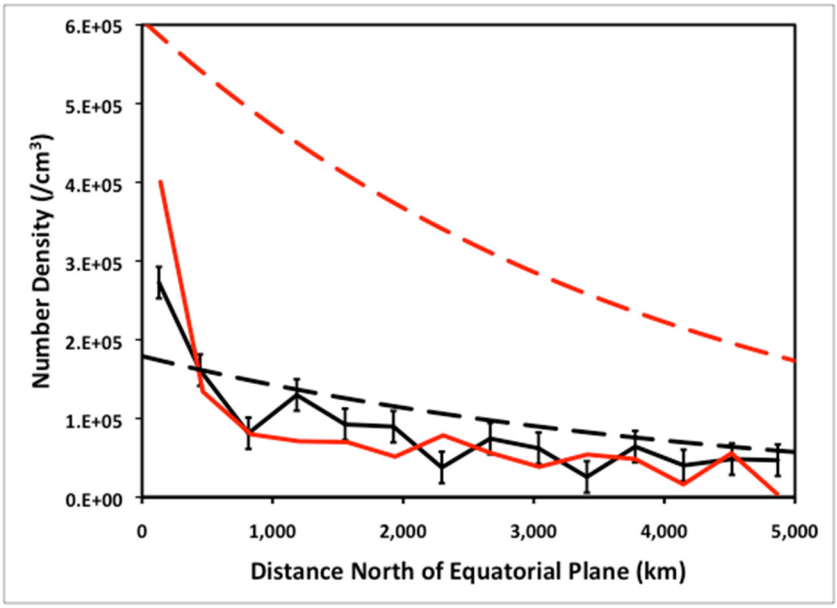

Figure MAPS-26. Neutral cloud density north of Enceladus, before close approach and outside of proximal influence of the south-pole plumes. The solid lines are the INMS data. The dashed lines are simulations using the charge-exchange model of the neutral cloud [Smith 2010]. The E5 simulation is based on the source rate derived from modeling the E5 plumes, and the E3 simulation is based on the source rate derived from modeling the E3 plumes. The E3 and E5 INMS densities are similar to each other and to the E3 simulation. E5 error bars (not shown to reduce clutter) are the same size as E3 error bars.

extending out to beyond L = 5. Persoon et al. [2015, 2009] found that this high density region is a plasma torus created by ionization and pick-up of new ions born in the Enceladus plume and a seasonal contribution from photo-ionized neutrals originating from the rings themselves. Thus, at equinox, the maximum in plasma density in this torus shifts radially outward to 4 R_S, but at solstice, the sun-facing rings become a neutral and plasma source shifting the torus plasma maximum closer to the A-ring—see Persoon et al. [2015] Figures 6 and 7. The peak density in the torus is about 10% of the Io torus at Jupiter and represents a dominant controlling element in the inner magnetosphere of Saturn [Gurnett et al. 2007]. These RPWS measurements in the inner magnetosphere have allowed Persoon et al. [2013, 2009] to develop an empirical plasma density model for the Saturnian system.

In addition to the direct measurements of the neutral distribution by the INMS instrument, one of the best pointers to the source of plasma in the magnetosphere is the composition. CAPS finds that the dominant magnetospheric ions are W^+, H^+, and H_2^+ [Young et al. 2005; Thomsen et al. 2010] were well explained by the later discovery of the prodigious output of water from the south-polar plumes of Enceladus. It was noted by Young et al. [2005] that the presence of H_3O^+ within the W^+ ion group indicated ion-molecule reactions occurring in a water-rich atmosphere, attributed to the E-ring and inner icy satellites, which ultimately was determined to be Enceladus. A careful separation of the individual components of the water-group species and determination of the radial distance dependence of their relative proportions [Wilson et al. 2015] provided vital constraints on models of the physics and chemistry of Enceladus-originating material.

INMS has extracted the water-group ion fractions from open source ion (OSI) measurements in Saturn's inner magnetosphere. These fractions are sensitive probes of the source, transport, and loss mechanisms that govern Saturn's magnetosphere. INMS samples only a small portion of velocity space at a time, which enables investigation of the distributions within velocity space but also limits sensitivity and complicates the separation of various factors that affect the relative ion fractions. Densities and count rates can be low, sometimes requiring the sum of 10,000 IPs for a two-sigma result. Figure MAPS-27 shows that ion fractions depend on distance from the orbit of Enceladus. Models show that the water-group fractions depend most strongly on the local fraction of neutrals. In contrast to CAPS results, INMS data show H_3O^+ fractions less than 0.1 except for measurements taken directly in the plumes. These fractions are now being used to calibration ion and neutral models of Saturn's magnetosphere.

Another example of source determination through composition is N^+ [Smith et al. 2008, 2007, 2005] (see Figure MAPS-28). Originally expected from Titan, the radial dependence of the N^+ phase space density and the energy of this population suggested instead an inner magnetosphere source, probably Enceladus, with both molecular nitrogen and ammonia emitted there. Surprisingly little N^+ has been found in the outer magnetosphere, indicating that nitrogen ions coming from Titan do not accumulate to significant densities.

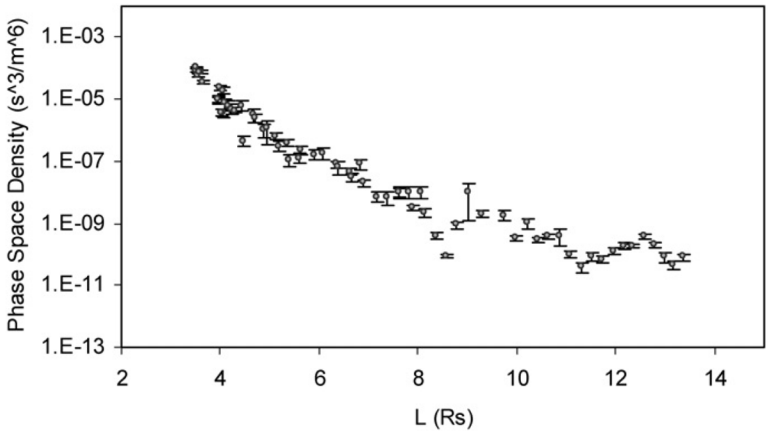

Figure MAPS-27. Nitrogen ion phase space density averaged over energy and angle, as a function of distance from Saturn. Clear decline with distance indicates a source in the inner region, inconsistent with a Titan source in the outer magnetosphere (L ~20). Figure from Smith et al. [2007].

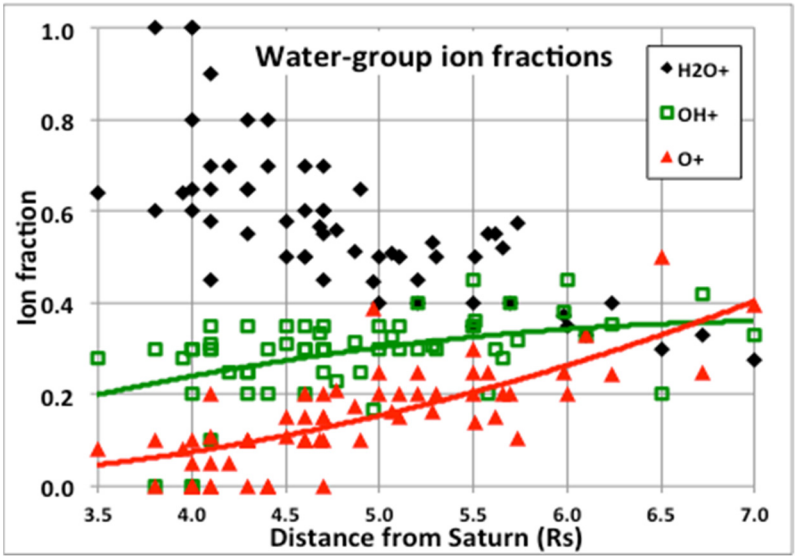

Figure MAPS-28. The fraction of water-group ions plotted as a function of distance from Saturn. INMS finds that the highest fraction of H_3O^+ is near 4 R_S, as expected, as that is the orbit of Enceladus, the source of the neutral water that becomes the plasma.

As indicated above, the dominant ion species seen throughout the magnetosphere are well explained by ionization of material from the water plumes of Enceladus. Cassini MAPS instruments observations of the plumes themselves are detailed in the section entitled Interaction of the Enceladus plume with the magnetosphere. In addition, MAPS instruments and CAPS in particular showed Enceladus to be the probable source of most of the N^+ observed in Saturn's inner magnetosphere, and CAPS measurements further helped reveal the existence of temporal variability in the plume source [Smith et al. 2010].

Before the arrival of Cassini in the Saturn system, Titan was regarded as the major source of neutrals and hence ions to the Saturn magnetosphere. The primary tracers of Titan's contributions to magnetospheric plasma have been N^+ and H_2^+. The finding of very little N^+ in the outer magnetosphere [Smith et al. 2005] indicated that Titan's contribution to the heavy-ion plasma is limited, whereas the fact that H_2^+ becomes comparable to H^+ and W^+ in the outer magnetosphere [Thomsen et al. 2010] indicates that Titan is an important source of lighter ions in that region. From observations during passage through Titan's wake region, the total mass loss rate from Titan is estimated to be a few × 10^{25} amu/q/sec (~0.8 kg/s) [Coates et al. 2012], compared to estimates of ~60–100 kg/s from Enceladus [Fleshman et al. 2013].

CAPS was turned off before the F-Ring and proximal orbits, so the only direct exploration of ring-associated plasma occurred during SOI, where a layer of O^+ and O_2^+ was discovered over the A-ring and B-ring [Young et al. 2005]. Subsequent analysis of the SOI data [Tokar et al. 2005] produced densities and temperatures of these two species (Figure MAPS-29). The ring atmosphere and ionosphere are likely produced by UV photo sputtering of the icy rings and subsequent photoionization of O_2^+. Significant O_2^+ was also detected outside the main rings, near the F-ring [Tokar et al. 2005], and analysis of the O_2^+ and W^+ profiles showed the seasonal dependence mentioned above, consistent with a ring source that depends on the solar illumination angle [Elrod et al. 2014, 2012]. The result indicates that the rings are an important source of O_2^+ and O^+ ions inside the orbit of Mimas.

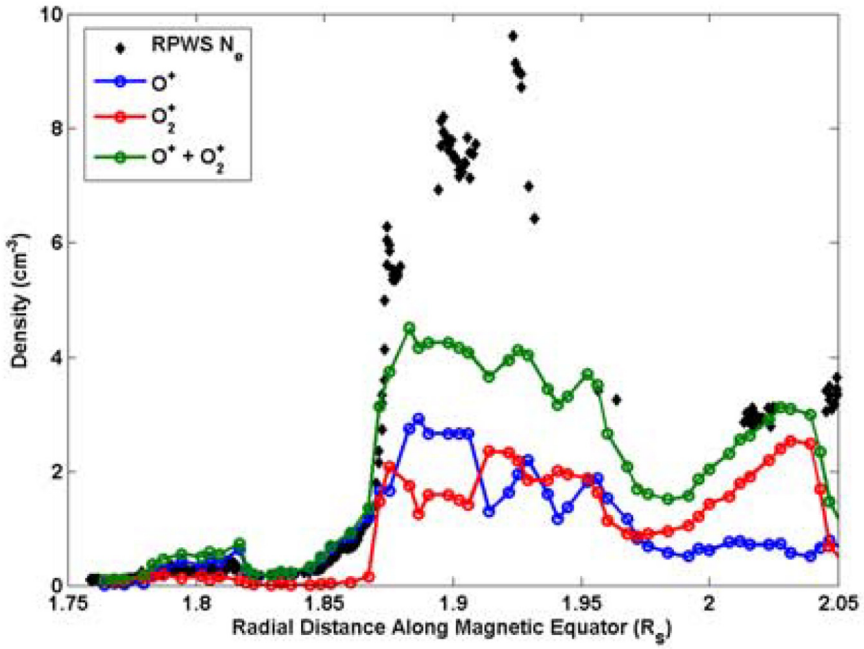

Figure MAPS-29. Radial dependence of O^+ and O_2^+ densities from CAPS observations over the main rings during SOI. Figure from Tokar et al. [2005].

CAPS has also detected O_2^+ in the vicinity of Dione [Tokar et al. 2012], and the observed radial dependence of the ratio O_2^+/W^+ suggested that there is a neutral O_2 source in the vicinity of Rhea [Martens et al. 2008]. Although the evidence for oxygen from Rhea is somewhat skimpy, CAPS has clearly detected non-gyrotropic outflowing CO_2^+ there, as well as another negatively-charged species, previously thought to be O^- but now found to be closer to mass 23 [Desai et al. 2018]. The latter is perhaps a carbon-based ion deriving from implanted exogenic compounds. Examination of the plasma conditions on flybys of Rhea [Wilson et al. 2010] revealed that the plasma flowing near it had no radial component on the Saturn-side of the moon, but had a radially outward component on the anti-Saturn-side. This is potentially due to an electric field enhancement near the moon, as observed in hybrid simulations.

Observation of probable plasma outflows from the ionosphere at the outer edge of the night side plasma sheet and extending into the lobes led to an estimate of some 10 s of kg/s lofted from the ionosphere (Figure MAPS-30) [Felici et al. 2016]. The observations occurred during a probable solar wind dynamic pressure enhancement, which may be important for producing significant outflow. It is not yet clear how often such outflow occurs, nor whether the outflow is actually captured into the closed region of the magnetosphere, rather than just escaping into the solar wind. Additionally, the field-aligned angular distributions of the suprathermal electrons within the plasma sheet/ring current region may indicate an ionospheric origin [Schippers et al. 2008], but no supporting evidence from the ion data has been reported.

With regard to dayside entry of solar wind plasma via reconnection or the K-H instability, there is considerable evidence that both processes take place. Magnetopause encounters frequently exhibit a low-latitude boundary layer (LLBL), in which magnetosheath plasma can be found just inside the magnetopause. From a survey of 354 crossings of the LLBL [Masters et al. 2011b, 2011c], the estimated thickness of the LLBL is only of the order of 1 Saturn radius, with no clear dawn-dusk asymmetry. Thus, while solar wind plasma can and does enter the magnetosphere on the dayside, it does not get very far in. This is supported by the fact that the ratio of m/q = 2 to H^+ ions in the outer magnetosphere is almost always significantly greater than the values of 1 to 10% typically seen within the solar wind [Thomsen et al. 2010], indicating that the plasma in the outer magnetosphere is dominantly of inner magnetospheric and/or Titan origin, with very little contribution from solar wind plasma there.

On the night side, plasma with solar wind-like composition has been observed at 37 R_S near local midnight [Thomsen et al. 2015a]. In that event, it appeared that prolonged high solar wind dynamic pressure may have caused erosion of the tail plasma sheet through ongoing Vasyliunas-type reconnection that then involved open lobe field lines and created a more Earth-like, Dungey-style outer plasma sheet dominantly of solar wind origin. Other evidence for Dungey-style reconnection following a Vasyliunas-style reconnection event is the post-plasmoid plasma sheet, for example, Jackman et al. [2011]. One other event that showed the possibility of a Dungey region, in which field lines were probably closed but the densities were quite low and there was very little O^+, was seen in a rapid high-latitude pass near dawn with clear evidence of Vasyliunas-type reconnection at latitudes just equatorward of the Dungey region [Thomsen et al. 2015b].

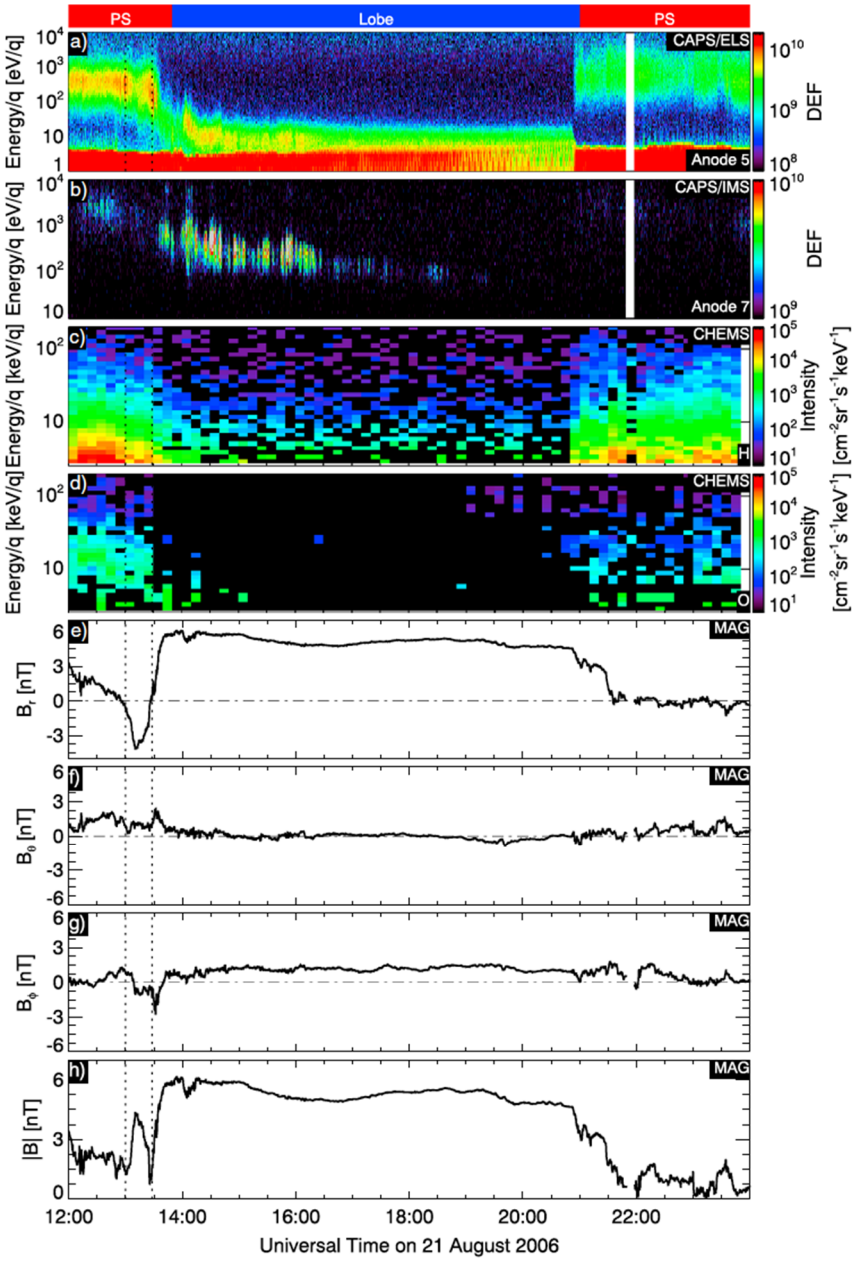

Figure MAPS-30. CAPS observations of an outflowing H^+ population from Saturn's ionosphere, seen in the lobe near the plasma sheet boundary at 36 RJ down tail. Figure from Felici et al. [2016].

CAPS measurements consistently show that plasma flow in the inner magnetosphere is dominantly in the corotation direction, with a magnitude near full corotation at low radial distances but tending toward a fraction (~60%) of full corotation by 10 R_S, see Sittler et al. [2005]; Wilson et al. [2017, 2009, 2008]; Thomsen et al. [2010]; Livi et al. [2014]. Radial velocities are much smaller and difficult to measure [Wilson et al. 2008].

There is widespread agreement that the primary mechanism for radial transport within the inner magnetosphere, which is needed to remove the continuously-produced plasma from Enceladus, is the process of centrifugally-driven flux-tube interchange. This process is described in detail in the section entitled Magnetospheric Structure and Convection, but CAPS data have been instrumental in the discovery [Young et al. 2005; Hill et al. 2005; Burch et al. 2005] and diagnosis [Andre et al. 2007; Chen and Hill 2008; Menietti et al. 2008; Rymer et al. 2009b; Chen et al. 2010; DeJong et al. 2010; Thomsen et al. 2014b; Paranicas et al. 2016] of the hot-plasma injection events that are the inward-moving half of the flux-tube interchange. There has been only one reported observation of the outward-moving cold plasma fingers that should form the other half of the process [Thomsen et al. 2015b]. Estimates of the inflow speeds within the injection channels range from a few km/s to ~260 km/s [Burch et al. 2005; Rymer et al. 2009b; Chen et al. 2010; Paranicas et al. 2016]. Composition suggests that the plasma inside the injection channels comes from the outer magnetosphere [Thomsen et al. 2014b].

One unanticipated discovery of the Cassini mission is the existence of an inner magnetospheric convection pattern superimposed on the dominant corotation pattern [Andriopoulou et al. 2014, 2012; Thomsen et al. 2012; Wilson et al. 2013]. The pattern consists of a general dusk-to-dawn drift, such that particles drift inward while they corotate from noon to midnight and outward as they return from midnight to noon (Figure MAPS-31). The result is an inward displacement at midnight compared to noon. A number of hypotheses regarding this convection have been advanced, but it remains an unsolved puzzle.

Beyond 10 R_S, CAPS measurements show consistently that the plasma flow overwhelmingly remains in the corotational direction at essentially all local times, indicating continued influence of connection to the corotating ionosphere, but the speed of the flow is well below full corotation, for example, McAndrews et al. [2009]; Thomsen et al. [2014a, 2013, 2010]; Wilson et al. [2017]. Beyond about 15–20 R_S, there is little evidence for inflowing plasma on the night side, where, particularly near the flanks, flows tend to have more of an outward component. From the lack of inward flow in the pre-dawn sector, it appears that dense plasma is not often able to make the turn and return sunward to the dayside magnetosphere at distances beyond ~15 R_S.

One of the principal ways in which plasma produced in the inner magnetosphere can be shed to the solar wind is through the process of magnetic reconnection in the tail. This is covered in greater detail in the section entitled Plasma loss into the magnetotail and Magnetotail configuration and dynamics flux tubes loaded with inner magnetospheric plasma are transported via interchange to the outer magnetosphere. Strong centrifugal forces distend them radially, especially near the equatorial plane. On the dayside, the pressure of the solar wind helps confine the distended flux tubes, but when they rotate into the night side, that confinement goes away, and centrifugal force can overwhelm the magnetic tension. The result is that the flux tubes pinch off (or reconnect), shedding a plasmoid that is no longer connected to the planet and which carries away the load of plasma the flux tube bore before reconnection occurred. This is the so-called Vasyliunas cycle. CAPS data have been instrumental in identifying the resulting down tail flows of the disconnected plasmoids [Hill et al. 2008; McAndrews et al. 2009; Jackman et al. 2015, 2014; Arridge et al. 2015;

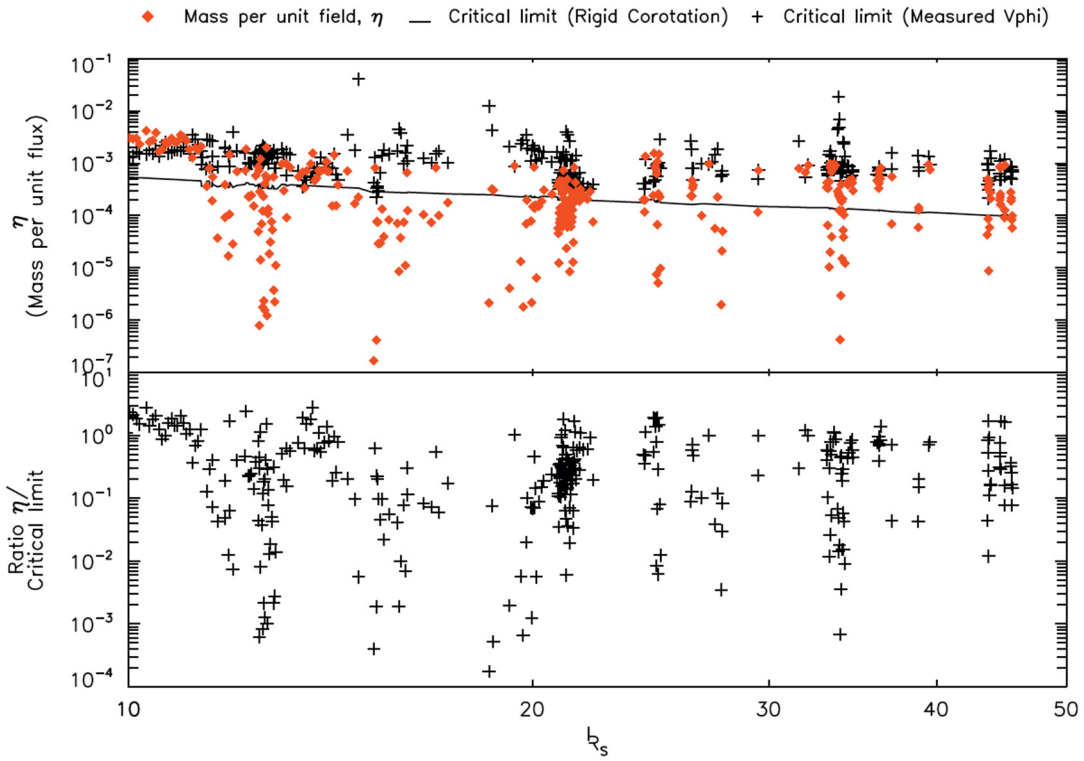

Figure MAPS-31. Comparison of nightside flux-tube content (red diamonds), estimated from CAPS/IMS data, with the theoretical critical limit above which the flux tube will pinch off and release a plasmoid downtail (black +). The observed flux-tube content is roughly bounded by the critical limit, suggesting that nightside reconnection and plasmoid formation keep the tail near marginal stability. Figure from McAndrews et al. [2009].

Smith et al. 2018a, 2018b, 2016]. There is ongoing debate as to whether plasmoids can carry away enough plasma to balance the new production in the inner magnetosphere.

Magnetic reconnection and nonlinear K-H waves at the magnetopause could both potentially allow magnetospheric mass loss. Evidence for the operation of both processes has been seen, for example, McAndrews et al. [2008]; Masters et al. [2012b, 2010, 2009]; Wilson et al. [2012]; Delamere et al. [2013]; Fuselier et al. [2014]; Jasinski et al. [2016]. However, to date the contribution of neither process to the overall mass balance problem has been quantitatively assessed. While energetic W^+ ions are commonly seen in the dayside magnetosheath, there is no evidence for thermal W^+ there [Sergis et al. 2013] or in the upstream region [Thomsen et al. 2007].

As mentioned in the section entitled Magnetotail configuration and dynamics, plasma flows along the night-side flanks of the magnetosphere tend to have an outward component, suggesting the likelihood that plasma is lost as a planetary wind down the flanks. An estimate of total mass loss from the tail (excluding plasmoids) [Thomsen et al. 2014a] is within the range of previous estimates of the total mass-loading rate from ionization of water gas from Enceladus.

Plasma kinetics and wave-particle interactions

- **M_AO3:** Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.

Similar to the section entitled Seasonal and solar cycle variations, many of the kinetic and wave-particle interaction results of the MAPS instruments is outlined in other sections of this document. Specifically, effects related to the magnetospheric interaction with Titan are outlined in the section entitled Titan's upper atmosphere and its interaction with the surrounding plasma, results related to the magnetosphere can be found in the sections entitled Magnetotail configuration and dynamics, Magnetospheric structure and convection, and Plasma loss into the magnetotail, and many results can be additionally found in the section entitled Time varying modulation of SKR and associated PPO signals. In this section, we reiterate just a few of those results.

Several MAPS instruments found that Titan's interaction with the magnetosphere of Saturn features important plasma kinetic physics. The CAPS instruments, for example, discovered pick-up ions in the form of beams of CH_4^+ and N_2^+ that can be explained theoretically as the result of kinetic interactions between Titan and the magnetosphere [Hartle and Killen 2006; Hartle and Sittler 2007; Hartle et al. 2011]. It is no surprise that beam composition is consistent with the composition Titan's exosphere and atmosphere which is dominated by N_2 (98.4%) and CH_4 (1.4%) [cf. Waite et al. 2005].

Sittler et al. [2010] observed nearly field aligned outflows from the topside ionosphere during the T9 flyby and estimated the loss of methane ions due to pick-up from the exosphere at ~5×10^{22} mol/s [Sittler et al. 2009a]. The outflows serve ultimately as a sink from Titan's atmosphere of roughly ~5×10^{24} mol/s. Later, Coates et al. [2012] observed similar amounts of ionospheric outflows during the T9, T63, and T75 flybys. The theoretical cause of these outflows was originally discussed in Hartle et al. [2008]. It is produced by a field-aligned polarization electric field Epol ~$-1/n_e e \nabla_{||} P_e$ so that above the ionospheric density peak the outward acceleration is > 10 times the force of gravity for m/q ~28 amu/q ions. Sittler et al. [2010] found that the resulting ion outflow speeds were ~7 km/s with T_{ION} ~50,000° K. Therefore, both significant accelerations and heating must have occurred at altitudes above 5000 km. Later, using electron observations, Coates et al. [2015] measured the total potential drop of this electric field to be ~0.2 μV/m to heights ~15,000 km, which is sufficient to accelerate methane ions to the observed speeds ~5–6 km/s. Future 3-D hybrid simulations similar to that done by Lipatov et al. [2014, 2012, 2011] will be required to understand the heating, for example, due to wave-particle interactions, of ions to the observed high temperatures. In addition to the outflows, Sittler et al. [2010] also found evidence of Alfven waves during the T9 flyby with transverse velocity and magnetic field fluctuations that were anti-correlated with time and thus consistent with field-aligned propagation of these waves.

The T9 flyby was further studied by magnetometer team, which considered the ionosphere of Titan with its embedded magnetic field a study of Titan's nightside ionosphere was published by Cravens et al. [2009a]. T96, the first encounter presumably occurring in the supersonic solar wind, was also modelled using a hybrid kinetic code [Feyerabend et al. 2016]. An important kinetic process

in the interaction between a streaming magnetized plasma and Titan's atmosphere is the pick-up process, which has been observed to lead to the generation of often strong ion cyclotron waves in the cases of atmospheric interactions (Venus, Mars, Galilean satellites of Jupiter, Saturnian satellites, comets). In the case of Titan only two flybys T63 and T98 were associated with ion cyclotron waves are of relatively high amplitude, as a study of the MAG team shows [Russell et al. 2016].

The T9 flyby was modeled by Ma et al. [2007]. The wake region of Titan is an important component of Titan's interaction with its surrounding plasma. The Cassini spacecraft passed through the distant downstream region of Titan on December 26, 2005 (T9 flyby). In this study, we compared the observational data with numerical results using a 7-species Hall MHD Titan model. There is a good agreement between the observed and modeled parameters, given the uncertainties in plasma measurements and the approximations inherent in the Hall MHD model. Our simulation results also show that Hall MHD model results fit the observations better than the non-Hall MHD model for the flyby, consistent with the importance of kinetic effects in the Titan interaction. Based on the model results, we also identified the controlling physical processes in different plasma regions based on ion gyradius.

Beyond Titan, kinetic effects also play a role at other satellite interactions. The current system, detected by MAG in Rhea's plasma wake, results from the combination of: i) ion kinetic effects in a hot plasma; and ii) relative motion between the plasma and an inert plasma absorbing body like Rhea. As the wake is refilled with plasma in the downstream co-rotation flow [Roussos et al. 2008a], the plasma pressure gradient directed back toward Rhea results in diamagnetic current closure across the wake and perpendicular to the co-rotation flow. The pressure gradient exerts a force directed towards Rhea and mimics a real exosphere by generating a field-aligned Alfvénic current system, which extracts momentum from the co-rotating plasma outside the wake and transfers it to the wake. The Alfvén wings from the wake [Khurana et al. 2017] produce flow-directed magnetic field perturbations north and south of Rhea's equatorial plane, detected by MAG at the locations of R2 and R3 and also during two distant (102 R_H and 54 R_H away from Rhea on June 3, 2010, and October 17, 2010) [Khurana et al. 2012] downstream flybys.

Finally, we highlight the acceleration of particles that can occur at the bow shock of Saturn. In the presence of an obstacle, shock waves in a neutral gas efficiently dissipate the supersonic flow to subsonic through the action of collisions. In space plasmas however, shocks cannot rely on collisions to adequately dissipate the flow since the collisional mean free path is many orders of magnitude larger than the shock's width. Here, electromagnetic forces play a role to compensate for the additional dissipation required. Their roles are well understood for modest Mach numbers (e.g., 2–10), however this becomes more problematic at larger Mach numbers since additional kinetic processes, namely ion reflection and reformation, come into play to complete the dissipation process. Fortunately, such high Mach number phenomena were explored using the Cassini magnetometer dataset. Sulaiman et al. [2015] showed evidence for the timescales of ions reflection at a shock undergoing reformation to be 0.3 times the upstream gyro period. This was in excellent agreement with what had been theorized.

Radiation belts

- **M_AO3:** Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.
- **MC1b:** Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.
  - Investigate what controls the interplay between the Dungey and Vasyliunas cycles?
  - Study the solar cycle dependence of the magnetospheric dynamics.
  - Investigate magnetospheric structure: variations in force balance.
  - Investigate non-static and other variant radiation belt features.
- **MN1b:** Conduct in situ studies of Saturn's ionosphere and inner radiation belt.
  - Investigate the effects on aurora of solar wind and seasons.
  - Are there UV satellite footprints on Saturn? (like at Jupiter)
  - Is there a seasonal variation in auroral activity?
  - Investigate solar wind–ionosphere–magnetosphere coupling through the auroral regions.
  - Investigate whether there are UV satellite footprints on Saturn and whether there are Region 1 currents connecting the ionosphere and the magnetopause.
  - Investigate the composition of Saturn's ionosphere.
  - Study whether there is a significant polar outflow from Saturn's high latitude ionosphere and whether the outflow exhibits seasonal or solar cycle variation.
  - Determine whether there is a radiation belt between the D-ring inner edge and the atmosphere.

Cassini MAPS instruments, especially the MIMI instrument, have made measurements of Saturn's magnetosphere that provide the most comprehensive description of the radiation belts of a planet besides Earth. More than 200 orbits crossed into the radiation belts, allowing us to understand and quantify their average structure, but also to monitor time variations, despite the single point measurements. The most detailed description of the radiation belts is given by Kollmann et al. [2011] where the L-shell, local time, and pitch angle (latitudinal) structure of the belts is given for electrons and protons of different energies. Heavier ions and their charge states are studied by DiFabio et al. [2011]; Dialynas et al. [2009]; Carbary et al. [2010c]; Christon et al. [2014a, 2014b, 2013]. The latter three studies provide the most detailed characterization of trace energetic ions and their charge states at an outer planet, showing how their origin may be connected to the planet's rings, the activity of Enceladus and seasonal or solar cycle effects.

Allen et al. [2018] conducted a mission long overview of internal to external sources of energetic plasma at Saturn. They found that solar wind-originating He^{++} ions are able to penetrate into the inner magnetosphere, although the fractional abundance in the inner magnetosphere is only about 0.001%.

Detailed investigations of the proton radiation belts in the MeV range have been published by Roussos et al. [2018a, 2016a, 2011]; Kollmann et al. [2017, 2015, 2013]; Armstrong et al. [2009]; Paranicas et al. [2010, 2008]; Buratti et al. [2018]. All studies establish how the protons belts are segmented by the icy moons of Saturn (Pandora, Prometheus, Janus, Epimetheus, Mimas, Enceladus, and Tethys) and the planet's main rings. They highlight interaction features with minor rings or ring arcs, such as those from Methone, Pallene, the G-ring, and the ringlets of the D-ring, most of which were unknown prior to Cassini. All studies established that the proton radiation belts inward of Tethys are disconnected from the short-term and large-scale changes that occur in the rest of the magnetosphere, and develop only over long time-scales due to the combined influence from variable particle transport effects and the solar cycle, with the former being much more important. The origin of those belts is attributed to CRAND, rather than to extreme solar wind transients, a possibility that was considered before Cassini. Transient extensions of these belts, outside Tethys, have been linked with certainty to the occurrence of Interplanetary Coronal Mass Ejections (CMEs) in the vicinity of Saturn [Roussos et al. 2008b, 2018c], one of the first direct demonstrations of space weather at an outer planet with in situ data.

The electron radiation belts in the MeV range have been studied in a series of papers by Roussos et al. [2018b, 2016a, 2014, 2006]; Paranicas et al. [2014, 2012, 2010]; Mauk et al. [2010]; Buratti [2019]. They are much more variable and longitudinally asymmetric than the corresponding proton belts, but on average they tend to increase monotonically in intensity inward towards the main rings at which point electrons get instantly absorbed. They evolve in time scales of weeks (as opposed to years for the protons) and are controlled by numerous factors, including the solar wind and internal magnetospheric dynamics. Interaction features of MeV electrons with material (e.g., scattering and energy loss in collisions with material) and moons have help to constrain radial transport rates in the magnetosphere and discover previously unknown ring arcs. The source population of the MeV electron belts is now believed to reside in the ring current (middle magnetosphere).

Between energies of tens of keV and few hundred keV, both electrons and ions are on average diminished significantly inward of the orbit of Tethys, due to interactions of these particles with the neutral cloud of Enceladus, the dust of the E-ring, or due to absorption by the moons [Paranicas et al. 2007; Kollmann et al. 2011; Carbary et al. 2009b; Kurth et al. 2006; Ye et al. 2016a]. The region between 5 and 9 R_S has been found to be dominated by transient population of interchange injection events, which have been analyzed in single case studies and statistically [Paranicas et al. 2010, 2008, 2007; Müeller et al. 2010; Mauk et al. 2005; Rymer et al. 2009b, 2008, 2007]. The results have been used to constrain the plasma corotation speed in the inner magnetosphere, the inward radial transport velocities of plasma, and assess the importance of interchange for energetic particle transport and acceleration with respect to other processes like diffusion. The inner magnetosphere is also dominated by energetic electron microsignatures (gaps

in the electron fluxes caused by electron absorption by Saturn's moons), which have been used to define the convective flows in the inner magnetosphere (a noon-to-midnight electric field) and radial diffusion rates [Paranicas et al. 2005; Roussos et al. 2018b, 2013, 2008a, 2007; Andriopoulou et al. 2014, 2012; Thomsen et al. 2012]. Statistically significant results on the angular distributions and energy spectra of electrons have been described for the first time in Carbary et al. [2011a, 2011b] and Clark et al. [2014].

In April 2017, the proximal orbits began, also called the mission Grand Finale. This enabled a comprehensive study of the proton radiation belt trapped approximately between the F-ring and A-ring. MIMI also found a previously unknown partial, transient electron belt within the F-ring, partial because it is only observed outbound at local noon, transient because it is very variable. These results are compiled in Buratti et al. [2019].

The LEMMS instrument discovered a previously unknown radiation belt collocated with the D-ring and extending up to the dense atmosphere of Saturn. This belt was predicted earlier [Kollmann et al. 2015], but its properties were unknown. It was found that the belt is dominated by protons up to the GeV range, which is the first time that such high energies were directly observed at any of the giant planets. Their pitch angle distribution is very steep, likely due to a strong interaction with Saturn's atmosphere. The suggested source is CRAND. There is no evidence for the presence of energetic electrons or ions heavier than protons. These results are compiled in Roussos et al. [2018c].

During SOI, Cassini remotely detected protons at tens of keV from low (atmospheric) altitudes [Krimigis et al. 2005]. The proximal orbits revealed that this was a huge coincidence since similar observations were only found once during the proximal orbits [Roussos and Kollmann et al. 2018], suggesting this this ion population is transient. Since the ions derive from ENAs produced in the magnetosphere, their intensity likely depends on the conditions in the magnetosphere. Because these ions were not observed in situ, they must be located at altitudes below 3800 km.

Saturn Science

High-order magnetic moments of Saturn

- **M_AO1:** Determine the configuration of the nearly axially symmetric magnetic field and its relation to the modulation of SKR.
- **MN1c:** Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the SKR periods are imposed from close to the planet (3–5 R_S) out to the deep tail.
  - Determine what controls the SKR periods and whether there is a solar cycle and/or seasonal variation.
  - Investigate the coupling mechanism between the SKR periods and the internal rotation rate.

- Study whether the ionosphere and/or thermosphere is differentially rotating.
- Determine which hemispherical SKR period dominates other periodicities in the magnetosphere and whether this varies with time.

Numerous planetary magnetic field models have been developed over the time of the Cassini orbital mission at Saturn beginning with SOI [Dougherty et al. 2005]. Burton [2009] derived a model of Saturn's internal planetary magnetic field based on data obtained from the first three years of the mission, from July 1, 2004–July 1, 2007. Due to the uncertainty in the rotation rate, the model was constrained to be axisymmetric. In that analysis, one-minute averages of the vector magnetic field data obtained by the fluxgate magnetometer from all orbits within 10 R_S (1 R_S = 60,268 km). Data from 45 orbits were used in that study. The contribution of the eastward flowing ring current is known to be significantly close to the planet. Its contribution was modeled using the analytical expression derived by Giampieri and Dougherty [2004] based on the simple axisymmetric equatorial current sheet centered on the planet's equator, first described by Connerney et al. [1981]. The ring current magnetic field was modeled separately for the inbound and outbound legs of each orbit because the current sheet structure and characteristics are known to vary with local time [Arridge et al. 2008b] and temporal variations in the solar wind and magnetosphere are likely to occur over time scales corresponding to that of a periapsis pass (several days). The ring current field was modeled and removed from the data and standard generalized inversion techniques were used to model the magnetic field presumed to originate in Saturn's interior.

The contribution of the eastward flowing ring current is known to be significantly close to the planet.

The internal field model derived in that study was found to be quite consistent with previous models. An axisymmetric octupolar (degree 3) model was found to fit the data adequately based on an examination of the root-mean-square misfit or residual for each orbit. The spherical harmonic coefficients derived were g10 = 21,162, g20 = 1,514, g30 = 2,283. (Units are nano-Teslas (nT) and are based on a planetary radius of 60,268 km.) Saturn's magnetic was found to be offset northward by 0.036 Saturn radii, consistent with earlier Pioneer-11 and Voyager models. Reanalysis and comparison with data obtained by Pioneer-11 and Voyager-1 and Voyager-2 showed little evidence for secular variation in the field in the almost thirty years since those data were obtained.

A subsequent study [Burton et al. 2010] used data from the entire Cassini prime mission (through July 2008) and a methodology that differed in significant ways from the earlier modeling approach [Burton et al. 2009]. Only data obtained at radial distances closer than the L-shell of Enceladus (dipole L-value of 3.8) were used to derive the model. Measurements obtained by all Cassini fields and particles instruments had demonstrated that the structure and dynamics of Saturn's inner magnetosphere are governed by plasma created at Enceladus [Kivelson 2006]. The observed field at radial distances outside the orbit of Enceladus is modified by processes in the inner magnetosphere and does not necessarily reflect the magnetic field generated in Saturn's interior.

The approach to modeling the external ring current field also differed from the earlier modeling approach. As time went on our understanding of Saturn's magnetodisc had evolved and a simple symmetric ring current centered on the equator was no longer thought to an accurately representation. Instead the current sheet was found to be displaced from Saturn's rotational equator and to assume the shape of a bowl or basin, referred to as a magnetodisc [Arridge et al. 2008a]. Instead of modeling the external field as an oversimplified axisymmetric ring current as in Burton [2009], the internal plus external field was modeled using the standard spherical harmonic formulation and a single set of spherical harmonic coefficients was obtained that describes the internal and external field in a least squares sense. Accordingly, the axisymmetric model coefficients differ somewhat from the previous model.

In Burton [2010] an attempt was made to determine the planetary rotation rate by deriving a number of non-axisymmetric magnetic field models for a plausible range of planetary rotation periods and assessing the power in the non-axisymmetric components of the field and the root-mean-square misfit between the model and the data. The methodology is as follows. A presumed planetary rotation period was varied in 1 second increments from 10 hours 28 minutes to 10 hours 40 minutes and a pseudo-longitude calculated for each measured data point. A degree 3, non-axisymmetric magnetic field model was derived and the power in the non-axial magnetic field and the misfit were calculated. The underlying premise is that the planetary rotation period could be determined based on a peak in the non-axial power and minimum in the misfit. Although no such peak was identified unambiguously, the analysis did provide an upper limit on the extent of the dipole tilt. Based on the distribution of the non-axial spherical harmonic model coefficients for the range of rotation rates, a mean value for the dipole tilt was determined to be 0.03 degrees. The upper limit of all tilt angles was found to be 0.1 degrees.

The magnetometer team have developed the state-of-the-art internal magnetic field model for Saturn using Cassini magnetometer measurements prior to the Grand Finale, which placed the most stringent constraint to date on the tilt and secular variation of Saturn's intrinsic magnetic field [Cao et al. 2011]. The tilt of Saturn's dipole must be smaller than 0.06 degrees from the spin-axis of Saturn, and the time variation of Saturn's intrinsic magnetic field must be an order of magnitude slower than that of the Earth's [Cao et al. 2011]. These results are very challenging for dynamo theory, as Cowling's theorem excludes the possibility of a purely axisymmetric magnetic field being maintained by dynamo action.

The magnetometer team have also derived degree 4 and degree 5 internal magnetic moments for Saturn, albeit with relatively large uncertainties, from re-analyzing the Cassini SOI magnetometer measurements [Cao et al. 2012]. Based on these observational findings, we worked out the implications on helium rain inside Saturn [Cao et al. 2012, 2011]. These also provided the framework for our current analysis of the magnetometer measurements from the Cassini Grand Finale.

The latest Cassini Grand Finale gravity measurements indicate that the ~100 m/s zonal flows observed at the cloud deck of Saturn extend almost ten thousand kilometers into the planetary interior. Given that the electrical conductivity at such depth are high enough for significant MHD

effects, zonal flow magnetic field interaction in the semi-conducting region of Saturn is now a central issue in understanding the interior dynamics. On the theoretical side, we have developed a mean-field model for zonal flow magnetic field interaction in the semi-conducting region of Saturn [Cao and Stevenson 2017]. In this work, we proposed that the interaction between zonal flow and magnetic field in the semi-conduction region of Saturn would generate small-scale axisymmetric magnetic field that are spatially correlated with zonal flows [Cao and Stevenson 2017]. The amplitude of the wind-induced magnetic perturbations would depend on the amplitude of the deep differential rotation as well as the amplitude of the small-scale deep convective flow. Thus, measuring/constraining wind-induced magnetic perturbations along the Cassini Grand Finale orbits would place important constraints on the properties (profile and amplitude) of deep differential rotation and convective flow in the semi-conducting region of Saturn.

With magnetic field measurements at unprecedented proximity to Saturn by Cassini Grand Finale [Dougherty et al. 2018], we are working on deriving: i) non-axisymmetric internal magnetic moments of Saturn from Cassini Grand Finale magnetometer measurements, which can tell us about the deep interior rotation rate of Saturn and/or helium rainout and stable stratification inside Saturn; ii) small-scale axisymmetric magnetic features (e.g., high-degree axisymmetric internal magnetic moments) which can be used to constrain deep differential rotation inside Saturn; and iii) time variations in the internal magnetic fields, which would reveal characteristic time scale in Saturn's internal magnetic field and deep interior dynamics. These expected results would constitute the observational facts about the internal magnetic fields of Saturn for many years to come, which would further serve as tests for theories about giant planet interiors and have profound implications about giant planets outside the solar system.

Time varying modulation of SKR and associated PPO signals

- **M_AO1:** Determine the configuration of the nearly axially symmetric magnetic field and its relation to the modulation of SKR.
- **MN1c:** Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the SKR periods are imposed from close to the planet (3–5 R_S) out to the deep tail.
  - Determine what controls the SKR periods and whether there is a solar cycle and/or seasonal variation.
  - Investigate the coupling mechanism between the SKR periods and the internal rotation rate.
  - Study whether the ionosphere and/or thermosphere is differentially rotating.
  - Determine which hemispherical SKR period dominates other periodicities in the magnetosphere and whether this varies with time.

Saturn's radio emissions started to be observed by Cassini/RPWS over the 10–1000 kHz range from distances of a few astronomical units. From late 2002 to early 2003, they were embedded in Jovian radio emissions and solar radio bursts. Their signal-to-noise ratio increasing with decreasing distance to Saturn, they became the dominant emission for the mid-2003 to mid-2004 preceding Saturn's orbit insertion. The most important and the most intense radio component is the SKR produced in the auroral regions. Several reviews of SKR properties have accompanied the Cassini mission [Kurth et al. 2009; Badman et al. 2015], the most recent one summarizing our current knowledge before Cassini Grand Finale [Lamy 2017].

The most important and the most intense radio component is the SKR produced in the auroral regions.

There are two important features of the SKR signal that we highlight here: 1) the SKR spectrum appears to be most intense when observed from the dawn-side at mid-latitude [Lamy et al. 2008; Kimura et al. 2013]. Southern SKR was predominant up to 2010-mid 2011 (slightly after the equinox of 2009), while the northern SKR was predominant after, consistent with a seasonal control of field-aligned currents driving auroral emissions by solar illumination of Saturn's ionosphere; and 2) the important feature of the SKR is that at the timescales of 11 hours (Saturn's rotation period), the emission is strongly rotationally modulated [Kurth et al. 2016, 2005; Clarke et al. 2005; Crary et al. 2005; Jackman et al. 2010, 2009a, 2005; Badman et al. 2016, 2008; Nichols et al. 2009; Lamy et al. 2013; Reed et al. 2018].

The remaining comments in this section concentrate on the modulation of the SKR.

Until the cruise phase of Cassini, the modulation of the SKR signal was taken to mark the rotation rate of the core of Saturn. Similar radio signals at Jupiter are clearly indicative of the rotation of the magnetic core of planet and therefore a similar interpretation was made for Saturn. Such magnetic rotation should theoretically be stable for planets as large as Jupiter and Saturn on a timescale not measurable by Cassini. However, the first SKR periodicity measured by RPWS witnessed a value differing by 1% to the SKR period identified from Voyager/PRA observations 25 years earlier [Gurnett et al. 2005]. Such a large variation implies that the SKR period does not probe the internal rotation rate. The measured SKR period was then found to display weak variations associated with those of solar wind speed [Cecconi and Zarka 2005; Zarka et al. 2007].

The major discovery brought by RPWS was the identification of two SKR periods [Kurth et al. 2008] corresponding to the two Kronian hemispheres, differing by ~1%. These periods were found to both vary with time in anti-correlation over yearly timescales and crossed closely after equinox, a trend which was interpreted as a seasonal driving of solar illumination [Gurnett et al. 2011a, 2010b, 2009; Lamy 2011], for example see Figure MAPS-32. These dual periods were later noticed in NB emissions and auroral hiss as well [Gurnett et al. 2010b; Ye et al. 2017, 2010] and more generally observed in numerous magnetospheric observables including magnetic oscillations, ENA emissions, aurorae [Mitchell et al. 2009b; Carbary et al. 2011a, 2010a; Nichols et al. 2010; Andrews et al. 2011, 2010a; Provan et al. 2011; Badman et al. 2012a, 2012b]. It is now accepted that these

dual rotational modulations all originate from two rotating hemispheric systems of field-aligned currents, whose origin may be atmospheric vortices [Jia et al. 2012].

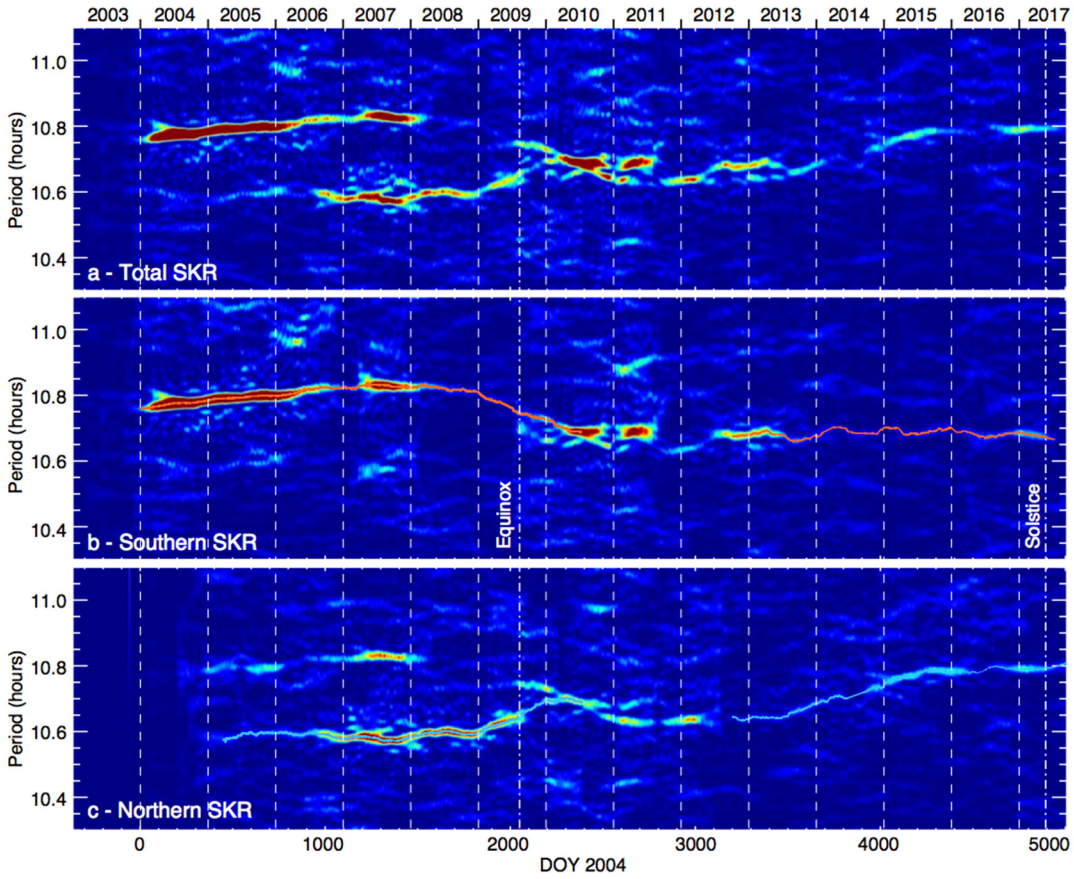

Figure MAPS-32. Lomb-Scargle periodograms of *Panel a*: total, *Panel b*: southern and *Panel c*: northern SKR flux density integrated over 100–500 kHz as a function of period and time from 2003-001 to 2017-258, extending of Lamy [2011] Figure 1. Southern and northern SKR were originally identified as LH and RH (X-mode) emission, excluding scarce intervals displaying ambiguous polarization measurements. The latter intervals were noticed to be more frequent at close distances and high latitudes which prevailed in the past two years. To improve the signal-to-noise ratio of *Panel b* and *Panel c*, southern and northern SKR were therefore identified as the total SKR signal observed beyond 10° latitude after days 2016-001 and 2016-180, respectively. Solid red and blue lines plot the southern and northern SKR periods derived by [Lamy 2011] from day 2004-001 to 2010-193, [Provan et al. 2016] from day 2012-278 to 2015-365 and tracked here from day 2016-001 to 2017-258. The latter will serve to build southern and northern SKR phases covering most of the Cassini mission.

This dual periodicity is not always detected, however, which may be a consequence of the observer location and/or its actual disappearance [Carbary 2016, 2014]. Single and dual periodicities were also observed in ENA fluxes detected by INCA [Carbary et al. 2014, 2008a; Carbary and Mitchell 2017]. INCA's global view of these periodicities revealed a local time dependence, namely, that one period might be detected at one local time but absent at another [Carbary et al. 2014]. Finally, the energetic electrons apparently have the same period (~10.8 h)

during the summer season when either the north or the South Pole tilts with respect to the direction to the Sun [Carbary et al. 2017]. This discovery, made possible by Cassini's solstice-to-solstice extension, has strong implications for the solar driving of these planetary periodicities. A complete review of Saturn's magnetospheric periodicities, as of 2013, appeared in Reviews of Geophysics [Carbary and Mitchell 2013], and should be consulted for the overall context within which particle periodicities can be placed.

The post-equinox period displayed a confused situation with poorly determined radio and magnetospheric periods. Over 2010–2012, they remained close to each other at locked phases, suggesting retro-interaction between both currents systems [Garnier et al. 2014], while sudden jumps of periods were tentatively attributed to Saturn's great white spot activity [Fischer et al. 2014] or to variable solar wind conditions [Provan et al. 2015]. Both periods eventually merged between mid-2013 and mid-2014 before crossing and diverging from each other after mid-2014 up to September 2017 [Provan et al. 2016; Ye et al. 2017, 2016b; Lamy 2017].

With the discovery that the SKR periodicity was not constant, the search for understanding began by all the MAPS instruments. Cassini observations have demonstrated the near ubiquity of oscillations near the planetary rotation period in essentially all magnetospheric plasma, field, and wave data despite the close axisymmetry of the internal planetary magnetic field. Due to the ubiquitous presence of these oscillations over most of the magnetosphere they were given the terminology PPO. Studying the PPO, with the goal to understand by the SKR period variation and the influence of PPO's on the magnetosphere has been a significant part of the Cassini mission.

Initial work on the magnetic PPOs established their basic properties, first confirming the rotational nature of the oscillations via the Doppler effect of the azimuthal spacecraft motion [Cowley et al. 2006], and second showing that while the perturbation fields in the equatorial region are quasi-uniform in nature [Andrews et al. 2010a], rotating in the equatorial plane as indicated by the earlier flyby studies, the fields at high latitudes are instead quasi-dipolar in form [Provan et al. 2009], associated with a rotating transverse dipole. The dipole moment is not internally generated by the planet, however, but by an external current system coupling the ionosphere and magnetosphere (see the section entitled Magnetospheric structure and convection). The PPOs are thus associated with a second large-scale current system, and, due to their ubiquitous nature, have proved to be a major aspect of the Cassini Magnetic Field Investigation throughout the mission. In addition, their imprint is seen more widely in the entire Cassini magnetosphere data set. It was shown that the radial distance of the dayside magnetopause and bow shock are also significantly modulated by this phenomenon [Clarke et al. 2010a, 2010b, 2006].

In the plasma data, the periodicities are clearest in the plasma sheet region. The density varies by more than an order of magnitude, depending on the SLS3 longitude [Arridge et al. 2008c]. This variability is likely due to periodic up-and-down motion of the plasma sheet. The temporal and spatial variations in plasma and field parameters are well organized by the flapping of the plasma disk about a periodically varying position [Arridge et al. 2008a; Szego et al. 2013, 2012, 2011; Nemeth et al. 2016]. Asymmetries in Cassini's periodic plasma sheet crossings [Thomsen et al. 2017b] are consistent with predictions of plasma sheet rocking and thickness variation made both

by the global MHD models that incorporate the effects of hypothesized atmospheric vortices [Jia and Kivelson 2012] and by the closely-related dual rotating current systems inferred from magnetic field observations, for example, Cowley et al. [2017] and references therein.

In the inner to middle magnetosphere, evidence was found for a plasma cam, in which the plasma density varies roughly sinusoidally with SLS3 [Burch et al. 2009; Goldstein et al. 2016] (see Figure MAPS-33). Theoretical arguments suggest that an asymmetric ring-current pressure coupled to Saturn's ionosphere can initiate a rotating two-cell interchange potential that is long-lived and stable [Goldstein et al. 2014]. Outflow from the dense sector was suggested as the driver of recurrent tail reconnection and plasmoid production (see sections entitled Plasma Loss Into The Magnetotail, and Magnetotail Configuration and Dynamics) inferred from periodic magnetic field variations in the tail [Burch et al. 2009], but subsequent authors argued that the field variations were more consistent with simple wave-like motion or periodic rocking of the plasma sheet rather than plasmoid formation [Jackman et al. 2009b]. In the more recent forward-modeling dataset of

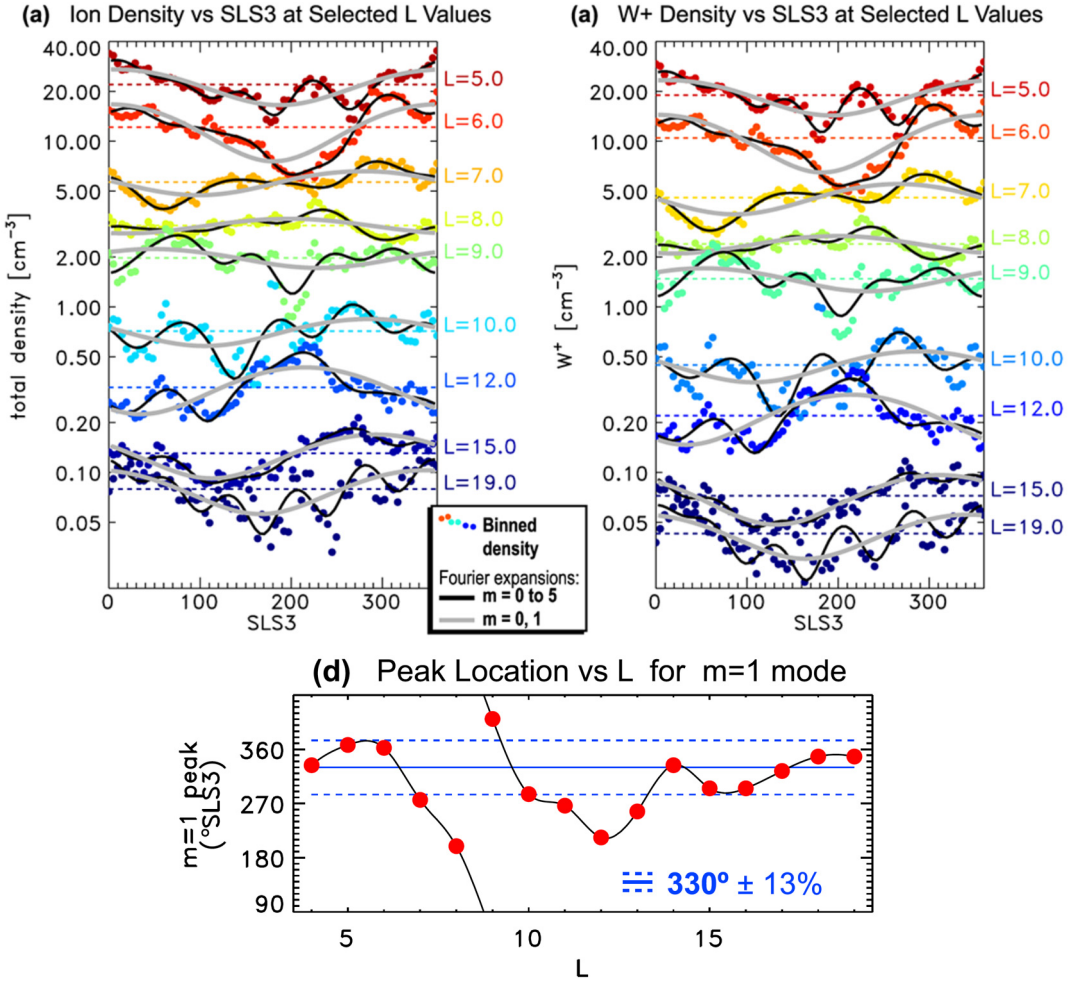

Figure MAPS-33. Evidence for the existence of a plasma cam, in which the density is generally highest in a particular SLS3 longitude sector. Figure from Goldstein et al. [2016].

ion densities [Wilson et al. 2017], the cam is not seen, so there remain questions about its existence and its consequences.

With the further realization, initially from SKR data, that two such oscillations are generally present with slightly different periods, one associated with the northern polar region and the other with the southern, it was shown that the phase jitter in the equatorial magnetic oscillations previously observed is due to the vector superposition of the two systems [Provan et al. 2011], while the polar oscillations were found to be pure northern and southern on the central polar field lines in the two hemispheres [Andrews et al. 2012]. Cassini data from the deeper tail passes in 2006 correspondingly showed that while the two tail lobes are modulated at their separate polar periods, mixed signals are again present within the plasma sheet that are associated with both north-south oscillations of the current layer together with significant modulations in its thickness [Provan et al. 2012; Szego et al. 2013; Nemeth et al. 2016, 2015]. A model of these PPO-related variations has been derived which provides a simple explanation of the sawtooth plasma sheet field variations observed during equinoctial conditions of near-equal northern and southern PPO amplitudes [Cowley et al. 2017; Thomsen et al. 2017a]. The model has further been successfully applied to the more northern-dominated conditions prevailing during northern spring [Cowley and Provan 2017].

With the additional realization that the two PPO periods slowly change with Saturn's seasons by ~ ±1% about ~ 10.7 h (i.e., ~ ±6 min), a long-term program of precise (~ ±10 s) measurement of the magnetic oscillation rotation period and phase has been carried out over the whole Cassini mission [Andrews et al. 2012, 2010b, 2008; Provan et al. 2018, 2016, 2014, 2013]. The results have subsequently been employed by many Cassini and HST teams as a framework to organize their data. The two PPO periods were found to be well-separated in late southern summer conditions at the beginning of the Cassini mission, ~10.6 h for the northern system and ~10.8 h for the dominant southern system, but then slowly converged with near-equal amplitudes to a near-common value ~10.7 h over a ~2 (Earth)-year interval centered near vernal equinox (August 2009) [Andrews et al. 2012]. There followed a ~3-year interval in early northern spring when the relative amplitudes changed abruptly at ~100–200-day intervals between southern and northern dominance and near-equal amplitudes [Provan et al. 2013], the southern period ~10.69 h remaining slightly longer than the northern ~10.65 h, before the periods of the two systems coalesced at ~10.70 h in antiphase during the first half of 2014 [Provan et al. 2016]. In mid-2014 the period of the then-dominant northern system began to increase towards ~10.8 h, similar to the southern system in southern summer, while the southern period remained near-fixed at ~10.7 h, thus leading to the first enduring reversal in PPO periods, northern longer than southern, during the Cassini era. The periods remained close to these values across northern summer solstice in May 2017 to the end of mission [Provan et al. 2018]. Possible physical origins of the post-equinox interval of abrupt changes have been discussed in terms of both atmospheric effects [Cowley and Provan 2013] and solar wind influences during the rising phase of the solar cycle [Provan et al. 2015], though clear causality remains to be demonstrated. An additional important theme of these studies has been the comparison of the magnetic field phases and periods with the related data derived independently by others from analysis of SKR modulations. Although some areas of contention

have been debated [Yates et al. 2015a, 2015b; Cowley and Provan 2016, 2015], the overall picture is one of good agreement [Andrews et al. 2012, 2011, 2010b, 2008; Provan et al. 2016, 2014].

The final proximal orbits have provided access to previously unexplored field lines crossing and inside Saturn's ring system. The behavior of the PPO oscillations on these field lines is presently under intense investigation.

Theoretical work [Southwood and Kivelson 2007] describes how a system of rotating field-aligned currents (cam currents) located on a magnetic shell in the range L = 12–15 would account for the periodicity observed in the magnetic field perturbations near the equator. Later it was shown that the interaction of the rotating cam currents would interact with the global magnetic structure of the magnetosphere to produce periodic variations of current intensity and account for the modulation of the power of SKR [Southwood and Kivelson 2009].

A series of papers elucidated how appropriately placed vertical flows in a rotating ionosphere drive field-aligned currents consistent with the cam current previously proposed. These rotating currents were shown to provide a quantitatively consistent description of all of the periodic dynamics reported in the system [Jia et al. 2012; Jia and Kivelson 2016; Kivelson and Jia 2014]. Theoretical work continues to best understand the origin of the two rotations rates [Southwood 2015, 2014, 2011; Southwood and Cowley 2014; Southwood and Chané 2016].

One important aspect of the PPO signal is to consider how reconnection fits into the bigger picture of global magnetospheric dynamics. Jackman et al. [2016] reported that, like so many other phenomena, tail reconnection at Saturn is organized by northern and southern magnetic phase. Events are specifically linked to current sheet thinning and outward displacement of field and plasma. Little evidence was found for visibility effects associated with the north-south motion of the plasma sheet.

One important aspect of the PPO signal is to consider how reconnection fits into the bigger picture of global magnetospheric dynamics.

Initial studies detected numerous reconnection-related events during the main Cassini tail exploration interval in 2006, namely planetward-travelling dipolarizations and tailward-travelling plasmoid structures, which were found to be related in timing to both the pulsing of the SKR emissions and the magnetic PPO phase [Jackman et al. 2016, 2009a]. Specifically, the events were found to be preferentially initiated during intervals when the PPO perturbations stretch the field lines radially outward from the planet and thin the plasma sheet leading to instability, especially when the two PPO systems act in this manner in concert, i.e., when they are near antiphase. Ongoing work is presently investigating dipolarization events and auroral storms during the sequence of proximal orbits observed just prior to end of mission.

The question of whether reconnection is linked to internal or external drivers is an important one, and one approach to exploring this is to examine the radio data which accompany the

magnetometer observations. Jackman et al. [2005b] explored concurrent IMF and SKR data from Cassini during SOI. They showed that the SKR intensified and extended to lower frequencies coincident with the arrival of a solar wind compression, while many other authors have also explored this strong link between the radio power (and frequency) and the nature of the solar wind.

Jackman et al. [2009a] explored the SKR in more detail, focusing on several case studies where reconnection had been observed in Saturn's magnetotail. In general, they found a good correlation between the timing of reconnection events and enhancements in the SKR emissions. A physical mechanism was put forward whereby reconnection increases the precipitation of energetic particles into the auroral zones, leads to the formation of a potential drop, and thus stimulates the motion of the SKR source region to higher altitudes along the field line (and hence lower frequencies of radio emission). These LFEs of the SKR were seen as strong proxies for dynamic solar wind compression and/or tail reconnection events.

Reed et al. [2018] attempted to automate the search for these LFEs in the SKR data and correlated 282 LFEs found during 2006 with a larger catalogue of reconnection events. LFEs were grouped into two categories, with short events of duration < 20 hours separated by a median waiting time of ~10 hours, and strongly correlated with the northern and southern SKR phases. Sixty percent of short LFEs have a reconnection event within the preceding six hours. The second category, long events, had duration > 20 hours, often lasting multiple planetary rotations and associated with increases in solar wind dynamic pressure.

Aurora and satellite footprints

- **MN1b:** Conduct in situ studies of Saturn's ionosphere and inner radiation belt.
  - Investigate the effects on aurora of solar wind and seasons.
  - Are there UV satellite footprints on Saturn? (like at Jupiter)
  - Is there a seasonal variation in auroral activity?
  - Investigate solar wind–ionosphere–magnetosphere coupling through the auroral regions.
  - Investigate whether there are UV satellite footprints on Saturn and whether there are Region 1 currents connecting the ionosphere and the magnetopause.
  - Investigate the composition of Saturn's ionosphere.
  - Study whether there is a significant polar outflow from Saturn's high latitude ionosphere and whether the outflow exhibits seasonal or solar cycle variation.
  - Determine whether there is a radiation belt between the D-ring inner edge and the atmosphere.

Cassini instruments have provided the first ever in situ measurements of the currents and particle populations that result in the Aurora and satellite footprints at Saturn. In addition to in situ measurements made by MAPS instruments, remote sensing images have been made by a range or Cassini instruments. This amazing set of Cassini data, together with a significant data from Earth-based observing platforms has resulted in a much more complete picture of the Kronian auroral processes. Fine structures of the aurora and nightside emissions have been revealed for the first time thanks to the observations acquired by the UVIS spectrograph on board Cassini. Spatial and dynamical characteristics of the complex pattern of auroral emissions at Saturn have been thoroughly described during the Cassini mission.

Previously observed with HST [Gérard et al. 2004; Grodent et al. 2005], the principal auroral component, so-called main emission, appeared through UVIS eyes as multiple substructures of various sizes. The dawn side of the main emission usually consists in a continuous narrow arc, rotating with the planet at approximately 70% of rigid corotation [Grodent et al. 2005]. This arc can get particularly bright during several hours while the emission rotates from midnight to noon, for example, Mitchell et al. [2009b]; Meredith et al. [2014]; Radioti et al. [2016]. Thanks to the combination between Cassini in situ measurements and auroral data, such a brightening has been associated with important magnetotail reconnection activity either induced by solar wind compression and closing magnetic flux [Cowley et al. 2005] or internally driven by stretching of the field lines in the nightside magnetosphere [Mitchell et al. 2009b; Radioti et al. 2016]. In both cases, the auroral intensification is produced by intense field-aligned currents on flux tubes moving from tail reconnection site to the dayside. Occasionally, these flux tubes could experience a blockage in the equatorial plane around noon local time, leading to the stagnation of the main emission dawn arc close to noon, as reported by Radioti et al. [2017a]. Furthermore, Yao et al. [2017c] surveyed Cassini-UVIS dataset, and revealed that transient auroral intensification near the noon local time is a systematic phenomenon, and proposed two potential mechanisms in driving such auroral phenomenon by analyzing simultaneous measurements from Cassini's magnetic field, plasma and auroral instruments.

In addition to the dawn arc, the main emission can exhibit isolated features of a few hundred kilometers wide which could be observed during the low-altitude orbits of Cassini. These individual spots have been tentatively interpreted as signatures of K-H vortices at the magnetopause [Grodent et al. 2011]. Alternatively, Meredith et al. [2013] argued that these spots might be produced by field-aligned currents of second harmonic ultra-low frequency (ULF) FLR waves propagating in Saturn's equatorial outer magnetosphere.

Furthermore, the main emission sometimes exhibits a localized brightening on the dayside which gradually gives birth to an extended arc-like structure rotating to the nightside with one extremity attached to the main emission while the other is moving towards the pole [Radioti et al. 2011; Badman et al. 2013]. These so-called bifurcations, together with an increase of the region threaded by open field lines (i.e., the polar cap), suggest that they are the signatures of dayside reconnection at the magnetopause, whereas the existence of magnetopause reconnection at Saturn was still subject of debate. Consecutive bifurcations and quasi-periodic brightening of an

individual bifurcation even suggest that such a dayside reconnection process can be pulsed [Radioti et al. 2013b, 2011; Mitchell et al. 2016].

Fixed in local time around noon, an auroral spot poleward of the main emission has been attributed to the auroral footprint of the cusp [Gérard et al. 2005, 2004; Palmaerts et al. 2016a; Kinrade et al. 2017] for which theoretical considerations connect it to high-latitude lobe reconnection [Bunce et al. 2005]. Thanks to extended UVIS observation time of Saturn's aurora, it has been shown that this polar cusp aurora can exhibit brightening with a periodicity of around one hour, indicative of a pulsed reconnection process [Palmaerts et al. 2016a]. In addition, Radioti et al. [2014] discovered a rare nightside auroral arc extending from the nightside main emission towards dayside, across the polar cap region. This polar arc is likely a tongue of closed flux tubes in the open field line region which appears during a period of enhanced tail reconnection combined with an absence of dayside reconnection.

Using the low-altitude UVIS observations during the Grand Finale phase of the Cassini mission, Radioti et al. [2017b] identified some auroral arcs which are azimuthally spread from high to low altitudes in the nightside sector. These arcs could be produced by plasma flows propagating from the outer tail magnetosphere toward the planet, akin to the terrestrial auroral streamers. Such plasma flows result from ballooning instability in the plasma sheet which has been shown to occur in Saturn's magnetosphere [Yao et al. 2017d].

Equatorward to the main auroral emission, two types of auroral structures can be encountered. The presence of a quasi-permanent partial ring of faint emissions mainly on the nightside sector has been established by Grodent et al. [2010]. These outer emissions are thought to be generated by an upward current layer carried by warm electrons detected by Cassini [Schippers et al. 2012]. Additionally, isolated transient auroral patches are occasionally observed along the equatorward edge of the dayside main emission. The combination of HST, in situ and remote Cassini observations, and simulations provided evidence that these spots behave as UV auroral signatures of energetic particle injections [Radioti et al. 2013a, 2009]. Furthermore, large-scale injections with strong corotation velocity gradients can give rise to spiral-shaped auroral features propagating from predawn to noon, as revealed by Radioti et al. [2015].

The combination of HST, in situ and remote Cassini observations, and simulations provided evidence that these spots behave as UV auroral signatures of energetic particle injections … .

During a coordinated auroral observing campaign on April 21–22, 2013, instruments onboard Cassini and the Hubble Space Telescope observed Saturn's northern and southern aurora while Cassini traversed Saturn's high latitude auroral field lines [Badman et al. 2016]. Signatures of upward and downward field-aligned currents were detected in the nightside magnetosphere, with the location of the upward current corresponded to the bright ultraviolet auroral arc seen in the auroral images, and the downward current region located poleward of the upward current in an

aurorally dark region. In the area poleward of the auroral oval, magnetic field and plasma fluctuations were identified with periods of ~20 and ~60 min. During April 11, the northern and southern auroral ovals were observed to rock in latitude in phase with the respective northern and southern planetary period oscillations. A solar wind compression impacted Saturn's magnetosphere at the start of April 22, 2013, identified by the intensification and extension to lower frequencies of the SKR. At this time a bulge appeared along the pre-dawn auroral oval, which appeared to have moved sunward when this region was next observed. The midnight sector aurora remained a narrow arc at this time. Subsequently, the post-midnight aurora broadened in latitude and contracted towards the pole. The motion in this sector was in the opposite direction to that expected from the planetary period oscillation. There was also an intensification of the auroral field-aligned currents. These observations are interpreted as the response to tail reconnection events instigated by solar wind compression, initially involving Vasyliunas-type reconnection of closed mass-loaded magnetotail field lines, and then proceeding onto open lobe field lines, causing the contraction of the polar cap region on the post-midnight sector.

During the same auroral campaign, Kurth et al. [2016] reports on the SKR measurements obtained during a Saturn auroral campaign carried out in the spring of 2013 which used multiple Earth-based observations, remote-sensing observations from Cassini, and in situ-observations from Cassini. Saturn kilometric radiation was remotely monitored nearly continuously providing a measure of the auroral activity and a means of understanding the temporal relationships between the sometimes widely spaced remote sensing observations of the auroral activity. While beaming characteristics of the radio emissions are known to prevent single spacecraft observations of this emission from being a perfect auroral activity indicator, a good correlation between the radio emission intensity and the level of UV auroral activity was observed, when both measurements are available, similar to what the previous studies had shown. Given the known influence of solar wind dynamics on both SKR intensity and auroral activity as discussed above, the SKR integrated power is also a proxy for solar wind activity. This study found that there is a good correlation between the 10 h averages of SKR power flux and the power estimated input to the aurora on the basis of the UV brightness, justifying the SKR as a simple proxy for auroral activity through the campaign. The SKR emissions also give evidence for a recurrent pattern of solar wind interaction with Saturn's magnetosphere, suggesting a two-sector structure and associated corotating interaction regions influencing the level of auroral activity on Saturn. But there are other SKR intensifications that may be due to internal processes.

Bunce et al. [2014] presented an unusual case in January 2009, where UVIS observes the entire northern UV auroral oval during a 2 h interval while Cassini traverses the magnetic flux tubes connecting to the auroral regions near 21 LT, sampling the related magnetic field, particle, and radio and plasma wave signatures. The motion of the auroral oval evident from the UVIS images was found to be consistent with the appropriate phase of the magnetosphere oscillations in the northern hemisphere, whereas previous interpretations have assumed a static current system. Concurrent observations of the auroral hiss (typically generated in regions of downward directed field-aligned current) support this revised interpretation of an oscillating current system.

Field-aligned current systems are at the heart of all aurora observed in the solar system. Large-scale field-aligned current systems which couple the magnetosphere to the planet's upper atmosphere, ultimately produce the auroral displays seen in, for example, UV images. As in other magnetized environments, field-aligned currents in Saturn's magnetosphere play a fundamental role in the transfer of momentum along field lines between the ionosphere, the magnetosphere, and (potentially) the solar wind. At their ends such currents close cross-field in association with j × B forces on the corresponding plasmas. Field-aligned currents further relate to the generation of bright discrete auroral forms at ionospheric heights, if current densities directed away from the planet exceed that which can be carried by the ambient precipitating magnetospheric electrons, at which point the latter are accelerated downward into the ionosphere by field-aligned voltages where they deposit their charge and energy. Initial theoretical expectations for Saturn related to meridional magnetosphere-ionosphere currents associated with the transfer of angular momentum from the planet's ionosphere to the net radially-outward transported equatorial plasma principally of Enceladus origin, i.e., the sub-corotation currents [Cowley et al. 2004], together with dawn–dusk asymmetries associated with the solar wind interaction [Jackman and Cowley 2006].

Observationally, field-aligned currents are detected and quantified via variations in the azimuthal magnetic field on high-latitude and relatively low-altitude passes across the planet's polar regions. The first such data were acquired by Cassini in 2006/2007, with simultaneous HST UV imagery on one pass confirming that Saturn's auroral oval indeed maps into a region of upward current requiring downward acceleration of the observed magnetospheric electrons [Bunce et al. 2008; Cowley et al. 2008]. An overall survey of these data showed that while their basic properties are consistent with theoretical expectations for subcorotation currents, with ~6 MA flowing down into the central polar ionosphere and the same return current flowing upward at lower latitudes in the auroral region, the currents are also modulated by the PPOs [Talboys et al. 2009a]. A much larger data set was then acquired in 2008 which allowed statistical studies to be undertaken [Talboys et al. 2011, 2009b]. It further allowed detailed exploration of the PPO dependence by comparing currents observed under conditions of differing PPO phase [Hunt et al. 2018b, 2015, 2014].

The principal PPO currents in a given hemisphere are found to be directed upward and downward on opposite sides of the planet's polar ionosphere and rotate around the pole at the PPO period of the corresponding hemisphere. They are also approximately co-located with the upward current region of the sub-corotation system, and of comparable strength, such that where the PPO current flows down, the total field-aligned current is reduced near to zero, while where it flows up the current is doubled, thus suggesting a dynamical connection. It is also found that the auroral region oscillates in latitude with amplitude ~1° in concert with these rotating modulations [Nichols et al. 2008; Provan et al. 2009; Hunt et al. 2014; Bunce et al. 2014]. A complementary multi-instrument study also established the typical locations of the boundary of open field lines in the two hemispheres at ~13° co-latitude in the north and ~16° in the south [Jinks et al. 2014], showing that the main PPO field-aligned currents flow just equatorward of this boundary on closed field lines. Correspondingly, inter-hemispheric coupling along closed magnetospheric field lines also occurs between the two PPO systems [Hunt et al. 2015; Provan et al. 2018]. Overall, the form of the PPO currents is consistent with driving by rotating twin-vortex flows in the two polar thermosphere/ionosphere [Hunt et al. 2014; Southwood and Cowley 2014].

Comparison between the 2008 data, obtained in the midnight sector, with the dawn-dayside data from 2006/2007 showed little difference, confounding expectations of observing long-term current asymmetries associated with the solar wind interaction [Hunt et al. 2016]. Highly unusual current distributions are observed in a small subset of passes, however, some of which have been associated with Saturn auroral storm solar wind compression events [Bunce et al. 2010]. Significant solar wind-related currents thus do flow in Saturn's magnetosphere at least intermittently. Indirect evidence of less dramatic solar wind effects have been obtained from HST studies of the dayside auroras (though not directly in field data), using Cassini as an upstream monitor of the IMF. Morphological auroral differences are found depending on the sense of the north-south component of the IMF, suggestive of dayside reconnection and related driving of flows and currents when the IMF points north [Meredith et al. 2014]. More generally, collaboration with colleagues at Moscow State University has resulted in the development of Saturn magnetospheric field models validated with Cassini data which incorporate ring/tail and magnetopause currents, and are also parameterized by the strength and direction of the IMF [Alexeev et al. 2006; Belenkaya et al. 2016, 2014, 2011, 2010, 2007, 2006]. These models have been used during intervals when Cassini was located in the solar wind measuring the impinging IMF to map auroral features observed by the HST along field lines into their magnetospheric source regions, namely the middle and outer ring current region typically at dawn, and to the vicinity of the open-closed field boundary for high-latitude emissions near noon.

While the 2006/2007 and 2008 high-latitude data sets both correspond to Saturn's late southern summer, a third interval of high-latitude data was obtained in 2012/2013 during northern spring [Bradley et al. 2018]. The PPO currents were found to be of similar form but somewhat weaker than in 2008, while the sub-corotation currents exhibited strong opposite seasonal asymmetries in the north and south Polar Regions, indicative of weak polar ionospheric conductivity in the winter polar cap. Investigation of the current signatures observed on the F-ring and proximal orbits spanning northern summer solstice at the end of the Cassini mission are currently ongoing [Hunt et al. 2018a].

Although Voyager radio data had previously demonstrated that SKR emissions are strongly positively correlated with solar wind dynamic pressure, the nature of the related magnetospheric dynamics remained unknown. This was partially revealed in early 2004 during Cassini approach to Saturn when an intensive HST campaign imaging Saturn's UV auroras was undertaken, with Cassini acting as upstream solar wind/IMF monitor. As expected during the declining phase of the solar cycle, the recurrent solar wind structure consisted of two corotating interaction regions (CIRs) per ~25-day solar rotation, exhibiting two few-day compression events of enhanced dynamic pressure, one major and one minor [Jackman et al. 2004]. The HST caught the impingement of the major compression region on Saturn's magnetosphere towards the end of the campaign, and observed a major increase in UV and SKR emissions with bright auroral forms extending throughout the dawn sector up to the planetary pole itself [Clarke et al. 2005; Bunce et al. 2006]. It was suggested that such auroral storms are caused by major bursts of compression-induced reconnection in Saturn's nightside tail, that inject hot plasma towards Saturn, which subsequently flows around the planet via dawn under the action of magnetosphere-ionosphere coupling [Cowley et al. 2005]. Estimates of the reconnection rate yielded associated voltages of at least several

hundred kV [Badman et al. 2005]. Monitoring of the interplanetary field prior to SOI showed that the same compression region would likely impinge on the system during the SOI fly-through of the magnetosphere [Jackman et al. 2005a, 2005b], and indeed did, with a corresponding magnetic dipolarization event, plasma energization, and enhanced SKR emissions being observed in the nightside magnetosphere on the outbound pass [Bunce et al. 2005]. Analysis of a larger number of compression events observed by Cassini acting as upstream IMF monitor during the approach phase, as well as outbound after SOI in late 2004, also showed characteristic enhancements in SKR, but with the regular pulsing at the PPO period generally being undisturbed in phase [Badman et al. 2008].

The passage of a moon through the magnetospheric plasmas of Jupiter, Saturn or the other giant planets is well known to create the potential for an auroral display at the footprint of the magnetic flux tube connecting the satellite and the planet's ionosphere. However, prior to Cassini all evidence of this process and of satellite footprints has been obtained at Jupiter. With the arrival of Cassini, the capability to perform coordinate in situ measurements yielded several new studies with the goal of observing the any such footprint if they existed. An initial study using a series of UV images of Saturn's aurora taken by the HST January 2004 and between February 2005 and January 2007 could not detect the faint auroral emission that would have been a signature of the Enceladus footprint [Wannawichian et al. 2008]. However, a follow-on study was able to report the detection of magnetic-field-aligned ion and electron beams (offset several moon radii downstream from Enceladus) with sufficient power to stimulate detectable aurora, and the subsequent discovery of Enceladus-associated aurora in a few per cent of the scans of the moon's footprint. The footprint varies in emission magnitude more than can plausibly be explained by changes in magnetospheric parameters, and as such is probably indicative of variable plume activity [Pryor et al. 2011].

Finally, using the spectra acquired by UVIS from 56 to 191 nm, it was possible to retrieve the characteristics of the energetic particles generating Saturn's aurora [Gustin et al. 2017, 2010, 2009]. Gustin et al. [2017] examined about 2000 FUV UVIS spectra to derive the mean energy of precipitating electrons for the different components of the aurora, using two different methods. The first one uses the absorption of the auroral emissions by hydrocarbons while the second one is based on the brightness ratio between the Lyman-α line and the total H_2 UV emission. Both methods give similar results with an average energy of the primary electrons ranging between 1 and 17 keV depending on the aurora component.

Composition of ionosphere and thermosphere

- **MN1b:** Conduct in situ studies of Saturn's ionosphere and inner radiation belt.
  - Investigate the effects on aurora of solar wind and seasons.
  - Are there UV satellite footprints on Saturn? (like at Jupiter)
  - Is there a seasonal variation in auroral activity?
  - Investigate solar wind–ionosphere–magnetosphere coupling through the auroral regions.

  - Investigate whether there are UV satellite footprints on Saturn and whether there are Region 1 currents connecting the ionosphere and the magnetopause.
  - Investigate the composition of Saturn's ionosphere.
  - Study whether there is a significant polar outflow from Saturn's high latitude ionosphere and whether the outflow exhibits seasonal or solar cycle variation.
  - Determine whether there is a radiation belt between the D-ring inner edge and the atmosphere.
- **MN2a:** Determine the coupling between Saturn's rings and ionosphere.
  - Study how field aligned currents are coupled to the rings and satellites.
  - Explore the dust dynamics in the proximity region.
  - Investigate the mid-plane of Saturn's D-ring.
  - Determine the grain composition in the proximity region.
  - Investigate the possible interaction of lightning with the inner magnetosphere and the rings.
  - Investigate Coupling Between E-ring and the Enceladus neutral and plasma tori.

Cassini was able to make unprecedented measurements of Saturn's topside atmosphere, neutral thermosphere and ionosphere. Some of these measurements were made possible by the Grand Finale orbits which dipped to the top of the atmosphere and allowed the first ever in situ measurements of Saturn's atmosphere and ionosphere.

Saturn Upper Atmosphere Major Findings (Neutral Thermosphere):

- INMS made first in situ measurements of Saturn's atmosphere, discovering the unexpected presence of several species of high mass neutrals, e.g., CH_4, CO, CO_2.
- The INMS made the first in situ characterization of the thermal structure in the upper atmosphere of Saturn, indirectly through its measurements of the H_2 densities.
- Helium has been measured for the first time in Saturn's upper atmosphere, providing constraints on possible deep-atmosphere mixing ratios of Helium and whether or not Saturn has a solar-like composition or something else.

During the Cassini Grand Finale, the INMS made an unprecedented series of measurements of Saturn's upper atmosphere during the proximal orbit phase, sampling from ~3500–1370 km altitude above the 1-bar pressure level. Prior to these orbits, it was anticipated that Saturn's upper atmosphere consisted primarily of H, H_2, with trace amounts of H_2O, and He. However, the INMS measurements revealed an atmosphere with an unexpectedly rich composition, containing significant amounts of organics spanning the entire mass range sampled by INMS, as seen in Figure MAPS-34. These results were completely unanticipated and they have effectively turned our understanding of the high-altitude thermosphere-ionosphere chemistry on its head.

In particular, INMS has identified methane, CH_4, as a significant component of the upper atmosphere of Saturn above 1370 km. As seen in Figure MAPS-35, INMS has found significant amounts of methane that reach up to ~10% of the composition near 3500-km altitude above the

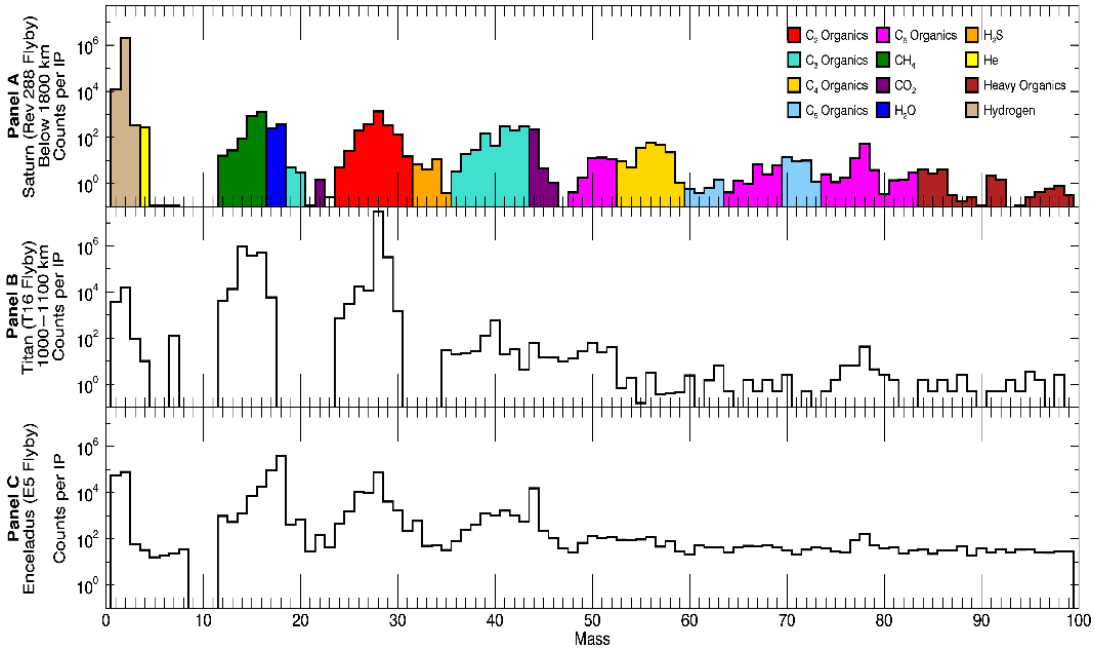

Figure MAPS-34. INMS Mass spectra from the Grand Finale orbits at Saturn (*Panel A*), compared with those of Titan (*Panel B*), and Enceladus (*Panel C*). Horizontal axis is in units of mass per charge.

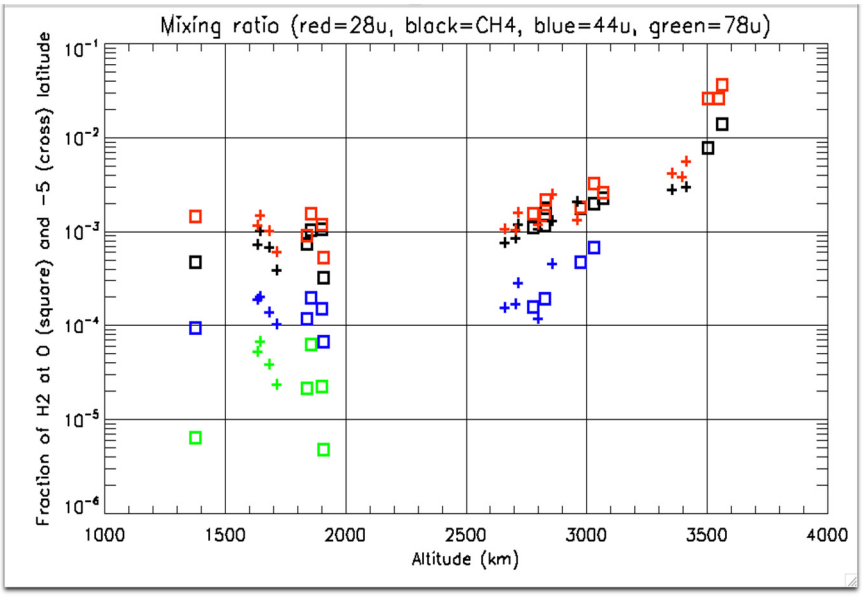

Figure MAPS-35. Volume mixing ratios (vertical axis) of the heavy species identified by INMS in the Saturnian upper atmosphere as a function of altitude above the 1 bar pressure level (horizontal axis).

1-bar pressure level. Additional heavy species (masses 28 u, 44 u, and 78 u) have also been identified. All of these species can potentially play major photochemical roles in the atmosphere of Saturn [cf. Moses and Bass 2000; Kim et al. 2014].

Using a combination of National Institute of Standards and Technology (NIST) data and calibration data collected using the refurbished engineering unit, preliminary fits to spectra at altitudes between 1700 and 1800 km for three representative orbits were made to identify contributing species. In general, the spectrum below ~70 u can be fit by a combination of species that is dominated by hydrocarbons. Ammonia (NH_3) is detected at 17 u. Other N-bearing species are neither excluded nor required by the spectra. The same is true for O-bearing organics. Inclusion of S species, especially H_2S, improves the fit of the spectrum. However, of the non-H_2, non-He material, less than 1 mol.% is contributed by S-bearing species. We estimate that between 30 and 50 mol.% of the non-H_2, non-He material measured by INMS is comprised of organics other than methane, which may constitute an additional 20 to 35 mol.%. C_4 species, including butane (C_4H_{10}) at 58 u, are particularly abundant compared to other hydrocarbons. Above 70 u, the spectra are consistent with contributions from heavier aromatic species, including species such as naphthalene ($C_{10}H_8$, 128 amu) with primary peaks that are beyond the range of INMS.

Other Cassini instruments, including the CHEMS from the MIMI, reported detections of heavy (8,000 to 40,000 amu) particles during the Grand Finale orbits [Mitchell et al. 2018, submitted]. To understand the relationship of these particles to INMS data, we compared the total amount of material detected by INMS to the particle sizes observed by MIMI. The results suggest that INMS may have mainly sampled smaller particles that were dominated by volatile and organic material with very little contribution from refractory mineral phases. The altitude-density profiles of these particles indicate very low densities, likely on the order of 0.1 g/cm^3 or less. These densities may be consistent with the densities of interplanetary dust particles from small bodies [Rietmeijer 1993]. Some masses, including 15 u (mainly from CH_4), 28 u (possibly N_2 or CO), and 17 u (mainly NH_3), have altitude-density profiles that are consistent with molecular radii. Other masses, including 58 u (possibly butane, C_4H_{10}) and 78 u (possibly benzene, C_6H_6), have profiles that suggest larger radii, on the order of nanometers or tens of nanometers.

In addition to the heavy species in the upper atmosphere of Saturn, INMS has also made the first in situ measurements of H_2, He, and H-D in the atmosphere of Saturn. Molecular hydrogen (H_2) is the dominant species in the thermosphere, and its density scale height reveals the expected background temperature of Saturn's upper atmosphere. Thus, measurements of H_2 reveal information about the thermal state of Saturn's upper atmosphere. Prior to the INMS measurements, only remote sensing observations were possible [cf. Koskinen et al. 2015; Vervack and Moses 2015], which provide temperatures through inversion techniques. The measurements in SIA3, however, provide the first-ever direct sampling of the Saturn atmosphere, allowing us to infer thermal structure from these measurements using models of the atmosphere, such as Müeller-Wodarg et al. [2012, 2006b].

Finally, there has been considerable uncertainty about the amount of Helium in the Saturnian atmosphere [Ben-Jaffel and Abbes 2015]. Helium abundances are key to determining the most

likely formation scenarios for Saturn's atmosphere. Currently, it has been suggested that Saturn would be depleted in Helium relative to Jupiter (~13.5% volume mixing ratio) or the protosolar value (~15.6%), due to Helium raining out in the lower atmosphere. The measurements provided by INMS, combined with diffusive modeling, can lead to constraints on the Helium content in the lower atmosphere, providing a missing component in our understanding of planetary evolution.

Saturn Upper Atmosphere Major Findings (Charged Ionosphere):

- INMS made repeated in situ measurements of Saturn's ionosphere, allowing the first determination of ion mixing ratios and number densities as well as their temporal variabilities.
- INMS measurements of the minor ion, H_2^+, represent a strong constraint on local ion production rates, providing a check on outer planet projections of solar irradiances.
- Combined with RWPS and MIMI measurements, INMS in situ data paint a clear picture of Saturn's equatorial ionosphere being dominated by heavy molecular ions that result from ring-derived material.

Prior to the Cassini Grand Finale, observations of Saturn's ionosphere were limited to altitude profiles of electron density (the presumed sum of the ion densities) at dawn or dusk, periods of rapid change in an ionosphere. Trace emissions from an expected major ion, H_3^+, were also detected, but column-integrated densities could only be derived at auroral latitudes. Therefore, ion densities throughout the majority of Saturn's ionosphere were based solely on model comparisons with radio occultation measurements, for example, Moses and Bass [2000]; Moore et al. [2010, 2006]. In situ measurements by INMS provided key constraints on the expected major ion species, H^+ and H_3^+, finally providing closure on a decades-long debate regarding the dominant chemical losses of H^+, for example, Connerney and Waite [1984].

In addition, INMS was able to measure the expected minor ion species H_2^+ and He^+. The chemistry of these ions is relatively straightforward, and the extremely short chemical lifetime of H_2^+ makes it an ideal marker for the in situ ion production rate. Therefore, H_2^+ densities from INMS measurements can be used to gauge the accuracy of commonly used projections of solar irradiances at Saturn. These projections rely on Earth-based data, and the assumption of a relatively stable solar irradiance over a period of days. Comparisons between measured H_2^+ with modeled H_2^+ based on projected solar irradiances find a ~50% discrepancy, implying that future outer planet modeling will require better estimates of the solar irradiance.

Finally, Cassini's high speed near periapse during the Grand Finale (~32 km s^{-1}), meant that INMS could only sample ions with mass up to 7 u. The sums of the light ions measured by INMS were found to be an excellent match with the electron density from RPWS at high altitudes (> ~2200 km), implying that Saturn's high-altitude ionosphere was charge-neutral and dominated by H^+ with minor contributions from H_3^+, as expected (Figures MAPS-36 and MAPS-37). However, at low altitudes the total ion densities from INMS differed significantly from the electron density.

This massive discrepancy could be interpreted as a signature of an ionosphere dominated by heavy (> 7 u) ions, which would be entirely consistent with the expected ion chemistry to follow from the ring-derived influx of complex neutrals measured by INMS.

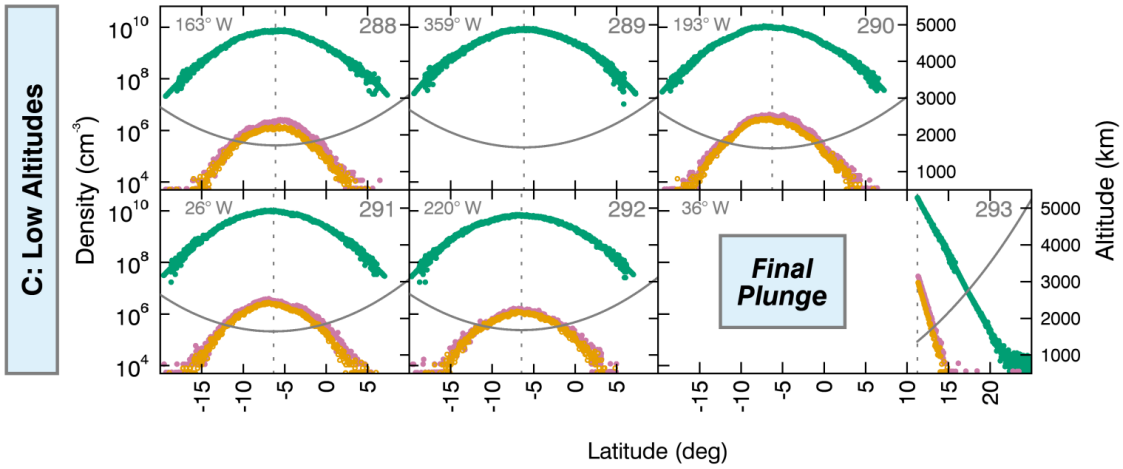

Figure MAPS-36. INMS measurements of H_2 (green), He (red), and Mass 3u (orange) as a function of altitude (right-hand axis) and latitude (horizontal axis).

Open Questions for Saturn System Science

Internal rotation rate and internal magnetic field of Saturn

- What is the rotation period of Saturn? How do the multiple, variable magnetospheric periods observed in radio, magnetic fields, energetic particles, plasma, aurora, and other phenomena tied to the internally-generated magnetic field at Saturn?
- How are the observed periodicities related to the actual rotation of Saturn, and does it matter? Most investigators agree that the observed periods of Saturn, which are generally magnetospheric in nature, do reflect the true rotation of the planet, and that such periods are probably slower than the real rotation period, which may be intimated from the planet's oblateness, see Helled et al. [2015] and references therein. If Saturn is a differential rotator, such as the Sun, then, indeed, the period may be ephemeral and not meaningful, for example, Dessler [1985].
- What are the implications of the extremely axisymmetric planetary magnetic field for the internal structure of Saturn? What is the dynamo process generating this planetary field?

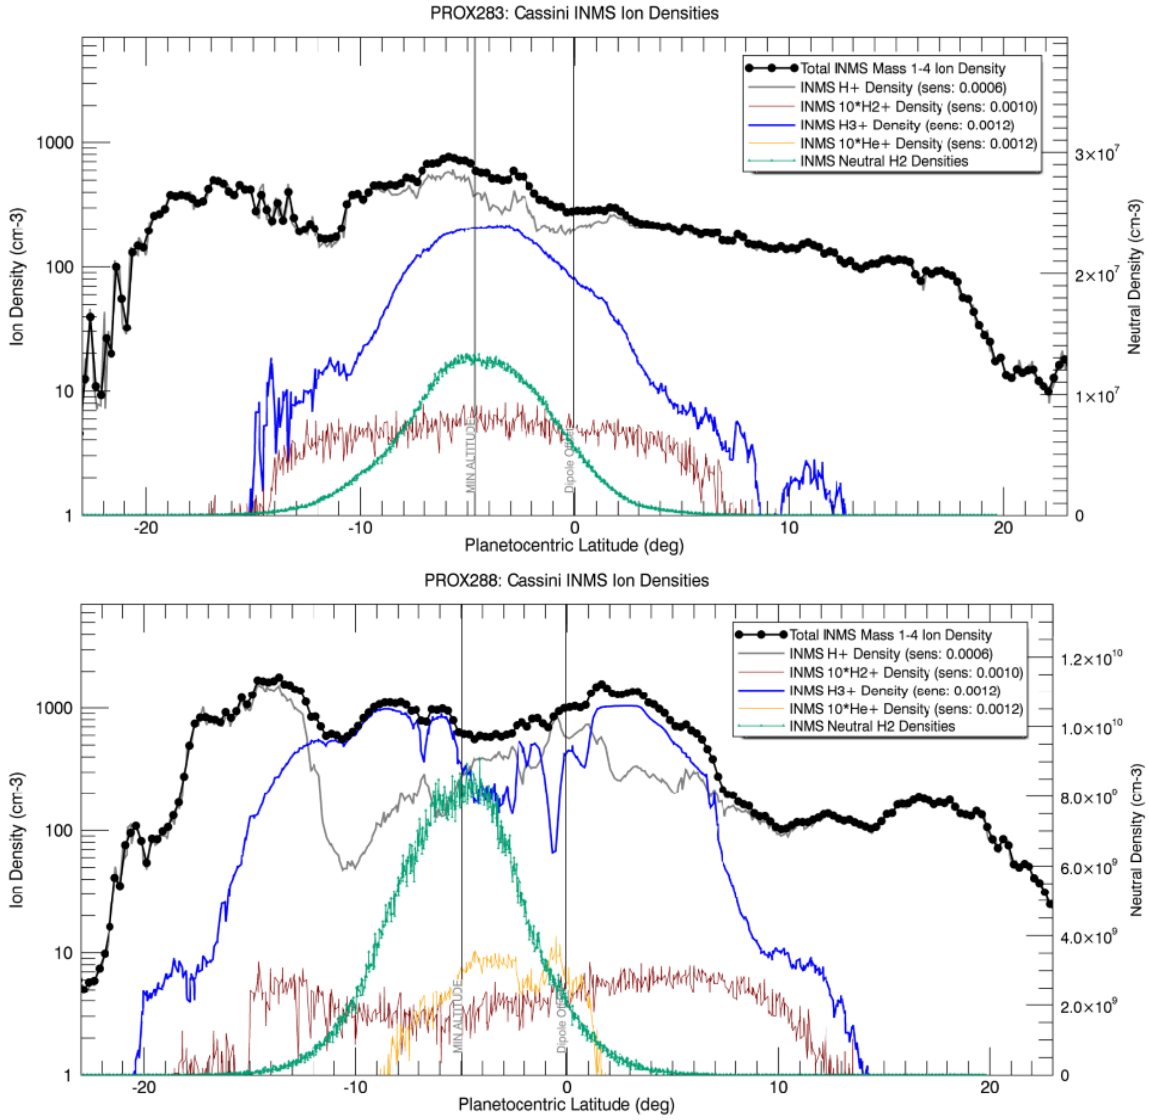

Figure MAPS-37. INMS measurements of H_2 (green), H^+ (gray), H_2^+ (red, multiplied by 10), H_3^+ (blue), He^+ (gold, multiplied by 10), and total light ion density (1–4 u, black) as a function of planetocentric latitude (horizontal axis). Ion measurements were taken for four proximal orbits, 283, 287, 288, and 292, though only one representative high altitude (283, *Top panel*) and low altitude (288, *Bottom panel*) orbit is presented here.

Rotational modulation in axisymmetric configuration

- Given the extraordinarily axisymmetric magnetic field, why are there such prominent rotational PPO modulations in Saturn's magnetosphere?
- What is the underlying cause of Saturn's periodicities? The current thinking is that the periodicities are related to disturbances, possibly vortices, in the upper polar atmosphere or lower ionosphere. The periodicities are not thought to arise in the

magnetosphere, although the magnetosphere probably provides a linkage, via field-aligned currents, between periods in the north and the south.

- How are the PPOs driven in the atmosphere, thermosphere and ionosphere of Saturn?

How are mass and magnetic flux transported in the middle and outer magnetosphere?

- Where and how does the magnetosphere unload its cold, dense plasma?
- How is plasma transported outward, and magnetic flux returned, in the region between 12 and 20 to 25 R_S?
- What is the connection between large-scale and small-scale injections at Saturn? How much material do injections transport relative to radial diffusion? What drives radial diffusion?
- What is the relationship between large-scale, tail-reconnection-driven injections and small-scale interchange injections?
- What determines the scale size and inflow speed of interchange injections? What determines the apparently variable rate and depth of such injections?
- Are the growth of the K-H instability and magnetic reconnection coupled?
- Where in the Saturnian system does Vasyliunas-type reconnection take place, and where does Dungey-type reconnection take place? Is there a region in Saturn's magnetosphere where one or the other dominates?

Solar wind control of the Saturnian magnetosphere

- What is the dominant mode of solar wind interaction with the magnetosphere, the viscous interaction or the large-scale reconnection interaction?
- How does the solar wind drive magnetospheric dynamics at Saturn? Is solar wind dynamic pressure the primary influence?

Neutral particle dominated Saturnian magnetosphere related to difference if compared to Jupiter?

- How does the abundant neutral population in Saturn's magnetosphere make it different from fully or mostly ionized magnetospheres?

Very limited plasma measurements in auroral acceleration and source region of related SKR

- What is the predominant form of the electron distribution function at the source of SKR?

Understanding the Enceladus plume-magnetosphere interaction

- What are the various populations of charged dust and molecules that balance charges in dusty media such as in the plumes of Enceladus and in Saturn's topside equatorial ionosphere?
- In the Enceladus plumes, the 28 u species measured during CSN operations is a fragment of a larger molecule. The identity of the larger molecule and of the 28 u fragment would help constrain the chemistry in the subsurface oceans of Enceladus. Similarly, the highly abundant 28 u neutral measured in Saturn's inner magnetosphere could be CO, N_2, or a fragment of a heavier molecule, and none of these is consistent with CAPS observations or with the Enceladus plume composition.
- How are heavy negative ions formed in the plume at Enceladus, and what is their contribution to nano-grain formation?

Composition of the negative ions at Titan and > 100 amu positive ions

- What are the detailed process that create the large ions and the negatively charge ions in Titan's upper atmosphere and ionosphere?

MAPS DWG Non-Saturn Science Results

Cruise-specific Science

Solar wind from Earth to Saturn

- **C_AO1:** Extend the sensitivity of composition measurements of interstellar ions by approximately three orders of magnitude.

The Cassini spacecraft obtained gravity-assists at Earth (August 1999) and Jupiter (December 2000–January 2001) arriving at Saturn July 2004. This extensive time spent in the solar wind allowed Cassini to make measurements that could be used, together with Galileo and Ulysses measurements, to better understand the evolution of the solar wind outward in the solar system.

During the cruise to Saturn the MIMI suite was able to make unique measurements of heliospheric suprathermal particles in the 2–60 keV/nuc range. There has never been an

investigation with species separation of this important class of particles, which ties the solar wind plasma to the energetic particles, beyond Jupiter. Hill et al. [2009] made CHEMS measurements that revealed that the radial intensity profiles of He^{+} and He^{++} are very different from both analytical and numerical theory, with the observations showing an increasing intensity with distance from the Sun, while the theory predicts the intensity should fall. This observation remains unexplained.

During same time period, the CAPS investigation made the first in situ observation of interstellar pick-up ions beyond the orbit of Jupiter. This was the first direct detection of mass-resolved interstellar pick-up ions, and confirmed the existence of helium focusing at these distances. Focusing of helium atoms at these distances is caused by the solar gravitational field (Figure MAPS-38). CAPS also made the first direct, in situ, measurements of a large shadow in the interstellar hydrogen population downstream from the Sun caused by motion through the interstellar medium [McComas et al. 2004]. The shape of the measured distribution function of the observed He+ as a function of energy was characteristic of a pick-up distribution with a flat top and cut off at about four times of the solar wind energy.

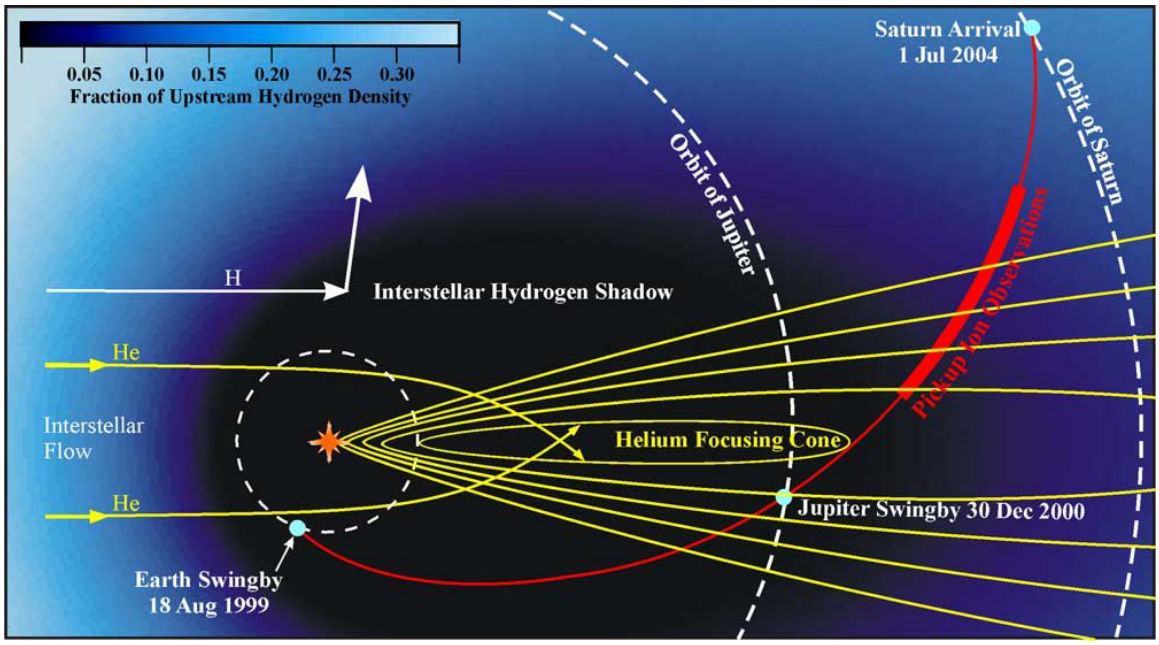

Figure MAPS-38. Schematic diagram of Cassini's trajectory between Earth swing-by and arrival at Saturn. Pick-up ion measurements were made between 6.4 and 8.2 AU (heavy line) as Cassini emerged from the down-stream direction. Simulation results show: i) the gravitational focusing of interstellar He in contours of 5/3, 2, 7/3, 8/3, and 3 times the upstream He density; and ii) the color-coded H density as a fraction of the interstellar value. The dark region downstream from the Sun is the interstellar hydrogen shadow. Figure from McComas et al. [2004].

CHEMS measurements of pick-up ions were used to determine solar wind speeds, which enabled a study [Hill and Hamilton 2010] of the spectral index of suprathermal particles. The slopes of the spectra were reported and widely put into and used to create context by the community, but Hill and Hamilton [2010] showed that the expected velocity v dependence was approximately v^{-5}

as reported by Fisk and Gloeckler [2008]. The solar wind speeds themselves are of inherent value for investigating the heliosphere and, near Saturn, as an input to magnetospheric studies. In 2014, data from 2001 to 2004, inclusive, at a 12-hour cadence, were published on the Cassini project's MAPSview website: [http://mapskp.cesr.fr/index.php].

The energetic particle population was further studied by Lario et al. [2004] using LEMMS observations. They found that intensity enhancements up to ~1 MeV were due to the passage of interplanetary shocks while at the highest energy (> 25 MeV), the prompt component of solar energetic particle events was responsible. For all but the largest SEP events the presence of magnetic field structures between the Sun and the spacecraft significantly modulates the intensity enhancements.

In addition to the measurements Cassini MAPS instruments made of solar system plasmas and neutrals, the RPWS instrument was able to make measurements of nanograin dust. During the flyby of Jupiter, Meyer-Vernet et al. [2009] reported wave measurements that corresponded to observations of nanograin dust streams moving at the solar wind speed made by the Cassini dust sensor. The result is the first wave detection simultaneous with a conventional detection by a dust analyzer attributed to nanoparticles. Following this detection, RPWS data from the cruise phase (between 1–5 AU) was analyzed in more detail. Schippers et al. [2015, 2014] analyze the low frequency bursty noise identified in the Cassini radio and plasma wave data during the spacecraft cruise phase and find the magnitude, spectral shape, and waveform of this broadband noise are consistent with the signatures of the nanoparticles that traveled at solar wind speed and impinged on the spacecraft surface. Nanoparticles were observed whenever the radio instrument was turned on and able to detect them at different heliocentric distances between Earth and Jupiter, suggesting their ubiquitous presence in the heliosphere. Analysis of the radial dependence of the nanodust flux with heliospheric distance and found that it is consistent with the dynamics of nanodust originating from the inner heliosphere and picked-up by the solar wind. The contribution of the nanodust produced in the asteroid belt appears to be negligible compared to the trapping region in the inner heliosphere. In contrast, further out, nanodust is mainly produced by the volcanism of active moons such as Io and Enceladus.

Due to a fortuitous alignment of the Earth and Jupiter during the Cassini Jupiter flyby Hanlon et al. [2004] were able to study the evolution of an interplanetary mass ejection during solar maximum. The pre-Jupiter data set reveals clear and numerous transient perturbations to the Parker Spiral solar wind structure typical of solar maximum. The limited plasma data is available at Cassini due to instrument pointing restrictions and this renders the identification of the nature of such structures ambiguous. However, the alignment of Jupiter and Earth during this encounter allowed the tracing of these structures back to those observed by the Wind spacecraft near the Earth. Of the phenomena that are satisfactorily able to

Due to a fortuitous alignment of the Earth and Jupiter during the Cassini Jupiter flyby Hanlon et al. [2004] were able to study the evolution of an interplanetary mass ejection during solar maximum.

trace back to their manifestation at 1 AU, two are identified as being due to interplanetary coronal mass ejections. One event at Cassini is shown to be a merged interaction region, which is formed from the compression of a magnetic cloud by two anomalously fast solar wind streams. The flux-rope structure associated with this magnetic cloud is not as apparent at Cassini and has most likely been compressed and deformed.

Other Non-Saturn System Science

Interstellar neutrals and the Heliotail

- **C_AO1:** Extend the sensitivity of composition measurements of interstellar ions by approximately three orders of magnitude.
- **J_AO4:** Obtain the first high-resolution images of the Io torus.

The Sun's atmosphere is not static but expands in the form of a magnetized fluid called the solar wind [Parker 1958], reaching to distances of potentially hundreds of Astronomical Units (1 AU = 1.5 × 10^8 km), shaping our local bubble, called the heliosphere, through its interaction with the Local Interstellar Medium (LISM). Voyager 1 and Voyager 2 (hereafter, V1 and V2) crossed the termination shock, where the supersonic solar wind presumably terminates at the shock front, at respective distances of ~94 and ~84 AU in 2004 and 2007 at +35° and −26° ecliptic latitudes [Decker et al. 2008, 2005], pinpointing both the—previously unanticipated—size of the local heliosphere and the scale of the heliospheric asymmetry.

After the discovery of the reservoir of ions and electrons that constitute the heliosheath (a region past the termination shock), V1 passed through an unexpected depletion region, where a decrease in ions of solar origin (by a factor of ~10^3) and a simultaneous increase of high energy cosmic rays (~9.3%) occurred, that forms part of the interface between the solar plasma and the galaxy, namely the heliopause [Krimigis et al. 2013], at a distance of ~122 AU. Since August 2012, V1 has continued its journey to the galaxy, measuring the distant and unexplored LISM (V1 is currently located at a distance of ~19 AU past the heliopause), while V2 is still surveying the heliosheath (expected to cross the heliopause in the next few years). Due to the powerful synergy between in situ ions from V1/LECP (Low Energy Charged Particle) instrument and ENAs from INCA (in overlapping energy bands), MIMI, beginning in about 2009, has made key discoveries that altered our past notions on the formation and interactions of the heliosphere, leading to a number of surprises concerning the physics that governs this enormous system, and providing insights on the plasma processes at ~100 AU that were substantially at variance with previous theories and models.

In 2009, an important paper by the MIMI team [Krimigis et al. 2009] showed, for the first time, images of the global heliosphere using > 5.2 keV ENA measurements obtained with INCA over the 2003–2009 time period, and identified two striking, previously unexpected, heliospheric signatures: i) the Belt, a broad band of emission in the sky, identified as a high intensity, relatively wide ENA region that wraps around the celestial sphere in ecliptic coordinates, passing through the nose the anti-nose (tail) and the north and south heliosphere poles; and (ii) the basins,

identified as two extended heliosphere lobes where the ENA minima occur. Interestingly, the ENA measurements are moderately well organized in galactic coordinates, with the Belt presenting a prominent tilt of ~30° with respect to the galactic equator, whereas the Basins were found to roughly coincide with the galactic north and south poles, although their boundaries were also tilted ~30° to the galactic equator. The same science issue hosted yet another significant publication (with contribution from the then-MIMI PI, Stamatios M. Krimigis), from the Interstellar Boundary Explorer team [McComas et al. 2009], showing, for the first time, images of the heliosphere in < 6 keV ENAs. A narrow bright ENA stripe known as the ribbon forms an incomplete circle around the heliospheric nose, most prominent at ~1.1 keV, surrounded by a broad ENA emission that became known as Globally Distributed Flux (GDF).

In a later publication, Dialynas et al. [2013] found that the deviation of the ENA emissions from the equator is effectively minimized in a rotated frame (interpreted interstellar magnetic field frame (ISMF)) where its north pole points toward 190° ecliptic longitude and 15° ecliptic latitude. The ENA spectra showed a power-law form in energy, presenting higher spectral slopes in the belt region and lower outside ($3.4 < \gamma < 4.4$), which are almost indistinguishable between the tail and the nose regions, i.e., no noticeable asymmetry was observed. Notably, the morphology of the belt (peak, width, and structure) is nearly energy independent of energy from 5.2 keV to 30 keV. The authors speculated that Interstellar Boundary Explorer (IBEX)-GDF evolves with increasing ENA energy to form the belt at high GDF energies, explaining that the GDF and the ribbon are distinct features that originate from different source plasma populations (heliosheath and outside the heliopause, respectively). This was recently confirmed by the IBEX team [McComas et al. 2017].

Taking into account the local partial pressure over the $\sim 5 < E < 4000$ keV energy range from V1, V2 and INCA (~ 0.1 pPa), an assumed thickness of the heliosheath (~50 AU) and the simulated pick-up ions (PUI) distribution [Giacalone and Decker 2010] that was used to estimate the $E < 6$ keV contribution (~0.12 pPa), Krimigis et al. [2010] concluded that there is a need for a substantially stronger magnetic field upstream of the heliopause than assumed before, in order to balance the non-thermal PUI pressure against the stagnation pressure of the interstellar plasma and the local ISMF at the heliospheric nose. The interstellar magnetic field was estimated to be ~0.5 nT and have an upper bound of ~0.64 nT. This calculation was confirmed a few years later after V1 crossed the heliopause and measured a strong interstellar magnetic field of ~0.5 nT [Burlaga et al. 2013] that exhibited a jump right outside the heliopause of ~0.6 nT. V1 is currently located at ~19 AU past the heliopause and still measures a magnetic field of ~0.5 nT, Burlaga and Ness [2016], and a relatively dense plasma of > 0.09/cm^3 that reached densities of ~0.12/cm^3 [Gurnett et al. 2015, 2013].

A different study, Dialynas et al. [2015] analyzed separately INCA images of the heliosphere and found that the very low (basin) and high (tail) ENA emissions in the heliosheath are separated with a relatively smooth boundary (called transition region), with a spatial width of ~30° in ecliptic longitude, which no theory had predicted to date. The ENA intensity gradient in this transition region was found to be almost invariant as a function of both ecliptic latitude and energy, with an average value of ~2.4% per degree and translates to a corresponding partial pressure gradient that occurs in the transition region, enabling a discussion on the Parker field towards the tail. Bearing in mind

that the plasma-β inside the heliosheath showed large fluctuations about an average of ~5–10, i.e., much larger than unity [Decker et al. 2015], this pressure gradient is possibly not consistent with a tail magnetic field configuration that is similar to the measured magnetic fields by the Voyagers in the nose hemisphere. Notably, the pick-up ion populations in the keV range play a dominant role in maintaining the pressure balance in the heliosheath.

In the pre-INCA imaging era, the size of the heliosphere had been estimated using several different models, where the heliosheath varied between 70 and 160 AU. By combining Voyager in situ ion measurements and remotely sensed INCA ENAs in overlapping energy bands, Krimigis et al. [2010, 2009], calculated that the heliosheath thickness should be ~54 (+30, −15) AU. A more detailed analysis performed by the MIMI team, included also the possible contributions from the Compton-Getting effect due to the radial velocity of the heliosheath plasma and concluded that the heliosheath appears to be twice as thick along the V2 line-of-sight (LOS) as it is along the LOS to V1: L_{V1} = 31(+31, −18) AU and L_{V2} = 71(+30, −15) AU [Roelof et al. 2012]. A breakthrough on this came in 2011, when the MIMI and Voyager teams published a brief report [Krimigis et al. 2011] showing that the radial component of the bulk plasma velocity had been decreasing almost linearly for three years, from 70 km/s to 0 km/s, and then it stabilized around this value for ~8 months. This study concluded that the ENA and ion spectra could be brought into agreement at V2 with a heliosheath thickness of L_{V2} ~54(+30, −15) AU, whereas the same normalization procedure applied to Voyager 1 results in L_{V1} ~27(+26, −11) AU. Surprisingly, the V1 crossing from the heliopause occurred ~1 month later than anticipated by Krimigis et al. [2011], in August 2012 [Krimigis et al. 2013], showing that the heliosheath thickness towards the nose (at V1 direction) is ~29 AU, i.e., much smaller and more compressed than expected in past models.

Admittedly, one of the milestones in the heliosphere research concerns the shape of this enormous system, because it strongly relates to the interpretation of several phenomena that were either theorized in the literature and/or resulted from measurements performed by modern detectors. For more than five decades, the shape and interactions of the heliosphere with the local interstellar medium have been discussed in the context of either a magnetosphere-like heliotail or a more symmetric bubble shape, posited in 1961 [Parker 1961]. Although past models broadly assumed the magnetosphere-like concept, the accurate heliospheric configuration remained largely undetermined due to lack of measurements.

Building upon previous analyses made by Krimigis et al. [2009] and Dialynas et al. [2013], and employing both Voyager in situ and INCA remote measurements, a recent MIMI publication, Dialynas et al. [2017a] used > 5.2 keV ENA measurements, obtained with MIMI/INCA over the 2003–2014 time period and provided a new paradigm on the heliosphere interaction with the LISM: the belt corresponds to a reservoir of particles that exist within the heliosheath, constantly replenished by new particles from the solar wind, while the ENAs that INCA detects are most likely associated with a region of enhanced particle pressure that is formed inside the heliopause and contributes to balancing the pressure of the ISMF (see Figures MAPS-39). The authors showed that the heliosheath ions are the source of > 5.2 keV ENA and that the heliosphere responds

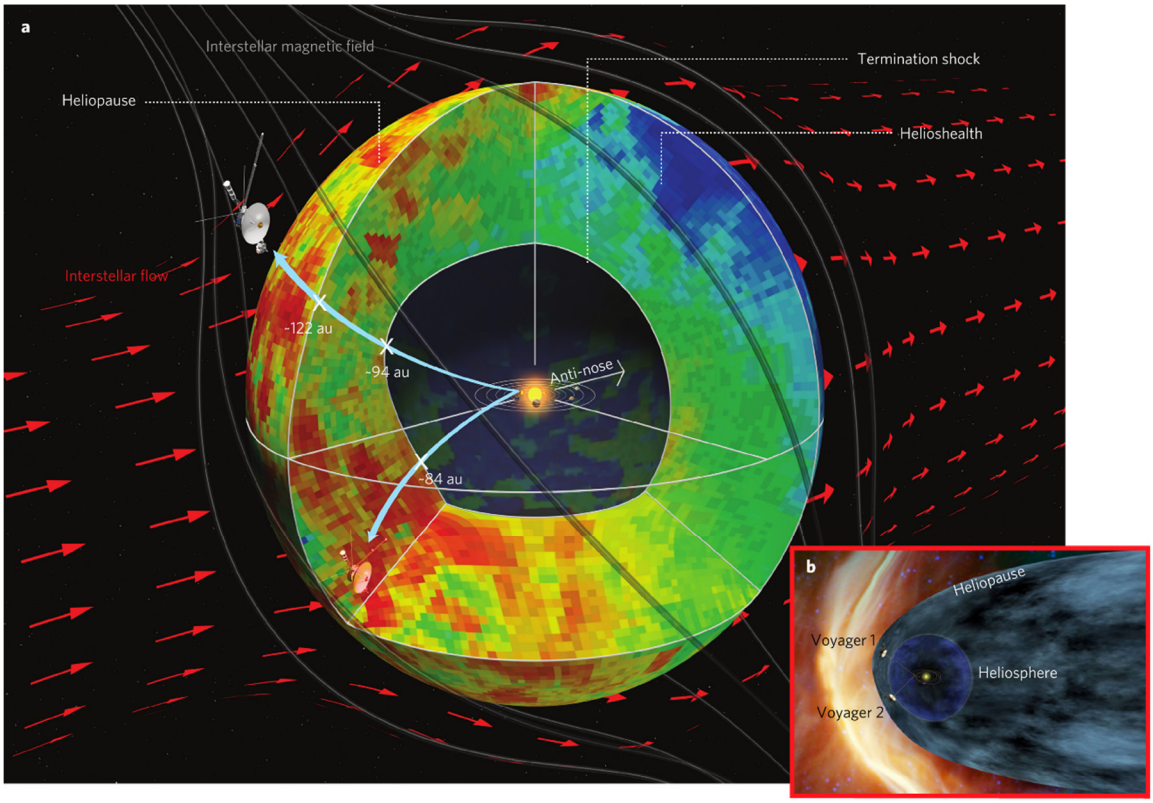

Figure MAPS-39. Adapted from Dialynas et al. [2017a] showing a conceptual model of the global heliosphere: (a) The gross shape and basic properties of the global heliosphere in three dimensions, summarizing our current understanding, based on both remote ENA and in situ ion measurements from Cassini/INCA and LECP/V1&V2, respectively. It shows a belt of varying ENA intensities surrounding the termination shock and extending to the outer boundary of the Heliosphere, called the heliopause, as identified by V1; it is anticipated that the heliopause south of the ecliptic will be crossed by V2 within the next few years. The red arrows represent the interstellar plasma flow deflected around the heliosphere bubble. The termination shock and heliopause are marked at the distances (in AU) observed by the Voyagers from 2004 through 2012 in their traversal of the heliosheath. The cutout illustrates the possible distribution of hot ion plasma in the heliosheath discerned by line-of-sight ENA images (E > 5.2 keV); relative scale ranging from 1 *(blue)* to 12 *(red)*. As the ENA emissions detected by INCA are LOS integrated, the 3rd dimension in this composite, conceptual representation of the global heliosheath (presenting the possible ENA distribution confined between the termination shock and the heliopause) is based on the knowledge of the variation of ion intensities measured at the Voyagers towards the nose hemisphere. These ion intensities are representative of the average ENA intensities along any LOS inside the heliosheath. Note that this concept of the heliosphere does not imply a closed system that cannot change its shape towards the tail to release the solar wind energy input. Inside the termination shock the ion intensities are lower by at least ×100. The orbits of the outer planets are drawn to scale around the Sun. Concept *(a)* is compared with *(b)*, a magnetosphere-like configuration (http://voyager.jpl.nasa.gov/mission/) widely adopted as one of two possibilities put forward by Parker [1961]. The termination shock is ~10 AU further out in the V1 direction, but the HS is possibly ~30–50% thicker towards the V2 direction (as detailed in the text), inconsistent with a compressed heliosheath in the southern hemisphere. That will be determined when V2 crosses the HP, expected in the next few years.

promptly, within ~2–3 years, to outward propagating solar wind changes (controlled by solar sunspot numbers and solar wind energy input) in both the upstream (nose) and downstream (tail) directions. These observations, taken together with the V1 measurement of a ~0.5 nT interstellar magnetic field, plasma density of > 0.09/cm^3 and the enhanced ratio between particle pressure and magnetic pressure in the heliosheath, strongly suggest a diamagnetic bubble-like heliosphere with few substantial tail-like features. A follow-up MIMI publication [Dialynas et al. 2017b] discussed the details of these results, and by calculating the recovery times of ENAs in the heliosphere, they found that the rough width of the heliosheath can be ~80–120 AU (or more) towards the tail, due to the ~2–3 year delay after solar minimum.

Dialynas et al. [2017a] also included two important implications concerning the heliosphere interaction with the LISM: 1) A perfectly symmetric and stable heliosphere in time would not be possible and/or physically correct, i.e., as the heliosphere cannot be a closed system, the heliosphere bubble can (and must) inflate with time in either the anti-nose direction (tail models) or along the direction of the interstellar magnetic field (Note: the polar jets [Opher et al. 2015; Drake et al. 2015], provide one of the possible mechanisms through which the solar wind input is evacuated from the system); and 2) due to the strong interstellar magnetic field, the Mach number of the local interstellar medium can be significantly decreased and the flow can become submagnetosonic, leading to the inability of forming a bow shock, as previously explained by Fahr et al. [1986] and simulated from Kivelson and Jia [2013] using the mini magnetosphere of Ganymede as a rough analogy to the heliosphere.

Jupiter

Jupiter's magnetotail

- **J_AO3:** Explore the dusk side of Jupiter's magnetosphere and intermediate regions of the magnetotail unvisited by previous spacecraft

Cassini flew by Jupiter on December 30, 2000, on its way to Saturn. Arriving from the pre-noon sector, closest approach occurred in the afternoon sector at 138 Jovian radii (~107 km) from the planet and was followed by an exploration of the dusk flank of the Jovian magnetosphere. During the Cassini flyby, the Galileo probe was still active (Figure MAPS-40).

In spite of the large distance of the flyby, several Cassini-MAPS instruments recorded high-quality data for about six months around closest approach. These observations benefited from the simultaneous presence of Galileo in orbit around Jupiter, enabling two-point measurements, and were complemented by remote observations by HST, Chandra, and ground-based radio. This resulted in a very rich data set that was the basis of many publications and will be further exploited in the coming years.

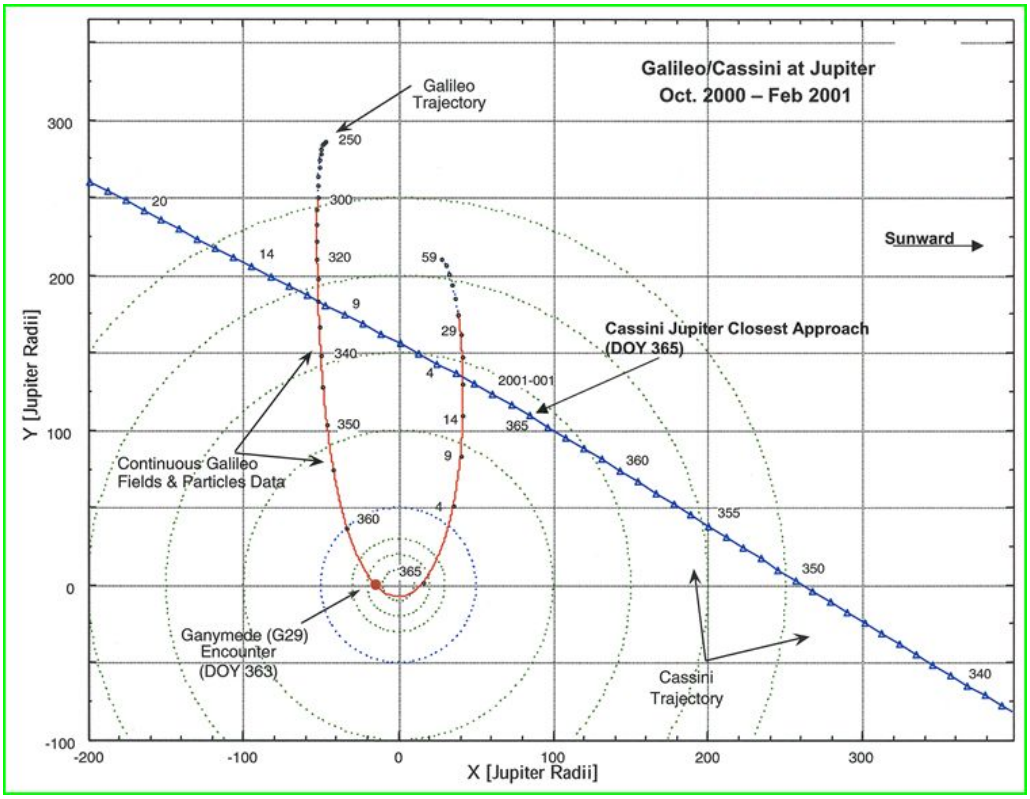

Figure MAPS-40. The orbits of Galileo and Cassini at Jupiter.

The dual Cassini/MAPS and Galileo measurements provided a chance to study the dynamic effects of the solar wind perturbations on the global configuration of the Jovian magnetosphere. These measurements showed clearly that magnetospheric particles leak directly into the interplanetary medium from the closed magnetosphere and are the source for the upstream particle events [Krupp 2002].

During its passage along Jupiter's dusk flank, Cassini made at least five bow shock crossings, one at ~1929 LT and four more between 2100 and 2130 LT on DOY 21. During the flyby, shock activity was high and variable, making a moving target for Cassini instruments. Cassini found that the shock is enormous, extending at least 700 R_J down the flank.

All three CAPS sensors were used to identify shock conditions and the times at which Cassini crossed into and out of it. See Szego et al. [2003] for a full description of shock studies based on all Cassini observations. By combining RPWS identification of Langmuir waves and IBS energy spectra, the upstream density could be measured at 0.5 to 1 cm^{-3} while at the same time ELS provided a measure of electron temperature at 2.6 eV. The data allowed the team to solve the Rankine-Hugoniot relations for transitions between the upstream and downstream conditions, deriving plasma density ratios of 2.74, and a downstream ion bulk energy of ~360 eV. The calculated downstream electron bulk temperature prediction was ~44 eV whereas ELS data gave ~11 eV and IMS ~24 eV, in fairly good agreement with the total energy jump predicted by theory.

IBS energy-time spectrograms were used to identify shock crossings far down the flank of the magnetosphere (Figure MAPS-41 is one example). Four examples that were observed using IBS data took place at 576, 618, 744, and 770 R_J were studied in detail by Szego et al. [2003].

Using CAPS, MAG, and RPWS, Cassini was able to investigate features of the downstream Jovian shock and magnetosheath out to ~700 R_R; a region not previously visited by any other spacecraft. As might be expected, the shock transition layer was broad and turbulent at that distance, but the transits were always easily observed using IBS data.

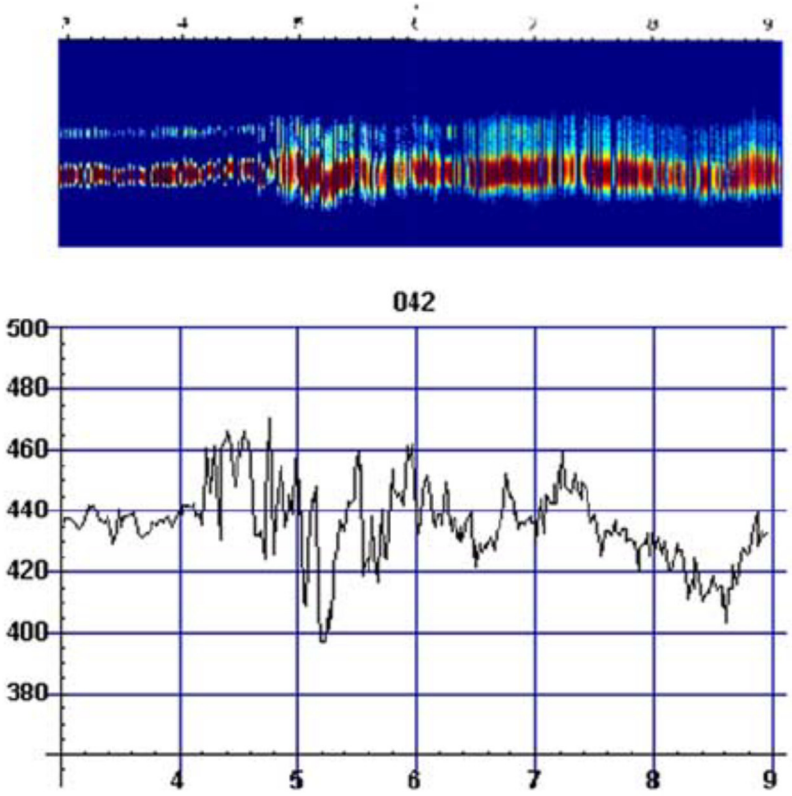

Figure MAPS-41. IBS data taken on DOY 042, 2000, 0300 to 0900 UT along the flanks of the Jovian magnetosphere. The velocity jump across the shock shows up as a jump in the velocity measured by IBS beginning at approximately 0420 UT. The most apparent feature is at ~4:40 UT when Cassini is inside the sheath and density and temperature both increase.

An important result of the coordinated measurements of Cassini and Galileo was good evidence of a change in magnetospheric shape in response to local solar wind magnetic field changes in the north-south component. There is increased flaring when the field is northward, opposite as to what happens at Earth. As the Jovian dipole is oppositely oriented, this is consistent with reconnection being important to magnetospheric configuration at Jupiter despite the high planetary rotation [Kivelson and Southwood 2005, 2003].

Not only did the passage of Cassini allow two-point measurements, but the MIMI/LEMMS and RPWS instruments on Cassini were very similar to instruments flown on Galileo. This allowed direct comparison of energetic particle and wave phenomena both inside and outside the magnetosphere of Jupiter. The comparison of energetic particle measurements made by both spacecraft is summarized in Krupp et al. [2004, 2002]. Figure MAPS-42 shows the differential fluxes and the pitch angle distributions of ions and electrons measured with LEMMS onboard Galileo and Cassini in the vicinity of the Jovian magnetopause.

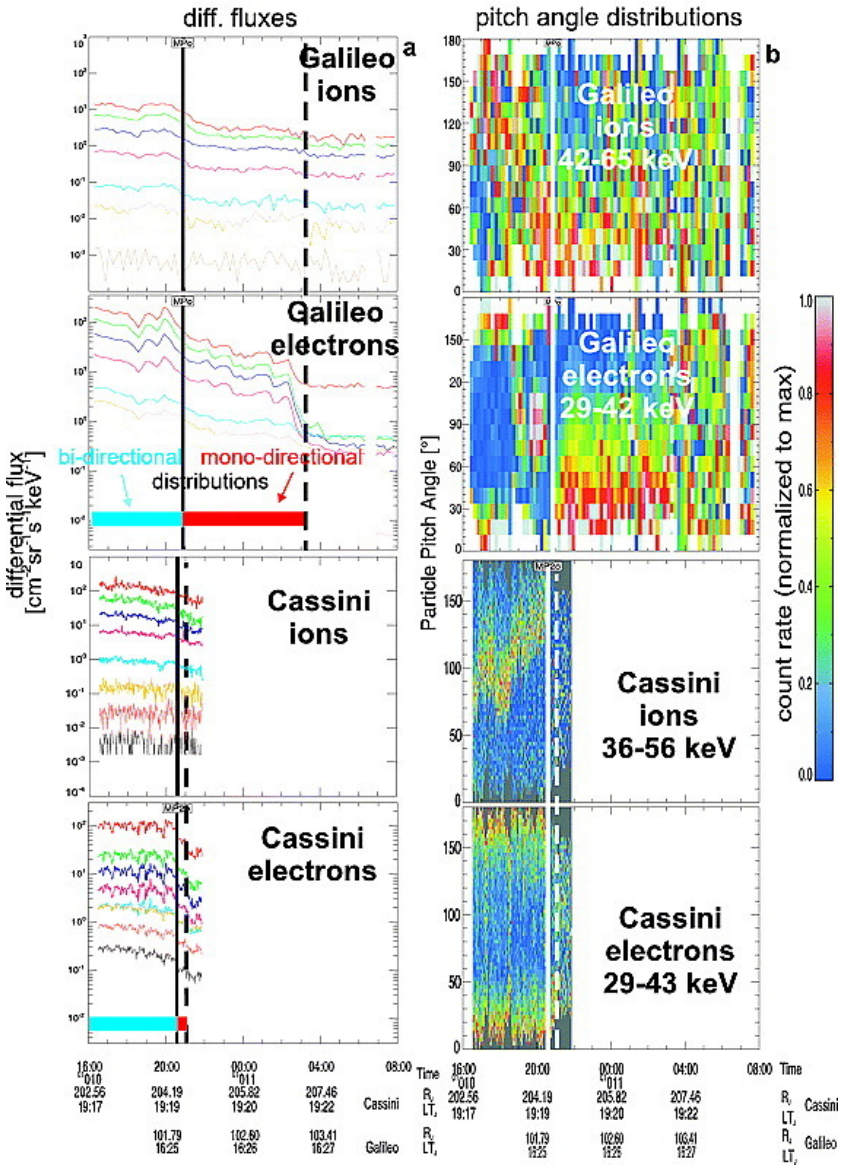

Figure MAPS-42. Differential fluxes and pitch angle distributions of ions and electrons measured with the LEMMS sensors onboard Galileo and Cassini in the vicinity of the magnetopause of Jupiter. Figure from Krupp et al. [2002].

Significant results from the coordinated measurements of the energetic particles include:

- Passage of closed to open planetary field lines with distributions from bi-directional to mono-directional, with respect to the magnetic field near the magnetopause.
- Periodic variations of electron fluxes on both spacecraft with 40 min periods near Cassini and about 60 min at Galileo's location.
- Leakage of magnetospheric particles into the interplanetary space.
- Sporadic electron beams outside the magnetosphere (Cassini at 300–900 R_J and Galileo at 130 R_J).

In addition, during the Jupiter flyby, INCA observed large fluxes of ENAs, primarily H and O, from the planet [Mitchell et al. 2004]. INCA discovered an ENA torus associated with and located just outside the orbit of Europa [Mauk et al. 2003]. The neutral densities in this torus were comparable to those found in the Io-associated cloud, and suggested that Europa is a strong source of neutrals. Figure MAPS-43 shows the discovery ENA image of the Europa torus.

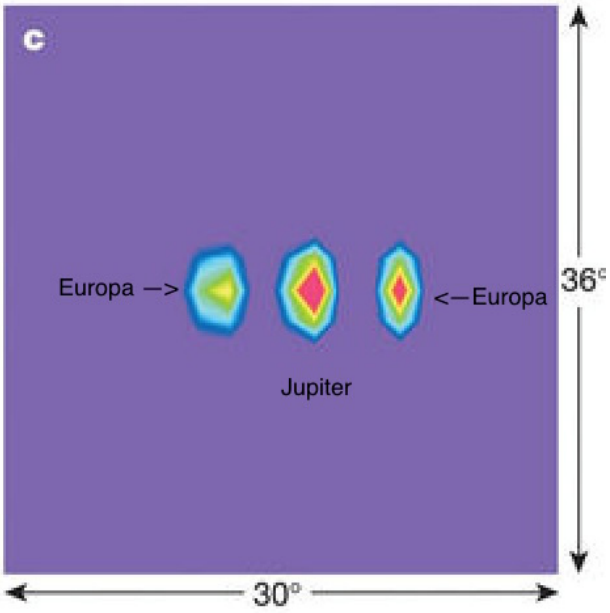

Figure MAPS-43. ENA image of the Europa torus, seen from the side, during the Cassini flyby of Jupiter in early 2001. The Europa torus appears on either side of Jupiter. The image was deconvolved for point sources and corrected for background. The intensity scale is linear.

Jupiter's radio emissions

The distant observations that Cassin made along the dusk flank of Jupiter's magnetosphere were well adapted to the study of the complex zoo of Jupiter's magnetospheric radio emissions, nicely covered by the Kronos receiver of RPWS, an example of which is given in Figure MAPS-44. An early overview is given in [Lecacheux 2001]. The intensity spectrum of all Jovian radio components was

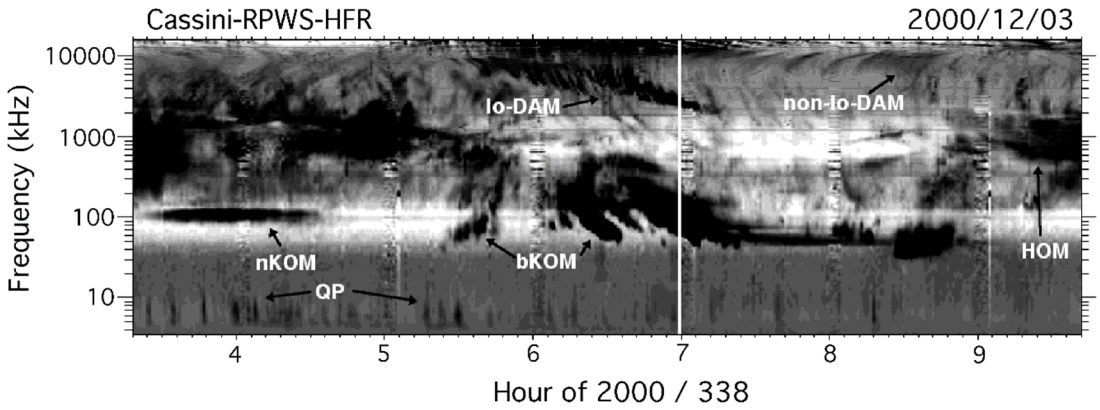

Figure MAPS-44. Jovian low-frequency radio emissions detected on December 3, 2000, by the RPWS experiment onboard Cassini approaching Jupiter. Frequency range is 3.5 kHz to 16.1 MHz. The Io-induced decameter emission (Io-DAM) appears here down to about 2 MHz, while weaker Io-independent (non-Io-DAM) arcs merge with the hectometer component (HOM) detected down to ~400 kHz. The auroral broadband kilometer component (bKOM) is detected down to ~40 kHz. The narrowband emission (nKOM) about 100 kHz is generated at or near the plasma frequency f_{pe} in Io's torus. The quasi-periodic (QP) bursts, spaced by 5 to > 15 min, are detected in the ~5 to 20 kHz range. Distance to Jupiter was 383 R_J (2.7×10^7 km) at the time of this observation.

accurately measured [Zarka et al. 2004] through calibration on the galactic background and Nançay observations, demonstrating in particular the absence of peak at 10 MHz in the decameter spectrum. The beaming of the decametric (DAM) and hectometric (HOM) components (a widely opened hollow cone of a few degrees thickness) were measured via two-point Cassini-Wind measurements [Kaiser et al. 2000] as well as frequency-longitude statistics and modelling [Imai et al. 2011a, 2011b, 2008]. The HOM low-frequency cutoff measured by Ulysses and Cassini provided constraints of its source location, in the outer regions of the Io plasma torus [Zarka et al. 2001].

The 6-month series of continuous homogeneous measurements provided unique measurements of time variations of the radio emission. Burst of auroral (non-Io) DAM emission were found to reoccur at a period slightly longer than the system III rotation period [Panchenko et al. 2013, 2010; Panchenko and Rucker 2011]. Gurnett et al. [2002] found from Cassini and Galileo observations that Jupiter's auroral radio and UV emissions were triggered by interplanetary shocks inducing magnetospheric compressions, in disagreement with theoretical predictions [Southwood and Kivelson 2001]. Hess et al. [2014] reconciled these views by a finer analysis of dawn and dusk radio emissions seen by Cassini, Galileo and Nançay, only dusk emissions being driven by both compressions and dilatations of the magnetosphere. They also used radio observations to deduce the subcorotation velocity of the magnetospheric plasma. Clarke et al. [2009] compared the effect of solar wind compressions on radio and UV aurora at Jupiter and Saturn, and found a weaker effect at Jupiter. Radio (non-Io-DAM, HOM and bKOM) and UV comparisons are used quite systematically in the study of Jupiter's aurora [Clarke et al. 2005, 2004; Pryor et al. 2005]. Comparison of Galileo/Jupiter and Cassini/Saturn observations also revealed similar energetic events where auroral radio intensifications are related to centrifugal plasma ejections, from the Io torus at Jupiter and from the equatorial plasma sheet at Saturn [Louarn et al. 2007].

Cassini, Galileo and Voyager radio observations were used to try to demonstrate the influence of satellites other than Io on DAM emissions. Marginal results were obtained statistically [Hospodarsky et al. 2001a], whereas clear evidence was obtained for Europa and Ganymede by comparison of observations with modelled dynamic spectra [Louis et al. 2017].

Fast recording modes of RPWS (spectral and waveform) allowed us to characterize the fine structure of Jovian radio emissions in the kilometer (bKOM) to decameter range [Kurth et al. 2001a; Lecacheux et al. 2001], including zebra-like patterns in the bKOM emission. Those were tentatively interpreted by bubble-like plasma inhomogeneities [Farrell et al. 2004] or the double plasma resonance mechanism involving ion cyclotron waves [Zlotnik et al. 2016]. Similar patterns have been observed at decameter wavelengths [Panchenko et al. 2018a, 2018b].

At the very low-frequency end of the radio spectrum (below a few 10 s of kHz), Cassini together with Ulysses and Galileo characterized the Jovian quasi-periodic bursts [Kaiser et al. 2004, 2001]. Stereoscopic observations demonstrated their strobe-like behavior and wide beaming [Hospodarsky et al. 2004], and direction-finding techniques localized their sources at high latitude regions of the magnetopause, implying complex propagation [Hospodarsky et al. 2004; Kimura et al. 2012]. Quasi-periodic (QP) bursts were tentatively related to the so-called Jovian anomalous continuum radiation [Ye et al. 2012]. Propagation of radio waves near the edges of the Io plasma torus were shown to generate the HOM attenuation lane, an intensity gap oscillating between ~1 and ~3 MHz, described by Boudjada et al. [2011] and modeled by Menietti et al. [2003] and Imai et al. [2015]. Occultations of Jovian radio emissions were used to probe the Io plasma torus [Boudjada et al. 2014].

Analysis of local low-frequency plasma waves recorded by RPWS was used to study the Jovian dust flank magnetopause and bow shock [Kurth et al. 2002; Szego et al. 2003], magnetosheath [Bebesi et al. 2011, 2010] and pre-shock [Szego et al. 2006]. The magnetopause was found to be in the process of being compressed by a solar wind pressure increase at the time of the Cassini flyby [Kurth et al. 2002]. Langmuir waves were detected upstream of the bow shock, and their level compared with that at other planets: the ratio of the energy density of the waves electric field to the plasma was found to increase with distance from the Sun [Hospodarsky et al. 2006].

Observations of Jupiter radio emissions were used to calibrate the Direction-Finding (actually Gonio-Polarimetric) capability of RPWS/Kronos [Vogl et al. 2004, 2001], which proved extremely successful at Saturn. Early use of this directional capability permitted to check the origin of lightning-like signals observed in Cassini's inbound leg to Saturn, which proved to be Jovian radio bursts [Fischer et al. 2006].

Overall, the radio observations made by the Cassini RPWS experiment were very successful at Jupiter. The obtained results were reported in several review papers about comparisons of radio waves [Zarka 2004, 2000; Zarka and Kurth 2005; de Pater and Kurth 2007; Rucker et al. 2014] and plasma waves [Hospodarsky et al. 2012] at the magnetized planets, as well as in reviews about auroras [Badman et al. 2015], magnetospheric processes [Blanc et al. 2002; Seki et al. 2015], or dust detection [Meyer-Vernet et al. 2017]. They greatly helped to prepare the magnetospheric measurements of the Juno mission in Jovian polar orbit [Bagenal et al. 2017].

Venus

Cassini made two very close gravity-assist flybys of Venus in route to Saturn. The first of the two flybys occurred on April 26, 1998, and the second occurred 14 months later on June 24. 1999. During the Venus flybys, the RPWS instrument conducted a search for high-frequency (0.125 to 16 MHz) radio impulses from Venus lightning. Despite the excellent sensitivity of the high-frequency RPWS receiver (down to the cosmic background), no impulses were detected [Gurnett et al. 2001]. During a subsequent close gravity-assist flyby of Earth on August 18, 1999, radio signals from lightning were observed essentially continuously at all radial distances inside of about 14 Earth radii, with maximum occurrence rates up to about 30 pulses per minute. These radio measurements made at Earth by Cassini are characteristic of terrestrial lightning and are commonly observed. The clear detection at Earth and the non-detection at Venus indicate that if lightning exists in the atmosphere of Venus, it is either extremely rare or is much weaker and at much lower frequencies than terrestrial lightning.

Earth

Cassini executed a flyby of Earth only 54 days after the second Venus encounter on August 18, 1999 in order to gain sufficient energy to continue its planned trajectory to Saturn. Although the principle purpose for the flyby was related to orbital mechanics, the flyby also offered an important opportunity for the Cassini MAPS instruments to operate in a well characterized magnetosphere. Operating the instruments in the Earth's magnetosphere allowed the MAPS teams to test planned operation modes and capabilities and to further characterize instrument performance in a planetary magnetosphere nearly five years prior to arrival at Saturn. Although the principle purpose of operating the MAPS instrument during the swift flyby of Earth was for calibration and other operational purposes, measurements made during flyby of Earth provided interesting scientific results [Burton et al. 2001; Kurth et al. 2001b; Lagg et al. 2001; Rymer et al. 2001; Southwood et al. 2001].

Figure MAPS-45, from Burton et al. [2001], shows the trajectory of the Cassini spacecraft during its encounter with Earth. The trajectory brings Cassini into the magnetosphere just past noon local time and carries it down the magnetotail in the post-midnight sector. Closest approach to Earth was just under 1200 km and was at a high rate of speed (~9 Earth radii per hour). The quick passage of the spacecraft through the magnetosphere provided a snapshot of the Earth's magnetosphere on a uniquely short timescale. In addition, Cassini's unique trajectory allowed near-continuous observations covering a range of distances down the magnetotail for the first time. Previous mission to the magnetotail (IMP 6, ISEE 1, ISEE 3, and Geotail), effectively made observations in the lobe at a single downtail distance due to their bound orbits. As Cassini flew by Earth, MAPS instruments were able to identify each of the typical magnetospheric boundaries and regions including the bow shock, magnetosheath, magnetopause, radiation belts, plasmasphere, plasma sheet, lobes, and crossings of the tail magnetopause [Burton et al. 2001; Kurth et al. 2001b; Lagg et al. 2001; Rymer et al. 2001; Southwood et al. 2001].

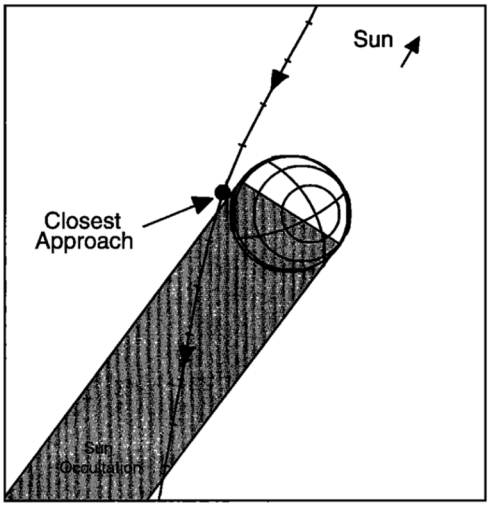

Figure MAPS-45. Trajectory of the Cassini spacecraft during it flyby of Earth on August 18, 1999. Reproduced from Burton et al. [2001] Figure 4.

During the Earth flyby the CAPS ELS sensor collected almost 9-hours of data in the Earth's magnetosphere and almost 10-hours of solar wind data upstream of the Earth. As noted above, CAPS, along with other MAPS instruments, sampled many plasma regions of the magnetosphere including electrons in the solar wind, bow shock, magnetosheath, magnetopause, radiation belts, plasmasphere, plasma sheet, lobes, and during crossings of the tail magnetopause. CAPS measurements were consistent with previous observations with a few exceptions and allowed the CAPS sensor to prepare for future operations at Saturn [Rymer et al. 2001]. In addition to anticipated results, CAPS found evidence of a low-energy field-aligned beam in the plasma sheet [Abel et al. 2001]. Bidirectional electrons were measured in the northern magnetotail lobe and were consistent with previous studies. However, measurements showed that was believed to be the first observations of a returning electron population in the magnetosheath. Bidirectional electrons were observed up to 0.02 keV, while at higher energies only unidirectional electrons were observed. The low energy of the returning electrons arises as a result of the electron populations' passage through the magnetopause twice and losses due to precipitation [Abel et al. 2001]. CAPS also found evidence of asymmetry on the dayside and nightside plasmapause position.

During the Earth flyby, the magnetometer performed important test and was able to make fairly original observations. One of the most important results of the Earth flyby for the magnetometer team was the testing of the helium magnetometer operating in the scalar mode and measuring the magnetic field magnitude with extremely high accuracy. Similar scalar mode measurements would be very important at Saturn for determining Saturn's intrinsic field, the near-Earth flyby provided a unique opportunity to test the magnetometer before arrival at Saturn [Smith et al. 2001]. In addition, the magnetometer observed what appeared to be interchange motions on the nightside outbound pass. Inbound, high resolution measurements of the whistler waves in the electron foreshock were reported [Southwood et al. 2001; Tsurutani et al. 2001].

Another important result of the Earth flyby was the large, international campaign of data gathering that was carried out on behalf of the magnetometer team by the Radio and Space Plasma Physics Group of the University of Leicester, United Kingdom [Khan et al. 2001]. Data obtained from various sources, together with the Cassini data, showed that during Cassini's outbound passage through the geomagnetic tail the magnetosphere underwent two complete classic substorm cycles and the data obtained by the fields and particles instruments on board Cassini confirmed that the flyby took place when the Earth's magnetosphere was generally in a disturbed state [Khan et al. 2001]. During the tail passage, RPWS observed a marked increase in the integrated auroral kilometric radiation power while at the same time CAPS and MIMI also saw evidence of these two substorm events in their data [Kurth et al. 2001b; Lagg et al. 2001; Rymer et al. 2001].

Finally, the RPWS instrument was able to make several different investigations to study Earth's magnetosphere and to test its capabilities in different modes. Figure MAPS-46 shows an overview of the RPWS observations during the Earth flyby. As one would expect, the RPWS observed broadband electrostatic waves at the bow shock, electron cyclotron harmonics and whistler mode chorus in the outer radiation belts and emissions between the plasma frequency and upper hybrid frequency in the ionosphere. Evidence for electron phase space holes was found in the near-Earth plasma sheet. At higher frequencies auroral kilometric radiation was observed on

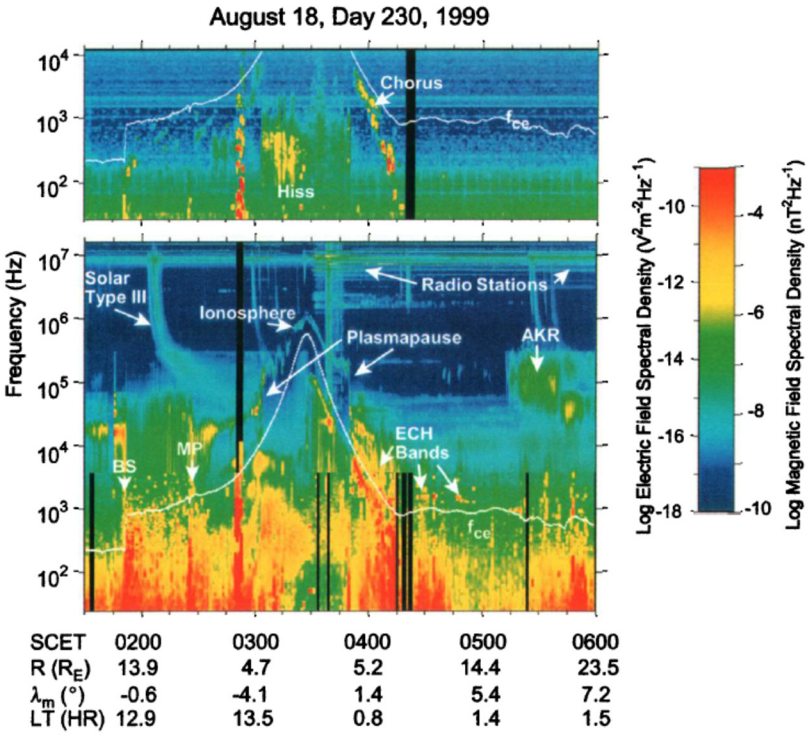

Figure MAPS-46. An overview of RPWS observations of the Earth flyby with magnetic fields shown in the top panel and electric fields below. The white trace is the electron cyclotron frequency f_{ce} derived from |B|. BS refers to the bow shock, MP refers to the magnetopause, ECH refers to electron cyclotron harmonics, and AKR refers to auroral kilometric radiation.

the night side indicating a series of auroral substorms and fixed frequency narrowband lines from man-made terrestrial radio stations were observed. Even Jovian hectometric radiation was observed from a position far downstream from Earth.

The RPWS instruments used a number of techniques to determine the plasma density from different wave excitations. The electron plasma frequency and upper hybrid resonance frequency are characteristic frequencies of the plasma dependent on the electron density. RPWS also includes a Langmuir probe that can determine the electron density and temperature. Finally, a relaxation sounder was used to stimulate the plasma frequency.

Another feature of the RPWS instrument that was tested during the Earth flyby was the capability of determining the wave normal angle of whistler mode waves using 5-channel waveform (WFR) measurements of three magnetic and two electric sensors. Hospodarsky et al. [2001b] used the WFR measurements to examine the propagation characteristics of a lightning whistler, chorus, and electromagnetic emissions in the magnetosheath, presumably lion roars.

Hospodarsky et al. [2001b] determined that the whistler analyzed was also detected at Palmer Station in Antarctica. The chorus waves were observed near the magnetic equator and appeared to reverse their direction of propagation at the equator, consistently propagating away from the equator where it is assumed the chorus source is located. The lion roars were found to consistently propagate nearly along the magnetic field but varied from burst to burst with some propagating near parallel and others near antiparallel to the field, suggesting multiple sources.

Cassini detected intense, fixed frequency emissions at close range to Earth in the frequency range above about 1 MHz that are attributed to man-made radio transmissions. Fischer and Rucker [2006] studied the occurrence of these in detail and demonstrated that most of the emissions could be identified with shortwave radio bands. A few brief detections of scientific transmitters include the High-frequency Active Auroral Research Program (HAARP) and the Russian SURA station, see also Tokarev et al. [2006]. Fischer and Rucker [2006] point out an interesting quiet period when Cassini was near closest approach over the Pacific Ocean where a combination of the rarity of transmitters in this location and ionospheric propagation characteristics effectively shielded Cassini from the radio transmission for a period of about 20 minutes.

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

amu	atomic mass unit
AO	Announcement of Opportunity
AU	astronomical unit
bKOM	broadband kilometer
CA	closest approach
CAPS	Cassini Plasma Spectrometer
CHEMS	Charge-Energy-Mass Spectrometer
CRAND	Cosmic Ray Albedo Neutron Decay
DAM	decametric
DOY	day of year
DSMC	Direct Simulation Monte Carlo
DWG	Discipline Working Group
ELS	electron spectrometer
ENA	energetic neutral atom
EUV	extreme ultraviolet
FUV	far ultraviolet
GCR	Galactic Cosmic Ray
GDF	Globally Distributed Flux
HAARP	High-frequency Active Auroral Research Program
HCN	hydrogen cyanide
HOM	hectometric
HST	Hubble Space Telescope
IBEX	Interstellar Boundary Explorer
IBS	Ion Beam Spectrometer
IDS	Interdisciplinary Scientist
IMF	interplanetary magnetic field
IMS	Ion Mass Spectrometer
INCA	Ion and Neutral Camera
INMS	Ion and Neutral Mass Spectrometer
ISMF	interstellar magnetic field frame
ISS	Imaging Science Subsystem
K-H	Kelvin-Helmholtz
LECP	Low Energy Charged Particle
LEMMS	Low Energy Magnetospheric Measurement System
LFE	low frequency extension
LISM	Local Interstellar Medium
LLBL	low-latitude boundary layer

LOS	line-of-sight
LP	Langmuir Probe
LT	local time
MAG	Magnetometer
MAPS	Magnetospheres and Plasma Science
MHD	magnetohydrodynamic
MIMI	Magnetospheric Imaging Instrument
NB	narrowband
NIST	National Institute of Standards and Technology
OSI	open source ion
PLS	plasma spectrometer
PPO	planetary period oscillation
PRA	Planetary Radio Astronomy
PUI	pick-up ions
QP	quasi-periodic
RCM	Rice Convection Model
RPC	ring plasma cavity
RPWS	Radio and Plasma Wave Science
RS	Saturn radii
SCET	spacecraft event time
SED	Saturn electrostatic discharges
SEP	solar energetic particle
SKR	Saturn's kilometric radiation
SOI	Saturn Orbit Insertion
TOF	time-of-flight
ULF	ultra-low frequency
UT	universal time
UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph
VIMS	Visual and Infrared Imaging Spectrometer
VLF	very low frequency
WFR	waveform

RINGS

Scientists had never before studied the particle size, temperature, composition and dynamics of Saturn's rings from Saturn orbit. Cassini discovered new rings, captured extraordinary ring-moon interactions, observed the lowest ring-temperature ever recorded at Saturn, discovered that the moon Enceladus is the source for Saturn's E-ring, and viewed the rings at equinox when sunlight strikes the rings edge-on, revealing never-before-seen ring features and details. Cassini data have swayed the lively debate over the age of the rings in favor of young rings.

The Ring Working Group (RWG) actively coordinated and enabled Cassini ring observations throughout the mission. Cassini has rewritten the textbooks regarding our understanding of Saturn's Rings, a full generation after Voyager first revealed their complex structure. Not only were all key science objectives successfully accomplished over the course of the Cassini mission, but a number of new science objectives were formulated and addressed along the way, either in response to unexpected results or capitalizing on observational opportunities. The Grand Finale orbits opened up new science opportunities not originally envisioned. There is no question that the science return of Cassini vastly exceeded the expectations as described in the original announcement of opportunity.

EXECUTIVE SUMMARY

… the rings are changing before our eyes dynamically and they are much younger than the solar system compositionally.

Cassini has rewritten the textbooks regarding our understanding of Saturn's Rings, a full generation after Voyager first revealed their complex structure. In fact, Cassini studies of Saturn's rings have already been thoroughly reviewed in two sets of review chapters and articles. In the first major review volume, Saturn after Cassini-Huygens, very thorough reviews are given by Colwell et al. [2009]; Charnoz et al. [2009]; Cuzzi et al. [2009]; Horanyi et al. [2009]; and Schmidt et al. [2009], which remain largely valid as of this writing even if they predate many important results. A short, nonspecialist review is given by Cuzzi et al. [2010]. More recent complete reviews can be found in the Cambridge Planetary Rings book, including Cassini's results prior to the Ring-Grazing and Grand Finale orbits [Charnoz et al. 2018; Cuzzi et al. 2018a; Estrada et al. 2018; Hedman et al. 2018a; Murray and French 2018; Nicholson et al. 2018; Spahn et al. 2018; Spilker et al. 2018]. Finally, Section 3.2 Instrument Science Results updates the story to the very end of the mission, including results from Cassini's last moments and chapters with exhaustive bibliographies. We attempt to cover the highlights of ring science from beginning to end of the mission as organized by our own goals and objectives, and in a readable way we provide a thread of continuity connecting Cassini's vast accomplishments to the big picture of ring origin and evolution. In summary, the rings are changing before our eyes dynamically and they are much younger than the solar system compositionally. Following is a list of our top 20 highlights.

Waves and Collective Dynamics

Spiral density and bending waves were discovered by Voyager. They are driven at orbital resonances with various satellites, blanket the A-ring, and are sprinkled throughout the B-ring and C-ring. Improved analysis tools have allowed even the weakest of these features to be studied in detail, and they provide powerful constraints on the underlying, local surface mass density on several-km spatial scales. About a dozen spiral density and bending waves in the C-ring have been shown to be caused by gravitational and pressure modes inside the planet, and most recently, even constrain the interior structure of Saturn and its rotation rate.

Ring microstructure on sub-km scales is seen everywhere by stellar and radio occultations, and varies on short timescales. Ubiquitous transient gravitational instabilities called self-gravity wakes arise and are torn apart by differential rotation. These wakes vary in configuration across the rings, and their properties imply a ring vertical thickness of tens of meters or less. An unrelated axisymmetric kind of microstructure, due more to viscous forces than self-gravity, can also be seen at various places in the denser parts of the rings. Images taken from close orbits, with sub-km resolution, show that fine-scale structure is widespread in optically thick regions (some of it granular and some axisymmetric or streaky). Dense clumps called straw, each the size of a convoy of aircraft

carriers, are seen in between the dense crests of strong spiral density waves, are probably compacted as particles pass through the crests, and are subsequently broken apart by collisions.

Embedded Moonlets

Analysis of Cassini images have now shown that skirted, embedded 10 km size moonlets are responsible for opening both the Encke and Keeler gaps in the A-ring (see the Icy Satellites chapter). In general, the small ringmoons lying within and near to the rings have very low densities and are likely rubble piles with dense cores. However, moonlets have not been found in similar gaps in the Cassini Division or C-ring with the ~1 km sizes previously thought necessary to clear them.

Flocks of smaller propeller objects of 100–200 m size, detectable only in their disturbance of nearby ring material, occupy three radial bands in the A-ring. A dozen or so of the largest of these objects, 0.1–1 km in size, wander in semi-major axis, perhaps because of gravitational scattering by the clumpy ring material they interact with. Discrete km-size objects have also been inferred from disturbances at the outer edges of the A-ring and B-ring and in the Huygens ringlet of the Cassini Division. One such object has been imaged in the B-ring. Some of these objects seem to disaggregate and perhaps reaggregate in place, on timescales of months or years, suggesting ongoing recycling of material driven by satellite forcing, self-gravity, and collisions.

Rings in 3-D

Cassini discovered dramatic vertical distortions of the rings, in addition to the well-known spiral bending waves, near Equinox when the sun's illumination was at a grazing angle. The edges of the Keeler gap are noticeably warped, consistent with the small inclination of its central ringmoon Daphnis, but those of the Encke gap are not. The outer edge of the B-ring showed alpen-like, spiky peaks and shadows. The outer edge of the A-ring showed a very clumpy structure, lacking distinct peaks, but with shadows suggesting vertical relief.

Ring Particle Properties

Voyager showed that the main ring particle size distributions tend towards powerlaws ranging between cm-m radii. Cassini has shown that the slope and the minimum and maximum sizes of these powerlaws vary across the rings. Enhanced collisions in spiral density waves create blizzards of small particles, which seem to affect the brightness and color of the surrounding region. As shown by comparison of occultations at ultraviolet (UV), near-infrared (IR), mid-IR, and radio wavelengths, and by the ring spectra and color, this effect is especially significant in the outermost A-ring, the region most strongly stirred by spiral density waves.

A combination of 10–400 μm thermal emission and scattering, and 2.2 cm radiometry, suggests that ring particles probably have a low density mantle (i.e., are porous aggregates), but

might also have more dense cores. The rings' thermal emission suggests a regolith of nearly pure water ice grains of 10–100 μm size. Cassini 2.2 cm radiometry detects a fraction of a percent of non-icy material through the A-ring and B-ring, greatly improving on pre-Cassini microwave observations which could constrain the total non-icy material only to less than a few percent relative abundance. However, when combined with spiral density wave surface densities/opacities, 2.2 cm radiometry has also revealed what looks like a buried silicate-rich rubble belt in the mid C-ring; possibly the remains of the core of the ring parent.

Visual and Infrared Imaging Spectrometer (VIMS) spectra show that A-ring and B-ring composition is nearly pure water ice without any other identifiable ices such as CO, CO_2, NH_3, or CH_4, but there is a strong UV absorption making the rings unusually reddish, that varies in strength from place to place. The red color of the rings is strongest where the water ice absorption bands are deepest, suggesting that the red material resides within the icy regolith grains, and increases radially inwards at a steady rate. A third, more neutral non-icy material has a completely different radial distribution. The very low mass fraction of non-icy material (except perhaps in the C-ring rubble belt) provides our strongest constraint on the age and origin of the Rings, as discussed below. The rings' red color in the UV-visible region may be explained by fragments of carbon-bearing tholins (perhaps similar to material blanketing the surface of comet C-G as observed by Rosetta), or (some argue) by tiny iron-rich particles, embedded in the dominant water ice. Recent Cassini in situ results and remote sensing analyses, and Hubble Space Telescope (HST)-Space Telescope Imaging Spectrograph (STIS) observations, favor the organics.

New in situ data from Cosmic Dust Analyzer (CDA) and Ion and Neutral Mass Spectrometer (INMS) on the Ring-Grazing (RG) and Grand Finale (GF) orbits have greatly enriched the ring composition story. Abundant, Fe-poor silicates and organic molecules are associated with the innermost D-ring and perhaps C-ring. Evidence for organics is also found outside the rings by INMS. Reconciliation of these in situ results with remote sensing is only beginning.

Ring Variability with Time

The outer edges of the dense A-ring and B-ring vary in complex ways with both longitude and time, indicating the interference of multiple free or normal modes; possibly the result of large-scale non-axisymmetric viscous overstabilities, with the expected satellite-driven forced modes. The outer 100 km of the B-ring shows complex, fine-scale brightness variations possibly caused by these deformations. Gravitational effects of the modes might even play a role in sculpting the narrower gaps in the Cassini Division; so far found to be free of small moonlets.

Channels open and close in Saturn's F-ring strands, in response to close approaches by Prometheus, and these effects vary as the orbits of Prometheus and the F-ring mutually precess, leading to stronger and weaker gravitational interactions. Kinks and mini-jets come and go in the F-ring core, excited by small unseen objects at low relative velocities, and more dramatic jets of material lasting months are triggered by objects eccentric enough to crash through the ring at high relative velocities. These violent collisions continue because the entire F-ring region is dynamically

chaotic, mostly because of Prometheus, and for this reason the long-term stability of the F-ring core has been problematic. The F-ring has a narrow true core of large particles, as characterized best by Radio Science Subsystem (RSS), confined into discontinuous arcs and stabilized by a corotational resonance due only to Prometheus. The fine dust seen in images and stellar occultations is a tiny fraction of the F-ring total mass. Clump activity has varied dramatically between Voyager and Cassini.

Vertical ripples or warps covering the inner part of the rings, which have changed even over the duration of the mission, suggest that Saturn's D-ring and inner C-ring were tipped relative to its equator several times over the last millennium, and as recently as a few decades ago. Impacts by rubble streams produced by disrupted objects are the most likely cause. Several impacts by individual m-size projectiles have actually been seen and catalogued.

Diffuse Rings Dominated by Tiny Dust Grains are Affected by Sunlight and Magnetic Fields

The source of the E-ring particles has been confirmed as the south polar jets of Enceladus (see the Icy Satellites chapter). Several new arcs and ringlets are associated with erosion of small embedded moons. The E-ring and other diffuse rings and ringlets (such as those in the Encke gap) are affected by sunlight and electromagnetic forces as well as by gravity, and thus show seasonal variations in their structure. Some diffuse rings, notably the D-ring and the faint material between the A-ring and F-ring, are modulated by azimuthal variations in Saturn's magnetic field.

The duration and behavior of the spokes Voyager discovered in the B-ring have been further constrained, though their ultimate cause or trigger remains unknown. Cassini found that they seasonally appear and disappear, probably due to variable photo-charging of the main ring layer, and their temporal periodicities match best that of the northern hemisphere Saturn Kilometric Radiation (SKR) during the 2008–2009 timeframe, though contributions from the southern SKR source could not be ruled out. Any association with the Saturn Electrostatic Discharges (SEDs) was ruled out.

Ring Mass

Voyager-era estimates of the ring mass were roughly 0.7–0.8 Mimas masses. It was since suggested that the breakdown of the ring layer into opaque clumps (the self-gravity wakes), separated by nearly empty gaps, could allow a lot of mass to be hidden in the clumps. Modeling of dozens of spiral density and bending waves over Cassini’s first decade had constrained the mass of the A-ring, C-ring, and inner B-ring, so any hidden mass had to reside in the densest parts of the B-ring. In the Grand Finale orbits, the Cassini RSS team tracked the spacecraft to constrain the ring mass by its perturbation on Cassini's orbit, and concluded that the ring mass is not very different from, and likely lower than, our Voyager-era expectations.

Origin and Age of the Rings

The strongest constraint on ring age is provided by the gradual darkening and restructuring of the rings with time by infalling meteoroids. Inferring the actual ring age requires knowledge of the current mass fraction in non-icy pollutant, as well as both the incoming meteoroid mass flux and the total mass of the rings. The Cassini CDA experiment has determined, cumulatively over the entire mission, the infalling meteoroid mass flux and dynamical population. The mass flux far from the planet is not too different from pre-Cassini estimates. However, the dynamical population is like that of Kuiper Belt objects, so has a lower encounter velocity and is more strongly focused by Saturn's gravity than thought previously. This means that the flux of meteoritic material actually hitting the rings is probably even larger than previously thought. Combining the ring mass with the CDA-determined meteoroid mass flux, and estimates of non-icy pollution currently in the rings, leads to a ring exposure age of 100–200 million years, perhaps even a little younger than Voyager-era young-ring scenarios.

Combining the ring mass with the CDA-determined meteoroid mass flux, and estimates of non-icy pollution currently in the rings, leads to a ring exposure age of 100–200 million years … .

The associated puzzles of “Why is Saturn the only giant planet with rings?” and “Is the ring system young?” have been, if not yet explained, at least illuminated by an emerging hypothesis involving a closely-coupled tidal evolution of the mid-sized icy moons leading to a Saturn-specific dynamical instability of the inner satellite system, with possible disruptions and reaccretion, on the order of 100 million years ago. Constraints from satellite surface geology will need to be folded in to evaluate the plausibility of the scenario.

Overall Assessment of Ring and Dust Science

All key science objectives listed in the Announcement of Opportunity (AO) and Solstice Traceability Matrix (TM) were successfully accomplished over the course of the Cassini mission. In addition, a number of new science objectives were formulated and addressed along the way either in response to unexpected results or capitalizing on observational opportunities (some not originally envisioned, and some in greater numbers than envisioned). When the mission was approved, the AO Objectives reflected a 4-year baseline tour with only 59 orbits, allowing at most 16 Radio occultations, and of course did not incorporate the RG or GF observing geometries.

By the end of the mission, even the four-year baseline tour had been optimized to include 74 (generally shorter) orbits, wasting less time far from the planet, and had also been extended by nine years, tripling the total time baseline for observations relative to the AO. The final tour lasted 13 years, sampling three different seasons and reaching northern summer solstice (the maximum opening angle of the rings as seen from Earth and the Sun) which allowed the radio occultations to better penetrate the optically thickest parts of the B-ring. The mission included 282 orbits capturing

many new combinations of illumination and viewing angles important for imaging—VIMS and Ultraviolet Imaging Spectrograph (UVIS) spectral reflectance mapping, and Composite Infrared Spectrometer (CIRS) thermal mapping. Datasets returned included 135 ring radio occultations (each at 3 wavelengths), 170,000 ring images (many at < 1 km/pxl), over 200 UV stellar occultations, 170 near-IR stellar occultations, 30 solar occultations, and even a few occultations at thermal, mid-IR wavelengths.

The stellar occultations made use of dozens of stars with different elevation angle relative to the rings; low-optical depth rings are best studied by low-elevation stars, and high optical depth rings by high-elevation stars. In addition, several complete 2.2 cm microwave emission maps or radial scan combinations were obtained in different geometries and resolutions, and three active radar backscattering scans were obtained in the RG and GF orbits when the spacecraft was close enough to overcome the fourth-power dependence of radar sensitivity on distance. Moreover, the RG and GF orbits provided in situ ring particle composition sampling opportunities for CDA, INMS, and Magnetospheric Imaging Instrument (MIMI) that were not part of the AO plan, and enabled direct determination of the ring mass from spacecraft tracking of the RSS signal. VIMS stellar occultations were not even envisioned in the AO, but were added after selection of the instruments. This new stellar occultation capability provided a very useful wavelength difference compared to UVIS, and an entirely different angular distribution of sources on the sky. Using the Radar as a passive pencil-beam microwave ring brightness mapper, or to obtain active radar backscattering radial profiles from the rings were also not part of the original plan.

The overall science data volume return of Cassini was more than 100 times that of Voyager in the instruments they both carried (not to mention the roughly 200 times longer time baseline at interesting resolution) and the numerous unique new remote and in situ observations provided by Cassini. There is no question that the science return of Cassini vastly exceeded the expectations as described in the AO.

Summary of Key Open Questions

Overall, Cassini has answered many of the questions raised by Voyager, raised new ones, and leaves us with a largely untapped reservoir of data with which to answer. These questions and others are discussed in more detail in the section entitled Unsolved Problems Suitable for Ongoing Research and Future Missions.

The overall ring mass is known now, but with low precision and no radial resolution. Is the B-ring mass uniformly distributed according to optical depth, or is it even more strongly concentrated in the still nearly opaque central regions? Does the C-ring contain a rocky rubble belt? Future missions with tracking capability and multiple close passes will be needed, and should be planned to also provide a better understanding of why Saturn's own interior is so different from Jupiter's.

Most ring structure is still a puzzle. The irregular structure blanketing the entire B-ring, with lengthscales narrowly concentrated near 80 km in the inner B-ring, but covering a wider range of scales from the resolution limit to several hundred km in the mid-and outer B-ring, remains a mystery. In the inner-mid B-ring there are very sharp optical-depth jumps (but not to empty space) that are barely explored and remain unexplained.

The entire ensemble of so-called plateaus in the outer C-ring, symmetrically placed around the Maxwell gap in the C-ring, which is known to be caused by structure in Saturn's interior, and incorporating other empty gaps is not understood. The plateaus also contain a unique kind of streaky microstructure not seen elsewhere, which was only seen in a limited way during the final orbits.

There are several significant features (A-ring inner edge, C-ring plateaus), which have sharp well-defined boundaries, that are defined only by changes in the particle size distribution across which the surface mass density does not change. This structural control of particle size distribution, or vice versa, is not understood.

The mere presence of the Cassini Division is an unsolved problem, although it is plausible that a strong density wave driven by the 2:1 resonance with Mimas had a role in creating it when the rings were more massive and material filled the region. The apparent lack of moonlets capable of clearing the 13 gaps in the Cassini Division and C-ring, especially the 5–6 that have no embedded ringlets[1], is a puzzle. A clue may be found in the apparently non-random spacings of the edges of the Cassini Division bands and gaps, perhaps somehow manifesting gravitational influence of the B-ring outer edge.

The unusually red color of the A-ring and B-ring, which are surely more than 95% water ice and probably more than 99%, seems to be due to organic material based on a combination of remote and in situ measurements. However, composition varies from place to place and on a range of scales. Models capable of interpreting color and spectral data quantitatively in terms of underlying composition are inadequate and need improvement. The hint of a rubble belt of non-icy material buried in the mid-C-ring is intriguing, but remote observations are ambiguous and the analysis of in situ observations is only getting underway. Whether or not organics explain the similarity, but relatively weak, UV absorption seen in most icy moons is not yet known—the dark side of Iapetus has been fit by carbon, nano-iron, and metal oxides. Why is the G-ring parent body, so close to the icy main rings, so dark?

Are the A-ring (and B-ring) propeller objects the shards left over from the ring parent? Why do the dozen or so giant propellers found only outside of the Encke gap wander in semi-major axis, and what (if any) patterns are present in the evolution? Are there cyclic, self-limiting processes of growth and disruption of sub-km sized objects in the outer A-ring (and B-ring)? The F-ring core is stabilized by Prometheus, but what causes its uniformly precessing eccentricity? Do relatively large

[1] Cassini Division gaps with ringlets: Huygens, Herschel, Laplace; and without ringlets: Russell, Jeffreys, Kuiper, Bessel, Barnard. C-ring gaps with ringlets: G1, Colombo, Maxwell, Bond; and without ringlets: Dawes.

objects form in regions compressed by Prometheus and go on to crash through the core, creating clumps and strands?

The rings seem to be much younger than the solar system based on nominal results to date, and there is one encouraging hypothesis (a 200-million year ago system-wide instability) providing the proper context. However, questions remain including consistency (or lack of it) of the observed icy moon cratering distributions with reaccretion of most of the inner icy moons on that same timescale.

Key Objectives of the Rings Working Group

The original ring objectives from the AO, and those added for the extended Cassini Solstice Mission, are given in Table RINGS-1. We assess Cassini as fully successful, at least in all regards. It is emphasized that in almost all cases there has been far more data obtained, reduced, and archived than the teams have had time to analyze and interpret.

Rings AO Objectives

- **Ring Structure and Dynamics (R_AO1)** – Study configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.
- **Ring Particle Composition and Size (R_AO2)** – Map composition and size distribution of ring material.
- **Ring-Satellite Interaction (R_AO3)** – Investigate interrelation of rings and satellites, including embedded satellites.
- **Dust and Meteoroid Distribution (R_AO4)** – Determine dust and meteoroid distribution both in the vicinity of the rings and in interplanetary space.
- **Ring Magnetosphere-Ionosphere Interactions (R_AO5)** – Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.

Rings CSM Traceability Matrix Objectives

- **Changing Rings (RC1a)** – Determine the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near Solstice.
- **Ring Temporal Variability (RC1b)** – Determine the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations.

- **F-ring (RC2a)** – Focus on F-ring structure, and distribution of associated moonlets or clumps, as sparse observations show clumps, arcs, and possibly transient objects appearing and disappearing.
- **Ring Age and Origin (RN1a)** – Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejecta trapped on field lines.
- **Ringmoons – Composition (RN1b)** – Determine the composition of the close-in ringmoons as targets of opportunity.
- **Ring Structure – High Resolution and Composition (RN1c)** – Determine structural and compositional variations at high resolution across selected ring features of greatest interest, using remote and in situ observations.
- **Ring Microstructure (RN2a)** – Conduct in-depth studies of ring microstructure such as self-gravity wakes, which permeate the rings.
- **New Ring Structures (RN2b)** – Perform focused studies of the evolution of newly discovered propeller objects.

Table RINGS-1. RWG Science Assessment.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

RWG Science Objectives	AO and TM Science Objectives	RWG Science Assessment	Comments (if yellow, partially fulfilled)
Ring Structure and Dynamics	R_AO1		
Ring Particle Composition and Size	R_AO2		
Ring-Satellite Interactions	R_AO3		
Dust and Meteoroid Distribution	R_AO4		
Ring-Magnetosphere-Ionosphere Interactions	R_AO5		
Changing Rings	RC1a		
Ring Temporal Variability	RC1b		
F-ring	RC2a		
Ring Age and Origin	RN1a		
Ring Composition - ringmoons	RN1b		
Ring Structure - high resolution and composition	RN1c		
Ring Microstructure	RN2a		
New Ring Structures	RN2b		

These objectives are discussed below in more detail.

RWG SCIENCE RESULTS

Prime Mission (AO) Original Objectives (Highest, Top-level Results)

Ring structure and dynamics (R_AO1)

Studies configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.

This objective, perhaps the broadest and deepest, was satisfied beyond our initial expectations. Stellar and radio occultations are the most powerful tool for exploring structure at high resolution. During initial planning sessions, the UVIS team was considering dozens of stellar occultations as an optimistic goal, and ended up with over 200, including the novel turnaround occultations in which the line of sight to the star moves parallel to the particle orbits, at very low velocity, allowing azimuthal structure to be determined with high resolution at perhaps a dozen radii and structure on the scale of a ring thickness to be addressed statistically. Moreover, VIMS developed a stellar occultation capability of their own that was not part of the original plan, and went on to produce almost 200 occultations of their own in geometries that were independent of and complementary to those available to UVIS, because they observed a different set of stars. All these stellar occultations reside on the Rings Planetary Data System (PDS) node in 1 and 10 km resolution format. In addition, RSS conducted 135 occultations at three radio wavelengths (0.94, 3.6, and 13 cm), which all reside on the Rings PDS node in 1 and 10 km resolution format, and for which further processing (by diffraction correction) can generally provide 100 m or even better radial resolution. More analysis of these data will provide additional surprises and constraints. Review chapters by Colwell et al. [2009] and Cuzzi et al. [2018] cover the major advances regarding observed ring structure, Schmidt et al. [2009] review advances in the theory of dense ring structure, and Horanyi et al. [2009] review advances in the theory of electromagnetic influences (most significant on tiny dust grains).

CONFIGURATION OF THE RINGS

The Grand Structure of the rings (Figure RINGS-1) was elucidated for the first time by Voyager, reviewed by Orton et al. [2009] and Colwell et al. [2009]. In this section we will discuss the so-called main rings (A-ring, B-ring, and C-ring) and the Cassini Division, all of which have optical depth > ~0.1 (Figure RINGS-1). The A-ring is the best understood by Voyager-era theory; blanketed by spiral density and bending waves from nearby moons, with embedded moonlets that carve empty gaps by the process of gravitational shepherding, and a ubiquitous non-axisymmetric microstructure having scales comparable to the ring thickness due to local gravitational instabilities. All of these structural properties have been closely observed by Cassini, in greater numbers, with greater radial coverage, in more geometries, in finer detail, and at better sensitivity than ever before. The B-ring and C-ring contain a few of these well-understood features too, but are overwhelmingly dominated by structure on all scales that is simply not understood at present (see

section entitled Electromagnetic and Radiative Processes). The so-called diffuse rings (D-ring, E-ring, and G-ring) and dusty rings associated with various moonlets, have optical depths much less than unity and are a separate class of structure discussed in sections entitled Dust and Meteoroid Distribution, and Ring Magnetosphere-Ionosphere Interactions. The narrow, kinky F-ring lying just outside the A-ring has captured a niche of its own and is discussed mostly in the section entitled F-ring.

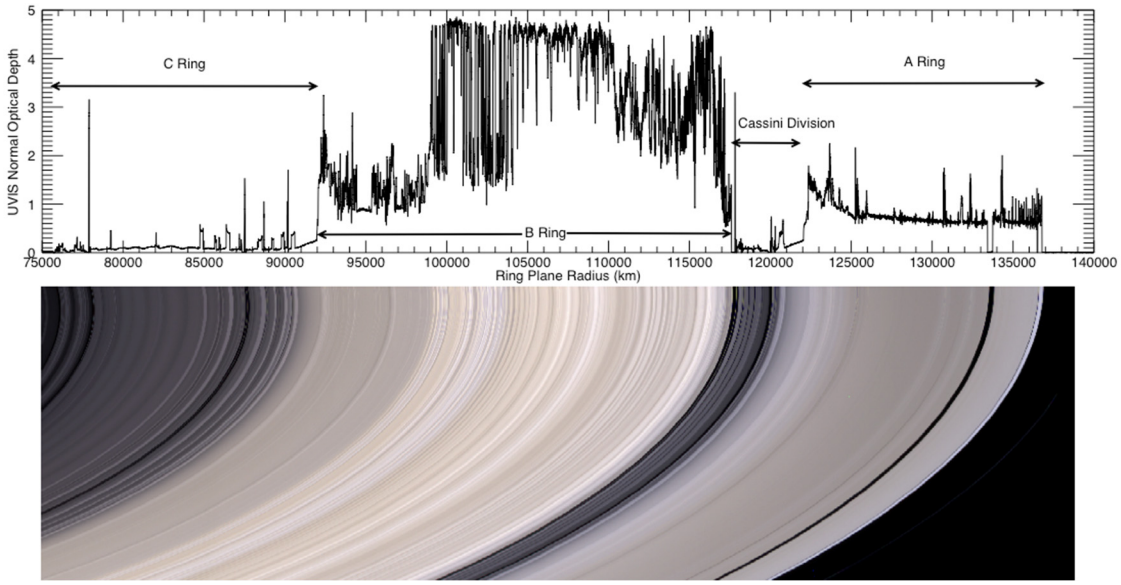

Figure RINGS-1: Main rings of Saturn. The image is registered along its top edge with a radial profile of the ring optical depth from a Cassini UVIS stellar occultation. The optical depth (usually denoted τ) is the vertical integral through the ring layer of the particle number density times its cross-sectional area, times extinction efficiency (for the plot above, the efficiency is unity). The B-ring (especially its central part) has the highest optical depth, but the highest values shown are just noise limits. Unlabeled regions mentioned in the following text include the series of plateaus in the outer C-ring, centered on the Maxwell gap near 87500 km, which contains an elliptical ringlet. The Encke gap is visible in the outer A-ring, around 133600 km. The narrow, stranded F-ring is just off the figure at right. Figure from Colwell et al. [2009].

The local ring thickness was a perennial topic of discussion before Voyager and measurements of kilometers were reported (now known to be better explained by vertical corrugations and/or the inclined F-ring). The single Voyager stellar and Radio occultations showed that ring edges were so sharp that the local thickness (at least at edges) could be no more than tens of meters. Cassini's hundreds of stellar and radio occultations have extended this knowledge to nearly all locations except the opaque central B-ring [Colwell et al. 2006, 2009; Hedman et al. 2007b]; see also Tiscareno et al. [2007]. This small vertical thickness means that the rings are not the many particle thick classical layer envisioned even in the Voyager era, and have a moderate volume density of 0.01–0.1 [Salo and French 2010] or even larger. There are implications of high volume density for ring viscosity (see section entitled Viscous Processes). Another indication of volume density (and thus local dynamics) comes from mutual shadowing. Visual brightness observations have long shown a sharp opposition peak that was traditionally interpreted in terms

of shadowing in a many-particle-thick layer; however, dynamical constraints and the increased recognition of the importance of coherent backscattering in grainy particle regoliths (see Cuzzi et al. [2009] for a review) complicate this interpretation [Salo and French 2010]. CIRS observations show a much broader phase effect in particle temperatures; however, that is plausibly shadowing-related (unlikely to be contaminated by coherent backscattering) and consistent with non-classical rings [Altobelli et al. 2007, 2009; Reffet et al. 2015; Morishima et al. 2017; Deau et al. 2019]. These thermal studies lead to midplane particle volume densities as large as 0.3–0.4 in the B-ring. Finally, analysis of 2.2 cm radiometry is best fit by modeling closely packed cm-m size particles in the near-field scattering regime [Zhang et al. 2017b, 2019].

There has been a start taken on modeling of imaging observations of the rings over a wide range of geometries, with an emphasis on unraveling opposition effects of different kinds using classical radiative transfer models [Deau et al. 2013, 2018; Deau 2015]. However, interpreting UV, visual, and near-IR observations using realistic models of closely packed particles with rough shadowed surfaces, which might provide more insight into radial variations of local particle volume density and thus local dynamics, remains in its infancy (see Porco et al. [2008] for the only example).

Gravitational processes (self-gravity wakes, spiral waves, and shepherding torques)

Probably the longest-known and most widespread gravitational process leads to the self-gravity wakes, caused by local, transient, incipient gravitational instabilities which are stretched into trailing clumps of scale comparable to the ring thickness (indeed defining the ring thickness) by Keplerian shear, keeping the ring in a constant state of frustrated satellite formation [Orton et al. 2009; Schmidt et al. 2009; Colwell et al. 2009]. Imaging observations have characterized the effect in the A-ring, using the azimuthal brightness asymmetry known for decades, but finding the particle collisional elasticity to be smaller than thought; indicating either a rough surface or a porous regolith [Porco et al. 2008]. The effect has also been observed and modeled in the thermal IR [Leyrat et al. 2008; Ferrari et al. 2009; Morishima et al. 2014]—see also section entitled Extended Mission (CSM) Objectives, Section 3.2 Instrument Science Results chapter entitled CIRS, and Spilker et al. [2018]. A CAT-scan technique of characterizing the horizontal and vertical scales of these structures as well as their angle relative to the orbit direction was developed based on stellar occultations from a variety of slant directions. These models of the dense gravitational wakes as optically thick granola bars or elliptical cylinders [Colwell et al. 2006, 2007; Hedman et al. 2007a; Nicholson and Hedman 2010] (see also Colwell et al. [2009] for a review) provide valuable mean values of the orientation, width, height, and separation of dense clumps for use in models of ring brightness. The pitch angle of the wakes, relative to the orbit direction, decreases radially inwards as differential rotation becomes stronger.

Perhaps the most obvious, beautiful, and useful gravitational ring structures are spiral density and bending waves at isolated satellite resonances. These striking features share the physics of the arms of spiral galaxies, but are tightly wrapped like watchsprings [Shu 1984; Schmidt et al.

2009]. They propagate away from their driving resonance with a decreasing wavelength—density waves move outwards and bending waves inwards. The wavelength itself is diagnostic of the underlying surface mass density on scales smaller than a wavelength. Thus, spiral density wave measurements provide our best idea of the radial profile of mass density, in regions where they are found. This property is extremely important, because the almost ubiquitous clumping due to self-gravity wakes breaks the rings into a set of opaque regions separated by nearly empty gaps, for which the optical depth (see Figure RINGS-1) is of questionable basic value.

For this reason, Robbins et al. [2010] suggested that inferences of ring surface mass density from a combination of observed optical depth and particle size distribution might greatly underestimate the ring mass. This reasoning led to a debate as to whether the ring mass could be much larger than Voyager-era estimates, because most of the B-ring (which contains most of the mass) is unsampled by diagnostic density and bending waves, with implications for ring age (see section entitled Ring Age and Origin). The debate tilted in favor of low mass when Hedman and Nicholson [2016] succeeded in obtaining some B-ring density wave measurements despite the noisy background, and has now been definitively resolved in that direction by the RSS total mass measurements based on gravitational tracking (see section entitled Determination of Ring Mass). The RSS gravity measurements have little or no radial resolution, but used A-ring and C-ring masses as determined from these waves [Colwell et al. 2009; Tiscareno et al. 2013] and assumed the remainder of the measured mass to be that of the B-ring. They do suggest, though, that the surface mass densities obtained from spiral density waves are insensitive to the suggested clumping difficulty.

One important surprise from measuring surface mass density is that several important structural features, long seen in images and occultations, actually manifest as distinct structures not because they have higher local mass density as was usually assumed, but because their local particle size distribution changes in a dramatic way making them more opaque than their surroundings without much change in their underlying surface mass density. This happens because the surface-to-mass ratio of a particle, or of a distribution of particles, increases as particle size decreases. The effect is seen at the inner edge of the A-ring and all of the C-ring plateaus—sharp optical depth jumps are seen where there is at most a gradual change in surface mass density [Tiscareno et al. 2007, 2013a; Tiscareno and Harris 2018]. Baillié et al. [2011] and Hedman and Nicholson [2014] show surface mass densities for the plateaus and background C-ring, and Colwell et al. [2018] show drops in effective particle size in the plateaus, consistent with a small change in surface mass density despite a large increase in optical depth. This important phenomenon of locally abrupt changes in the particle size distribution is not currently understood, but is clearly of central importance to understanding the formation of these structures.

Another important clue from density and bending waves is obtained from sparse sampling of the C-ring, showing that the surface mass density radial profile differs from the optical depth profile in a fashion most easily explained if the local particles (whose sizes are well known from RSS occultations) are several times more dense in the central C-ring than elsewhere in it; possibly hinting at buried rocks in unusually high abundance and perhaps to a hidden rocky rubble belt [Zhang et al. 2017a], see also section entitled Ring Particle Composition and Size. Sampling of the

B-ring is even sparser, but generally points to surface mass densities somewhat lower than previously thought [Hedman and Nicholson 2016; Tiscareno and Harris 2018].

An interdisciplinary bonus was the confirmation of the prediction by Marley et al. [1987, 1989]; Marley [1990]; and Marley and Porco [1993] that density fluctuations in Saturn's interior produced by planetary scale acoustic oscillations (modes) can drive spiral density and bending waves similar to those driven by an external satellite. A number of unidentified waves had been noted by Rosen et al. [1991] in Voyager RSS occultation data. Marley and Porco [1993] suggested several specific associations between predicted resonance locations and these Rosen waves. They also suggested that the strongest predicted (two-lobed, or m = 2) planetary interior resonance might be associated with the unexplained Maxwell gap, where there was an unexplained eccentric (m = 1) ringlet.

Cassini, along with subsequent improvements in the Saturn interior model, have confirmed the Marley and Porco [1993] predictions, putting the study of ring seismology on firm ground and finding in the process other features likely due to variations in internal structure not accounted for in the simple 1993 interior model. The great advantage of Cassini data is multiplicity and accuracy of occultation measurements, allowing both the number of spiral arms and the pattern speed of the waves to be determined unambiguously, and thus finer associations to be made with theoretical predictions [Hedman and Nicholson 2013, 2014; Marley 2014; French et al. 2019; Mankovich et al. 2019; Hedman et al. 2019]. Initially, some Rosen waves, and newly discovered ones [Baillié et al. 2011] were found to have the same value of m, something not predicted by Marley and Porco [1993]. However, Fuller et al. [2016] showed that allowing a compositionally-stratified layer deep inside Saturn could explain these multiplicities because such a gradual density transition would allow different types of modes to mix inside the planet. Next, a two-armed spiral density wave was discovered within the (m = 1) Maxwell gap ringlet [French et al. 2016b] validating the association of the gap with the strongest (m = 2) mode as predicted by Marley and Porco [1993]. Finally, Mankovich et al. [2019] have recently shown that slightly changing the interior rotation period of Saturn allows the detailed predictions of Marley and Porco [1993] to be very well matched across 16 sets of waves over a wide range of relative strengths, with the strongest perturbation opening the Maxwell gap. In fact, this excellent agreement provides the best constraint yet on the deep interior rotation period of Saturn—a fundamental property that has been elusive because of the almost complete lack of magnetic field azimuthal asymmetry [Dougherty et al. 2018] (see also Section 3.1 Discipline Science Results chapter entitled MAPS). In addition, a new class of density waves has been found in the B-ring and A-ring; waves that are driven by density structures of unknown origin, fixed to the body of Saturn [El Moutamid et al. 2016a, 2016b]. Surprisingly, some of these wave features are actually seen to drift radially inwards in the rings, indicating temporal changes in Saturn's interior structure on a decade timescale [Hedman et al. 2017, 2018b; Hedman and Nicholson 2014]. Therefore, ring properties and physics have led to three new important insights into the deep interior of Saturn. See section entitled Ring-Satellite Interaction for more

… a new class of density waves has been found in the B-ring and A-ring—waves that are driven by density structures of unknown origin, fixed to the body of Saturn .

discussion of interactions between satellites and moonlets with the rings, which are mostly gravitational.

VISCOUS PROCESSES

Because of their innumerable particles in a constant state of gentle collisions, the rings act like a gas or fluid and obey the equations of fluid dynamics with local pressure and viscosity. They spread radially due to viscosity, an important aspect of their evolution that combines with other angular momentum and mass transport processes like shepherding, wave torques, and ballistic transport of meteoroid ejecta. The theory of spiral density waves is mature enough that the rate at which their amplitude damps as they propagate can be used to constrain the local ring viscosity [Schmidt et al. 2009, 2016; Colwell et al. 2009].

A second kind of so-called ring microstructure, called a viscous overstability, occurs on scales of the ring vertical thickness and is partly driven by viscosity [Schmidt et al. 2009]. In this effect, a stable (non-growing) radial oscillation can develop that comprises axisymmetric, alternating ringlets of high and low density that pulsate on the orbital timescale. These structures are aligned with the orbital direction and were first distinguished by subtle Doppler effects in off-axis scattering during Cassini RSS occultations [Thomson et al. 2007], but have also been detected using statistical analysis of stellar occultations [Colwell et al. 2009; Hedman et al. 2014a]. They are widespread across the rings and generally found with the expected lengthscales (comparable to a ring thickness) in regions where the optical depth is moderate to high. Self-gravity plays only a small role in these structures.

Viscous overstabilities can take on non-axisymmetric forms as well. For example, in a densely packed ring, collective behaviors akin to those seen in granular flow can occur and viscous stress can actually decrease the damping between adjacent orbital motions effectively by locking particles and their orbits together. Where there is also the opportunity for double reflection of spiral density waves, as within a narrow isolated ring bounded by sharp edges, or a so-called resonant cavity, they can become amplified [Borderies et al. 1985; Hedman and Nicholson 2019] generating low-order (m = 1, 2, 3, etc.) modes. The m = 1 and m = 2 structure of the narrow sharp-edged rings of Saturn and Uranus may be explained in this way. For instance, the Maxwell ringlet exhibits an m = 2 spiral density wave forced by an m = 2 acoustic mode within Saturn (see section entitled Gravitational Process), but attains an m = 1 overall structure. However, Cassini discovered large-scale, unforced, or free modes with m = 1, 2 and 3 in the outer portion of the B-ring, in addition to the resonant m = 2 mode forced by Mimas at the B-ring's edge [Spitale and Porco 2010], see also section entitled Ring Temporal Variability). The large-amplitude m = 1 mode, in particular, would damp quickly without both the overstabilizing viscous effects described above and the amplification accompanying multiple reflections within the resonant cavity formed by the B-ring outer edge and the mode's own resonant radius some 250 km inwards. The discovery of these unforced modes is the first indication of substantial wave amplification on large scales, in broad rings. These modes may have applications to other celestial disks, such as protoplanetary nebulae [Laughlin et al. 1997] and spiral galaxies.

Viscosity and pressure due to ring particle collisions determines the ability of ring particles to move from one face of the rings (lit face) to the other (unlit) face, and models have been applied to CIRS thermal observations to address this constraint [Flandes et al. 2010; Pilorz et al. 2015; Morishima et al. 2016]. Another manifestation of particle collisions would be to pack surface regoliths to varying degrees, depending on local dynamics. CIRS tried to measure radial variations in particle thermal inertia (higher for more packed particle surfaces), but the complexities of the models, the complications due to small and/or rapidly rotating particles, and the incompleteness of the observing phase space has so far precluded more than a basic determination that the ring particles look like other frosty outer solar system objects. Section 3.2 Instrument Science Results chapter entitled CIRS describes how models of ring thermal observations can address these and other issues in more detail.

Erosional processes

Pollution of the mostly icy ring material by meteoroid bombardment, erosion of ring particles into impact ejecta, and restructuring of the rings by Ballistic Transport of the ejecta, were first suggested and discussed in the pre-Cassini era—see Durisen et al. [1989, 1992]; Cuzzi and Estrada [1998]; and see also the section entitled Ring Origin and Age for more discussion. The process is a little subtle and counterintuitive—see more recent work in Charnoz et al. [2009] and Estrada et al. [2015]. Extrinsic meteoroids hit the rings at tens of km/s, not only depositing their substantial amount of non-icy material, but ejecting chips of the target ring particle at 1–100 m/s. These chips go off on orbits that re-impact the rings where they become part of a new ring particle. Exchanges of losses and gains of mass and angular momentum can result in significant radial restructuring of the ring surface mass density over a time short compared to the age of the Solar System, given what we now understand about the meteoroid flux—see section entitled Dust and Meteoroid Distribution.

Signatures of this process can be found both in ring structure and ring composition. To date, intriguing possible correspondences to observed structure have been seen (amongst them the abrupt inner edges of the A-ring and B-ring and the odd linear ramps inward of them, and the 80 km scale irregular structure in the inner B-ring and inner A-ring) and a good match is provided to the smooth compositional profile that accompanies the abrupt B-ring–C-ring boundary. These independent structural and compositional properties suggest a young ring age of a few hundred million years, extending the simpler pollution argument relying on deposition of non-icy material alone, see section entitled Ring Particle Composition and Size, but the models have many parameters and face new challenges from new discoveries of several kinds (see section entitled Non-Saturn-System Science Results).

Electromagnetic and radiative processes

Particles in the space environment tend to attain a maximum charge that is only large enough to affect the dynamics of tiny (at most 10 micron size) grains. An entire branch of ring dynamics has to do with resonances involving forcing of tiny charged grains by the periodically fluctuating

planetary magnetic field; so-called Lorentz Resonances [Burns et al. 1985; Schaffer and Burns 1987], see also Horanyi et al. [2009] and Hedman et al. [2018a] for reviews of these and other electrodynamical effects. The most obvious places where these processes will be important is in the diffuse rings, such as the D-ring, E-ring, and G-ring, which are known to be most easily delineated by their tiny particles [Hedman et al. 2009a, 2018a; Chancia et al. 2019]. The E-ring shows the most clear influences, including its preference for a near-monodispersion of particle size at around one micron radius, a radial profile with a local minimum in vertical thickness at the location of Enceladus, and 3-D variations that correlate with the orientation relative to the Sun [Hedman et al. 2012; Ye et al. 2016]. It is now known that the E-ring is the frosty breath of Enceladus, and analyses of ISS images have clarified how it is fed in some detail [Mitchell et al. 2015].

A second ring phenomenon widely thought to be connected to electromagnetic forces is the flickering of shadowy spokes across the A-ring and B-ring, discovered by Voyager, see reviews by Orton et al. [2009] and Horanyi et al. [2009]. Various periodicities in the Voyager spoke occurrence rates, rotation rates at spoke boundaries, and the angular and spectral scattering properties of spoke regions have implicated electromagnetic effects acting on tiny grains; with sizes most recently shown by D'Aversa et al. [2010]. The tiny grains are probably released sporadically from ring particle surfaces somehow, perhaps by m-size particle impacts, energy beamed from the planet, or magnetic field/plasma instabilities near the ring, reviewed by Horanyi et al. [2009]. Earth-based observations also contributed to this understanding [McGhee et al. 2005]. Surprisingly to most of the Cassini team, spokes were invisible on approach and for the first year or more of the mission, and initially seen only weakly in late 2005 [Mitchell et al. 2006]. This observation supported an idea first suggested by Nitter et al. [1998] that seasonal changes in photocharging by the Sun were responsible. In this theory, dust is constantly being lofted out of the ring plane by impacts, but when the solar elevation is high, electrons are photosputtered out of the dense main ring layer causing the main rings to be positively charged while embedded in a vertically extended negatively charged electron plasma. Grains ejected from the rings become negatively charged in this plasma and are swept immediately back into the rings by the strong vertical electric field. The process is like an electrostatic dust precipitator in an industrial smokestack. The theory predicted that at a certain low elevation angle, the electrostatic precipitation would cease and spokes would reappear (Voyager 1 and 2 flybys were both at a time of low solar elevation) and indeed their disappearance again a year or so after equinox proved this to be the case. During the brief time spokes were abundant (roughly 2009–2011), detailed studies of their morphology [Mitchell et al. 2013] showed that the spokes had extended active growth times, both radially and azimuthally, and that their activity level was most likely associated with one of the SKR periods, but maximizes at a different longitude in that system than found by Voyager.

Finally, certain dusty ringlets in various otherwise empty gaps in the rings suggest evidence for electromagnetic or even solar radiative control on their predominantly micron-sized grains. The very obvious dusty, eccentric so-called "charming" ringlet in the outermost Cassini Division gap, that was not very noticeable during either Voyager encounter, always points its apoapse towards the Sun due to radiation pressure [Hedman et al. 2010a]. Several dusty, clumpy ringlets in the Encke gap have similar properties [Hedman et al. 2013b]. In general, one would expect that these tiny grains are constantly resupplied by generally unseen strands or clumps of macroscopic

particles with comparably low optical depths, but such a belt of more massive particles would not be influenced by electromagnetic or radiative forces.

Ring particle composition and size (R_AO2)

Maps composition and size distribution of ring material.

As described in more detail in the section entitled Ring Origin and Age, understanding the non-icy mass fraction in the rings is critical, as it provides perhaps the strongest constraint on the age and origin of the rings.

COMPOSITION (REMOTE SENSING)

The goal was to determine the composition of the ring material with the best possible radial resolution across the main rings. Spectral observations at UV, visual, and near-IR (NIR) wavelengths are generally insensitive to ring particle size because the ring particles were known to be much larger than these wavelengths from groundbased and Voyager observations. Known ring structure is on scales of 100–300 km, so observations needed to be planned to enable VIMS, UVIS and CIRS; all having much lower resolution than ISS, to resolve these scales. Longer observation times allowing deeper integrations were possible at greater distances, and high SNR spectra of broad segments of the A-ring, B-ring, and C-ring were also obtained. As time went on, we learned more about the observations and about the rings. For instance, Saturnshine was found to contribute organic-looking spectral features in certain geometries (ring longitudes between 120–240° solar hour angles as observed from high phase angles, for instance). The VIMS and UVIS calibration pipelines evolved and improved as the mission went on, and data analyzed and published early in the mission might still profit from reanalysis. ISS, while having much higher resolution and typically obtaining 3–5 km/pxl in extended color sequences, has very limited spectral resolution. In-depth ISS sequences were planned, but only one lit face observation in all 15 filters was obtained in Prime Mission, which was corrupted, so extensive and redundant follow-up was planned for the extended or Cassini Solstice Mission (CSM), over a range of illumination and viewing geometries (see section entitled High-resolution Ring Structure and Composition). Regional and local radial variations in color and spectra were seen by UVIS, ISS, and VIMS, greatly expanding geometrical and wavelength coverage to a depth of data that has yet to be plumbed. However, going from observed reflectivity (or I/F, the ratio of observed intensity to that of a colocated Lambert surface) to quantitative constraints on ring particle composition is a somewhat imperfect modeling step, involving the poorly understood way closely spaced particles with rough, grainy regoliths scatter light (see section entitled Non-Saturn System Science Results).

Allowing for most of these complexities, VIMS spectral data has been especially powerful in connecting the abundance and regolith grain size of water ice with the relative abundance of other materials. Early in the mission, Nicholson et al. [2008] found, and subsequently Hedman et al. [2013a] showed in more detail, that the redness of the main rings correlated very well with the water ice band depth suggesting that the UV absorber was spatially colocated with water ice, most likely

as tiny submicron or smaller size inclusions within the water ice regolith grains (new in situ observations may have even detected these tiny few-nm-size inclusions directly, see section entitled Composition of Rings From Ring Ejecta). Detailed studies of radial variation of color and spectra are reviewed by Cuzzi et al. [2009, 2018b, and references therein]. Regarding the actual nature of the UV absorber, a lively debate has continued for a decade as to whether the rings' redness can be better explained by good old-fashioned rust or other metal oxides, as on Mars, or by large organic molecules like Polycyclic Aromatic Hydrocarbons (PAHs) that give fruits and vegetables their orange-red color, see Cuzzi et al. [2009] for a discussion.

Broadly speaking, the optically thinner C-ring and Cassini division are more polluted by some spectrally neutral non-icy material than the A-ring or B-ring, making them darker at visual wavelengths and decreasing the strengths of the near-IR water ice bands; this is the natural outcome if the darkening material is deposited from extrinsic meteoroid bombardment [Cuzzi and Estrada 1998; Elliott and Esposito 2011], see also Cuzzi et al. 2009 for a review. More recent results from CIRS thermal models give the ring particle bolometric albedo; another measurement of their non-icy pollutants. It is interesting that, like inferences from visual wavelength reflectivities, the bolometric albedos are not only lower in the C-ring and Cassini division, but also vary smoothly across the sharp A-ring and B-ring boundaries [Morishima et al. 2010], as generally predicted by ballistic transport models.

Cassini's late-orbit in situ observations find plenty of organic material and some silicates, but no discernible free metal or metal oxides … .

Cassini's late-orbit in situ observations find plenty of organic material and some silicates, but no discernible free metal or metal oxides—see section entitled Composition of Rings from Ring Ejecta for details. Moreover, the most recent Cassini and non-Cassini studies using both classical and Monte-Carlo ring radiative transfer models agree that the spectra are more consistent with reddish organics than with other suggested materials [Ciarniello et al. 2019; Cuzzi et al. 2018b]. However, even the best current regolith scattering models simplify the physics and involve several parameters. Because different flavors of Hapke-like regolith scattering models lead to systematic, model-based uncertainties in absolute abundances at the factor-or-several level, or even worse, quantitative inferences about abundances must be treated with caution. For instance, Hedman et al. [2013a] interpreted fine-scale radial color variations in terms of regolith grain size, but this may have been because of the limitations of their (classical) model, whereas other secondary optical-depth-related effects may likely be the cause. On the other hand, Cassini's UV spectrometer UVIS observed the strong 170 nm water ice absorption edge and how it varies across the rings [Bradley et al. 2010, 2013]. These analyses provide a sensitive measurement of the regolith grain size, which can remove ambiguities in regolith models at comparable wavelengths and lead to absolute abundances of non-icy material—see section entitled Ring Particle Composition and Size for more discussion of grain size effects. Therefore, while the compositional debate has clarified regarding overall composition, there is a need for considerably more work regarding radial variation and inference of quantitative abundances of non-icy material, see section entitled Non-Saturn-System Science Results.

Other new contributors to the ring composition were the CIRS far-IR capability[2] and the Cassini 2.2 cm Titan Radar Mapper (RADAR), used in radiometer mode[3]. These observations have considerable historical motivation, as microwave observations were the first to constrain the ring composition as nearly pure water ice particles of cm-m size, see Esposito et al. [1984] for a review. The basic observation is that the brightness temperature of the rings drops from the physical temperature in the thermal IR, to a small fraction of it in the microwave (thus requiring a low particle emissivity). CIRS was able to get ring spectra covering the transition spectral range between thermal IR and several hundred micron wavelength, resolving inconsistent Voyager-era observations [Spilker et al. 2005, 2018]. CIRS and 2.2 cm radiometry was used to create sensitive high-resolution maps of the very low microwave brightness temperature [Zhang et al. 2017a, 2017b]. Microwave radiometry is unique because the long wavelengths penetrate to depths of several meters in cold water ice that has a very low microwave absorption coefficient, thus microwaves sample the bulk composition of the ring particles in a way that micron and submicron wavelengths cannot. The Cassini 2.2 cm radiometry had sufficiently high resolution to separate the A-ring, B-ring, and C-ring into dozens of radial bins and greatly improved on groundbased interferometry by setting upper limits of a fraction of a percent on non-icy material in the A-ring and B-ring.

Analysis of the 2.2 cm radar radiometry observations also found that the C-ring (with up to 6% non-icy material uniformly mixed) is much dirtier than the A-ring and B-ring [Zhang et al. 2017a, 2017b]. The assumption of uniform mixing may seriously underestimate the C-ring non-icy material abundance. Constraints on surface mass density from a handful of spiral density and bending waves strongly suggest that the particles in the same belt of the central C-ring, where unusually high abundances of silicates are found, have an internal density several times higher than water ice; far heavier than explained by a mere 6% in uniformly mixed silicate dust. The situation suggests buried solid chunks of non-icy material (silicate or carbonaceous) in large volume fraction. This rubble belt is what we might expect the remains of a disrupted core of a differentiated object to look like. However, modeling the microwave emission/scattering problem in the main rings is very difficult since the particle sizes and separations are not much larger than the wavelength and are in the near field of each other. Therefore, approximations are needed even in the very best current models, leading to some degree of compositional uncertainty. Moreover, these analyses are insensitive to the nature of the non-icy material.

Recent comparisons of spectral properties of the main rings with those of the ringmoons and classical icy moons are provided by Filacchione et al. [2012, 2013, 2014], and other recent reviews are by Cuzzi et al. [2009, 2018a]. For complementary discussion of the ring composition based on in situ observations (not part of the AO objectives), which are especially relevant to the D-ring, see section entitled Ring Age and Origin. The so-called diffuse rings (D-ring, E-ring, F-ring, and G-ring)

[2] It had been hoped that the longest wavelength channel of CIRS – advertised as 0.5mm wavelength, but more realistically 1 mm, could be used as a radiometer in this way. However, complicated calibration problems with the Michelson interferometry technique precluded this even after considerable effort by the team.

[3] Little was proposed or expected along the lines of ring science from RADAR in the AO or early discussions, as the team was exclusively focused on Titan. However, as the mission went on and the antenna beam was carefully calibrated, the very low ring brightness temperature was mapped even in the presence of the 10-times-brighter, huge globe of Saturn looming in the complex sidelobes.

and smaller rubble belts are discussed in the section entitled Dust and Meteoroid Distribution, both regarding structure and composition.

SIZE DISTRIBUTION

Even before Voyager, it was known from groundbased microwave observations that by far most of the main ring particles were in the cm-few meters size range [Orton et al. 2009], and for this reason microwave wavelengths were expected to be the most powerful at specifying their details. To this end, Cassini's observation planning incorporated 135 radio occultations of the main and F-rings, at three wavelengths: 0.94, 3.6, and 13 cm. These occultations provide the direct-path optical depth at all three wavelengths, clearly showing local and regional differences in the abundance of the smaller particles (a few cm in radius). In addition, the off-axis scattering (so-called bistatic scattering) of the radio beam can be used to constrain variations in the particles at the large-size end of a (usually) powerlaw size distribution, as well as the slope of the powerlaw, for example, Zebker et al. [1985]; Cuzzi et al. [2009]. The RSS occultation profiling observations have been reduced, corrected for diffraction, and provided to the Rings Node of the PDS, some examples are shown in Cuzzi et al. [2009] Figures 16.1a–16.2. Distinctions as subtle as changes in the slope of the powerlaw size distribution and the minimum and maximum particle size between typically a few mm and a few meters can be discerned. In addition, stellar occultations contribute information on the relative abundance of smaller particles.

Some generalities can be extracted even at this preliminary stage of the investigation. The fraction of small particles increases outwards through the A-ring based on the RSS data, consistent with more vigorous collisions associated with the increasing radial density of resonances and spiral density waves [Cuzzi et al. 2009; Becker et al. 2016; Jerousek et al. 2016].

In the RSS data, C-ring "plateau" structures show local drops in the differential optical depth, characteristic of locally fewer (short-)wavelength-size particles, and a similar effect is seen crossing from the outer C-ring to the inner B-ring, and from the outer Cassini Division to the inner A-ring; with the optically thicker rings having relatively fewer wavelength-size particles lying near the small end of the size distribution [Cuzzi et al. 2009].

Stellar occultation variance data[4] from UVIS provides an independent and complementary particle size determination to the RSS data. Analysis of this type reveals that all of the C-ring plateaus and narrower embedded ringlets have a smaller mean particle size compared to the background C-ring. The background C-ring has an undulating optical depth over scales of hundreds of km, and effective particle size correlates positively with this structure, this may suggest size-dependent dynamical transport within the ring. The innermost 700 km of the B-ring, and regions around the strong resonances in the A-ring, exhibit different effective particle sizes based on occultation variance (even though self-gravity wakes in these regions dominate the signal). There is a marked decrease in effective particle size coinciding with the Mimas 5:3 bending wave in the

[4] Showalter and Nicholson [1990] introduced this technique to relate the excess variance in the occultation signal (about a radially variable, locally defined mean) to the size of the largest local particles.

outer A-ring. This and other observations suggest a vertically extended haze of small particles across the wave; oddly, the effect is not seen in the nearby density waves where collisions might be expected to be even more vigorous. The variance in the Cassini Division ramp reveals the particle size distribution there to be more similar to the A-ring than to the Cassini Division, with a discrete increase in effective particle size at the inner edge of the ramp. On the other hand, the comparable C-ring–B-ring boundary transition is more gradual in variance and implied particle size [Colwell et al. 2018].

Because the optical depth does change abruptly by a factor of several, there must be a corresponding abrupt change in the opacity at these locations, requiring a change in the particle size distribution.

More information on particle sizes can be gained by comparing the local surface mass density from wavelengths of spiral density and bending waves, see Colwell et al. [2009]; Schmidt et al. [2009], with the local optical depth. For identical particles, the opacity (ratio of optical depth to surface mass density) is inversely proportional to particle size. Based on a number of observations of spiral density waves, there seem to be only very smooth, or no, dramatic changes in surface mass density across the plateaus or across the inner A-ring boundary [Tiscareno et al. 2013a; Colwell et al. 2009], see also the section entitled Gravitational processes. Because the optical depth does change abruptly by a factor of several, there must be a corresponding abrupt change in the opacity at these locations requiring a change in the particle size distribution. The sense of this is that the particles are on average smaller in the plateaus, and in the inner A-ring and B-ring, than in adjacent material, consistent with the variance data noted above. However, RSS occultations show that these same regions have fewer cm-size particles, requiring either that there must also be fewer large particles or that the largest particles are smaller, in the plateaus and similar regions. All together this suggests narrower size distributions for the plateaus, and inner A-ring and B-ring, than for their surroundings; relatively fewer particles at both size extremes. There is currently no explanation for this strong structural control on particle size, with very abrupt boundaries.

An important kind of size distribution is the size distribution of regolith grains on the surfaces of ring particles. While not what a dynamicist would call a ring particle, these grains along with their underlying material composition determine the spectral signature at any wavelength. Regolith grain sizes are usually best determined in and around strong absorption bands. UVIS, for instance, sees the strong water ice edge at 170 nm, and from the details of its position determines a regolith grain size of about 5 microns [Bradley et al. 2010, 2013]. However, at longer wavelengths (the near-IR water bands) larger grain sizes in the tens of microns are generally derived [Cuzzi et al. 2009; Clark et al. 2012; Filacchione et al. 2012, 2013]. This is consistent with the idea that shorter wavelengths sense and are scattered by smaller scale structures. Indeed, even before Cassini, models by Poulet and Cuzzi [2002] and Poulet et al. [2003] of Earth-based spectra of the rings covering the 0.3–4.5 um spectral range required very broad regolith size distributions; from 10 microns to several millimeters. Analyses of the long-wavelength roll off from much longer wavelength CIRS data [Spilker et al. 2005], and a 30 micron ice absorption feature [Morishima et al. 2012] suggest (not

surprisingly) a broad size distribution from tens of microns to centimeters radius with the larger ones perhaps starting to merge from regolith particles to freely-floating particles. Much more work is needed with improved regolith radiative transfer models and broader spectral ranges.

The so-called diffuse rings (D-ring, E-ring, F-ring and G-ring) have their own distinct size distribution; generally dominated by micron-sized particles that diffract, rather than backscatter, light at UV, visual, and NIR wavelengths (see section entitled Dust and Meteoroid Distribution).

Ring-satellite interaction (R_AO3)

Investigate interrelation of rings and satellites, including embedded satellites.

The first actual sighting of a small moon embedded in a clear gap was Pan, in the A-ring Encke gap … .

The first actual sighting of a small moon embedded in a clear gap was Pan, in the A-ring Encke gap [Showalter 1991], see also Colwell et al. [2009]; Orton et al. [2009]. Cassini quickly found a second example: Daphnis, in the Keeler gap, has an inclined orbit and the wavy edges it imparts to the gap flap vertically [Weiss et al. 2009]. The known dimensions and masses of these objects [Porco et al. 2005, 2007], combined with the estimated ring viscosity, provides our best validation of the shepherding torque theory [Goldreich and Tremaine 1980, 1982; Schmidt et al. 2009]. Cassini then embarked on an extensive systematic mapping of the other multiple empty gaps in the Cassini Division and C-ring over the duration of the mission, coming up empty handed, and (even though not every longitude of every gap was mapped) concluding that these gaps do not seem to be cleared by moonlets [Spitale 2017], at least based on the shepherding torque theory as currently understood [Schmidt et al. 2009]. Clues about other gap-clearing processes may be found in some of the details of the edge locations of the Cassini Division gaps [Nicholson and Hedman 2010; Spitale and Porco 2010; French et al. 2016a]. However, there are no corresponding clues regarding the few C-ring gaps lacking moonlets, which may instead be explained in the context of whatever mystery process generates the C-ring plateau ensemble, with which the unexplained gaps are associated. It is ironic that the Voyager imaging team redirected resources late in the planning phase to test a (then-new) hypothesis for gap-clearing by searching for gap-embedded moonlets, but resource and time constraints forced a choice of targeting only one gap, and as it turns out, the Cassini Division where they looked was not the right place [Smith et al. 1982].

Ring edges can also be maintained by single, isolated resonances, as at the outer edges of the B-ring (Mimas 2:1 resonance) [Spitale and Porco 2010, and references therein] and the A-ring outer edge (Janus 7:6 resonance) [Porco et al. 1984]. Recently El Moutamid et al. [2016c] and Tajeddine et al. [2017a] showed in detail how Janus actually is able to create an abrupt edge for the outer A-ring and restrain its spreading, even as it swaps orbits back and forth with Epimetheus, in somewhat of a team effort with all the other ringmoons and resonances acting on different parts of the A-ring, so the classical shepherding theory seems to be in good shape. The kinky, stranded

F-ring has a more complicated, often chaotic, relationship with its nearby moons, though (see section entitled F-ring).

A special kind of embedded moonlet is one that is too small (smaller than 1 km radius) to actually open a gap; these were predicted by Spahn et al. [1994], but most Cassini scientists were surprised to actually see some, initially in the Saturn Orbit Insertion (SOI) images [Tiscareno et al. 2006]. These have been dubbed “propellers” by virtue of the disturbances they create, which are too weak to prevent viscosity from backfilling the disturbance before the next encounter of the moonlet with the same material. It seems there are on the order of a million of these objects in the A-ring, and they are confined mostly to three distinct bands in the A-ring [Sremčević et al. 2007; Tiscareno et al. 2008]. There have been reports of propellers in the B-ring as well [Sremčević et al. 2012, 2013, 2014a, 2014b]. It is not currently understood whether these objects are shards of a ring parent, or are somehow spontaneously forming and perhaps dispersing in place [Esposito et al. 2012]. The three A-ring propeller bands are anti-correlated with the halos of large spiral density waves, and correlated with the strength of self-gravity wakes, which might favor the local formation idea or might simply indicate changes in the photometric balance or local viscosity that causes propellers to be visible. A subset of much larger objects, dubbed Giant Propellers, was discovered, which could be tracked and found to be evolving in semi-major axis [Tiscareno et al. 2010]. This discovery motivated significant dedicated observing during the extended mission (see section entitled New Ring Structure). Meanwhile, the theory of these disturbances has been actively discussed and continues to advance [Schmidt et al. 2009; Crida et al. 2010; Pan and Chiang 2010, 2012; Rein and Papaloizou 2010; Pan et al. 2012; Bromley and Kenyon 2013; Tiscareno 2013; Seiler et al. 2017; Seiß et al. 2018].

A possible physical extension of these objects to smaller sizes has been seen in the optically thicker bands of the C-ring (including the plateaus) and Cassini Division (including its outer ramp); so-called ghosts or partial clearings appear in UVIS occultations with very small lengthscales [Baillié et al. 2013]. These are thought to be caused by relatively large ring particles (maybe meters to tens of meters in size) smaller than the A-ring and B-ring propellers (objects so small would not clear gaps in the generally higher optical depth, and more strongly stirred, A-ring and B-ring). These objects would need to be more than three times larger than the largest ring particle in a powerlaw size distribution in order to create the ghost clearings.

Fleeting glimpses of what appear to be embedded Keplerian objects have also been obtained near the edges of several rings and ringlets. At the outer edge of the A-ring, the so-called “Peggy” object was seen briefly [Murray et al. 2014], seemingly getting ready to break free of the main rings. This exciting moment might, it was thought, allow the object to be spun away from the rings due to ring torques such as modeled by Charnoz et al. [2010]; an effect by which the age of the rings might be constrained (see section entitled Ring Origin and Age). However, Peggy actually was reabsorbed back into the rings and apparently broke into several pieces, proving that leaving home can be difficult. Moderately large Keplerian objects, but still too small to be seen directly, were also seen near the edges of the A-ring Keeler gap [Tajeddine et al. 2017b], in the Huygens ringlet of the Cassini Division [Spitale and Hahn 2016], and near the outer edge of the B-ring itself [Spitale and Porco 2010—see also Cuzzi et al. [2018a]. It has been suggested that many or even all of these

objects are transient, forming by compaction due to satellite perturbations, and then being disrupted as they increasingly stir the regions around them [Esposito et al. 2012].

Finally, it cannot be forgotten that all the wonderful dynamical relationships we are starting to understand between the rings and various moons depend on a good understanding of the orbital dynamics of the moons themselves, and the so-called ringmoons in particular, that interact strongly with the rings [Spitale et al. 2006; Jacobson et al. 2008; Tajeddine et al. 2013]. Additional results can be found in the ISS Instrument Science Results. Of special importance is the paradigm-breaking observational result of Lainey et al. [2017] that the midsize icy moons of Saturn, from Mimas through at least Rhea, are tidally evolving outwards much faster than had been previously assumed based on traditional tidal "Q" theory. This was extremely surprising, because Saturn's interior had been thought to be quite non-dissipative, like Jupiter, with a high "Q" value (see section entitled Saturn System Science Results). A more recent tidal theory suggests that "Q" is highly frequency dependent, and that moons get trapped on a comb of low-Q frequencies that slowly decrease as Saturn's interior structure evolves, driving the entire set of moderate-sized icy moons outward at a more or less distance-independent rate instead of the strongly distance-dependent rate of traditional tidal theory—see for example, Fuller et al. [2016]. This new perspective has profound implications for the origin and (now increasingly believed to be) geologically youthful age of the rings (see section entitled Ring Origin and Age).

Dust and meteoroid distribution (R_AO4)

Determines dust and meteoroid distribution both in the vicinity of the rings and in interplanetary space.

THE DIFFUSE RINGS

The so-called diffuse rings (D-ring, E-ring, F-ring and G-ring) are best studied by tracing their micron-size particles. Such small particles scatter UV, visual, and near-IR light into small solid angles in the forward direction so they may be more easily detected than in the lower brightness of their larger particles, which is spread over more angles near backscattering and also may be subject to the low brightness of individual particles. In all these cases where only fine dust belts are observed, it is generally accepted that a larger-particle skeleton (or some small parent moonlet) must be present to resupply the micron-sized material, which is rather quickly lost [Burns et al. 1984; Hedman et al. 2018a]. Based partly on observations of charged particle depletions [Van Allen 1982]—see also Section 3.1 Discipline Science Results chapter entitled MAPS for Cassini-based examples; the G-ring has long been known to contain an underlying rubble belt or arc of macroscopic particles—see reviews by Orton et al. [2009] and Hedman et al. [2018a]. Cassini discovered that the ultimate source of this rubble belt is a 0.5 km size, highly non-spherical object called Aegaeon, which has a very dark primitive-body type surface [Hedman et al. 2011a]. Moreover, Aegaeon is trapped in a 7:6 resonance with Mimas [Hedman et al. 2007c, 2010].

Several other dusty arcs of material were discovered, supplied by the small moonlets Anthe, Pallene, and Methone—of these, Methone and Anthe are trapped in Mimas resonances [Hedman et al. 2009b]. A composite dusty ring phase function and size distribution was obtained from wide phase angle coverage of the D-ring and G-ring, for application to so-called Debris Disks around young stars [Hedman and Stark 2015]; a certain similarity in the two ring phase functions may point to some family and/or process similarity in the particles; such as an aggregate, fractal structure. The D-ring shows several kinds of time variability, and is discussed more in the section entitled Ring Temporal Variability. Also, the giant, diffuse Phoebe ring, discovered in 1999 by the Spitzer Space Telescope [Verbiscer et al. 2009], was further constrained in extent, dynamics, and particle size using shadow-edge imaging observations [Tamayo et al. 2014, 2016].

A disadvantage of necessary reliance on forward scattering for the diffuse rings, is that it is essentially diffraction, and only weakly dependent on composition, so the composition of these rings is not quite as well known. Even when there is some signal in backscattered intensity or reflectivity, it remains problematic to derive even albedos for the large F-ring and G-ring particles (whose scattering would be compositionally diagnostic) because their optical depths are variable and/or small, and so uncertain. The F-ring is known to be dominated by crystalline water ice [Vahidinia et al. 2011; Hedman et al. 2011b], but may be significantly polluted by drifting G-ring material [Clark et al. 2012]—see also Cuzzi et al. [2018a], Figure 3.22, and the section entitled F-ring for more discussion. By comparison, the composition of the E-ring is known very well from CDA in situ sampling (mostly water ice, with embedded organics and salt, all characteristic of the underground Enceladus Ocean from which it comes), and its structure is discussed in the section entitled Changing Rings. In situ sampling of nanoparticles in the D-ring is discussed in sections entitled Ring Magnetosphere and Determination of Ring Mass.

THE EXTRINSIC (INTERPLANETARY) MASS FLUX - A PRIMARY GOAL OF CASSINI

The CDA instrument [Srama et al. 2005] estimated detecting 100 extrinsic particles of micron-size and larger. However, early in the mission it started to look difficult or impossible to measure it directly (it is a very dusty system in reality), so an indirect approach was explored to look for dust ejecta haloes around Rhea and Tethys, by analogy to Galileo results at Jupiter [Sremčević et al. 2005]. This led to only upper limits and an initial conclusion that the extrinsic meteoroid flux was lower than previously assumed. However, the basic direct approach simply counting up the detections and velocities of small particles with identifiably extrinsic orbits was ultimately successful partly due to the much longer time baseline of the CSM (13 years) relative to the baseline mission. The lack of indirect detection (satellite dust haloes) was reconciled after the fact by uncertainties in the ejecta yield model. For example, the ongoing snowfall caused by Enceladus' geysers might have influenced/changed the mechanical surface properties of Rhea and Tethys compared to the Jovian icy moons. Future analyses of thermal inertias might provide useful constraints on satellite surface properties, in this regard.

The CDA meteoroid mass flux measurement works as follows [Kempf et al. 2019], see Section 3.2 Instruments Science Results chapter entitled CDA. For each particle detected entering

the instrument there is an instrumental ambiguity that allows two equally valid predetection velocity vectors. A lower limit to the incident mass flux comes from only the 25 particles for which both velocity vectors trace back to extrinsic projectiles, from beyond Saturn. An upper limit of a sort also includes the 75 or so particles for which only one of the velocity vectors requires an extrinsic origin. Because the size distribution of the detected particles is not well known, the largest particles might carry most of the mass, and their rarity suggests that the nominal detection values could be a lower limit. For instance, a solitary 250 μm particle was not included in the mass flux calculations (including it would increase the mass flux by a factor of five) and another year of mission time might have captured more large particles. Future, more detailed (perhaps Bayesian) analyses might refine the uncertainties more, but at present it seems that the nominal CDA minimum flux is conservative. The values for the minimum flux at infinity (before gravitational focusing by Saturn) are within a factor of order unity of pre-Cassini assumptions [Cuzzi and Estrada 1998]. However, the CDA discovery that the pre-Saturn orbits were dynamically Kuiper Belt object (KBO)-like (low eccentricity and inclination) rather than comet-like (and thus have lower encounter velocities), leads to an order of magnitude increase in Saturn's gravitational focusing factor and thus in the flux at the rings. The implications of this new result for models of ring structural and compositional evolution, which have multiple parameters [Estrada et al. 2015] are not yet well understood, but they are unlikely to allow a ring age older than previous estimates of some hundreds of millions of years.

Perhaps a simple, large field-of-view (FOV), NIR photometer experiment to monitor impacts might be considered for a future mission.

Along the lines of mass flux into the rings, we should mention flux at larger sizes as perhaps providing additional constraints on ring evolution; as yet, no effort has gone into merging these datasets and results. An observation by RPWS only reported at meetings [Gurnett et al. 2004] may suggest impacts by dozens of particles during the 30 minutes Cassini was skimming across the face of the rings at SOI. Significant theoretical development is needed to translate these observations into responsible projectile sizes (sand-grains?), but if this can be done, the rates would surely be of interest. Impact ejecta trails from a handful of meter-sized particle impacts were imaged by ISS [Tiscareno et al. 2013; Schmidt and Tiscareno 2013]. UVIS mounted an early attempt to detect actual impact flashes themselves, but subsequent thought and modeling concluded that the flash could only be seen in the near-IR [Chambers et al. 2008] so the UVIS searches were discontinued. Perhaps a simple, large field-of-view (FOV), NIR photometer experiment to monitor impacts might be considered for a future mission. Finally, as discussed in the section entitled Ring Temporal Variability, there is evidence for multiple impacts on the rings by 1–10 km size objects over decades and centuries.

Ring magnetosphere-ionosphere interactions (R_AO5)

Studies interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.

It has long been known that the rings have an atmosphere of their own due to photosputtering and meteoroid bombardment, and interact with both the magnetosphere and the planet, even reducing the ionospheric electron density [Shimizu 1982; Connerney and Waite 1984]. During SOI, Cassini obtained the first-ever in situ measurement of the ring atmosphere, and it was a big surprise. It had been expected to be dominated by water products (WP) (molecules and ions of H_2O and its fragments), but instead Cassini Plasma Spectrometer (CAPS) found it was dominated by neutral and ionized O and O_2 [Tseng et al. 2010]. The observations and theory are reviewed in Cuzzi et al. [2009]; essentially, WP recombine on ring particle surfaces, but O and O_2 do not, building up in the ring atmosphere without freezing out or adsorbing onto ring particle surfaces, and ultimately filtering out to the magnetosphere and into the planet [Tseng et al. 2010]. Since that review, the effect has been modeled in more detail, and the observed seasonal variation of magnetospheric oxygen ions transported from the rings (see Section 3.1 Disciplines Science Results chapter entitled MAPS) suggests that photosputtering of ring ices dominates over material from Enceladus in producing the ring atmosphere [Tseng et al. 2010, 2013; Elrod et al. 2014]. This discovery of the ring atmosphere alone would satisfy the AO objective, but indeed during the RG and GF orbits, Cassini discovered far more about the particulate component of the ring atmosphere and its flux into the planet; the so-called ring rain long speculated upon, for example, Connerney and Waite [1984]. We discuss this in detail in the section entitled Ring Age and Origin.

The D-ring is now known to be embedded in a high-energy-particle radiation belt that is separated from Saturn's main radiation belts [Kollmann et al. 2019; Roussos et al. 2019]. This may help explain its possible shortage of water ice (see section entitled Composition of Rings from Ring Ejecta). The diffuse E-ring and G-ring interact in more intimate ways with the magnetosphere; their tiny grains get charged and undergo electromagnetic forces (see section entitled Electromagnetic and Radiative Processes).

Extended Mission (CSM) Objectives

The objectives below were developed in 2010, to prioritize upcoming planning by focusing on specific problems, either unresolved AO goals or unexpected new phenomena, and to take advantage of the unique geometries of the CSM.

Changing rings (RC1a)

Determines the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near Solstice.

The emphasis here is on observing at the seasonally maximum opening angle of the rings near Solstice. The dominant operative intention was to take advantage of the maximum ring opening angle as seen from Earth and the Sun to: a) allow CIRS to determine the energetics of thermal heating and cooling of the rings as they opened to their maximum opening angle to the sun; and b) allow RSS occultations to penetrate the most opaque parts of the rings (the central B-ring), which they had not yet been able to do even during the maximum opening angle allowed

during Prime Mission (21°). The difference relative to true maximum opening angle of 23.7° can be critical for RSS, as it appears in the exponential of the optical depth term. The objective was very well satisfied, in that 36 more radio occultations were obtained, with various combinations of resolution and sensitivity, at opening angles larger than available during prime mission and more suitable for probing the dense B-ring. The data have been reduced and deposited in the Rings PDS node at 1 and 10 km spatial resolution. CIRS also obtained data over a wide range of opening angles; one important conclusion has to do with the seasonal cooling of the rings through equinox; their minimum temperature is considerably larger than instantaneous thermal equilibrium with Saturn's reflected and emitted energy, constraining the internal density of the particles (at least in the A-ring where the model was applied) to be closer to solid ice in the central A-ring than in its inner or outer regions [Morishima et al. 2016]. Perhaps this can be correlated with the radial variation of self-gravity wakes and/or the radial distribution of propeller objects.

When this goal was written, it was still not known as to whether the spokes would vanish again, and if so, exactly when and under what geometrical conditions. Indeed that situation is now well understood in terms of photocharging of the main rings (see section entitled Electromagnetic and Radiative Processes).

The diffuse E-ring, composed largely of micron-sized grains jetted out of Enceladus, deforms and changes shape with the seasons in response to the elevation angle of the sun, as solar radiation pressure influences the orbits of these tiny grains [Hedman et al. 2012].

The waxing and waning of the magnetospheric oxygen ion content is dominantly seasonal; implicating photosputtering of ice in the main rings rather than impacts by grains from Enceladus, one previous candidate [Tseng et al. 2013].

Ring temporal variability (RC1b)

Determines the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations.

The rings are changing before our eyes. The F-ring may be the most extreme example of time variability, and merited its own strategic objective (see section entitled F-ring). Here we discuss other aspects of ring temporal variability.

The sharp edges of the A-ring and B-ring flop around loosely, revealing the fluid nature of the rings. The A-ring outer edge seven-lobed structure derives from a 7:6 resonance with (mostly) Janus, and it reorganizes itself, diminishing in amplitude, when Janus swaps to its outer orbit and the resonance moves off of the A-ring edge [Spitale and Porco 2009; El Moutamid et al. 2016c]. The B-ring outer edge is more complicated, showing the predicted two-lobed forcing of the Mimas 2:1 resonance, but in addition, showing interference with m = 1, 2, and 3 patterns that are probably free modes driven by ring pressure and viscosity. Sometimes the pattern almost vanishes because

of this interference [French et al. 2010; Hedman et al. 2010b; Esposito et al. 2012; Nicholson et al. 2014; Spitale and Porco 2010]—see section entitled Viscous Processes.

Saturn's innermost ring (D-ring) is only visible with effort and in favorable geometry. However, after the F-ring fireworks, it has provided some of the most interesting evidence for time variations (usually observed by virtue of its fine dust component, in forward scattering geometries, as discussed in the section entitled The Diffuse Rings). Hedman et al. [2007b] first noticed that its structure of irregularly spaced bands or belts had changed dramatically since Voyager. They also pointed out a pattern that they interpreted as a vertical spiral ripple, and suggested that the ripple was the result of an ongoing wrapping up by differential node regression of a tilted mean ring plane. From the wavelength of the wrap, which shortens with time, they dated the event to the early 1980s. Hedman et al. [2011c] found the ripple to extend through the C-ring, and suggested that the tilt was imposed by an impacting stream of rubble, perhaps from a disrupted, 1–10 km size, Shoemaker-Levy-9 type object, with an extended node crossing the D-ring and C-ring. Hedman et al. [2015] determined, from further analysis, that the event may have had two parts, separated by months. Hedman and Showalter [2016] subsequently found pattern evidence for two other disturbances that occurred in 1979 (in Voyager data) and 2011. Marouf et al. [2011] discovered a similar pattern in the C-ring, from higher-resolution radio occultation data, that they interpreted as two events, separated by 50 years that occurred in the late 1300s. It is fascinating that the rings still bear silent witness to these long-lasting scars of cometary impacts. A related example of time variability is ongoing impacts onto the ring by discrete particles large enough to create detectable disturbances; the little cousins of these ripple-forming comet-size objects. Impacts by meter-size particles have been observed directly; once a leading candidate for triggering spokes (see section entitled Electromagnetic and Radiative Processes), the connection between the observed meter-size impact rates and spoke formation rates has not been pursued in depth. These impact effects were discussed in the section entitled The Extrinsic (Interplanetary) Mass Flux.

The D-ring and C-ring show two other, still unexplained, kinds of time variation. Hedman et al. [2014b] found that one of the most prominent bright ringlets in the D-ring, also seen by Voyager, is moving inwards at more than 2 km/year, and apparently moved outwards to its current position between Voyager and Cassini. The ringlet also has strong azimuthal clumpiness that seems stable, but cannot be associated with any plausible resonance with either some known moon, or some known planetary interior modes or rotating structures; all in all it is a puzzling dynamical feature. Also, there are time-variable aspects to several C-ring spiral density waves that appear to be driven by density fluctuations fixed to Saturn's internal structure and rotating with its winds; so-called tesseral resonances (see section entitled Gravitational Processes). Hedman et al. 2017, 2018b; Hedman and Nicholson 2014] have found that some of these wavetrains seem to be drifting inwards at about 1 km/year, as if the density fluctuations causing them were moving in latitude or depth inside the planet. The D-ring also revealed a new set of bright clumps near the end of the mission, possibly related to time variation in the INMS GF observations (see section on Composition of Rings from Ring Ejecta).

F-ring (RC2a)

Focuses on F-ring structure, and distribution of associated moonlets or clumps, as sparse observations show clumps, arcs, and possibly transient objects appearing and disappearing.

Because of the strong time variations seen during prime mission, the F-ring became a central focus for Cassini imaging observations during CSM. The F-ring lies about 3000 km outside the A-ring edge, and is unique in the family of planetary rings. Faintly glimpsed by Pioneer 11, its kinky, multi-stranded structure was revealed in Voyager images to be dominated by small dust grains, and Voyager radio and stellar occultations showed it to have a very narrow core of larger objects. Earth-based observations between Voyager and Cassini showed it to be highly variable, with large clumps coming and going, having orbital periods that differed slightly from that of its central strand [McGhee et al. 2001]. As it was straddled by the 100 km diameter ringmoons Prometheus and Pandora, classical shepherding theory was quickly proposed to explain its survival. However, almost immediately, problems arose with that interpretation, growing over the years when it was realized that not only were the so-called shepherds on chaotic orbits themselves, but objects orbiting between them were excited to even more chaotic orbits [Cuzzi et al. 2014]. In fact, Cassini very quickly observed some of these objects (2004S6, etc.) [Porco et al. 2005] on orbits that crossed the F-ring, but could not be tracked for more than a few months before they vanished [Cooper et al. 2017]. Meanwhile, large jets of material were seen splashed out from the central core due to collisions by these careening objects [Charnoz et al. 2005; Murray et al. 2008; Becker et al. 2018], and evidence was found for smaller, unseen objects embedded within the F-ring strands themselves. Dynamical models showed how the perturbations of Prometheus alone could explain the alternating streamer-channel appearance of the F-ring [Murray et al. 2005; Beurle et al. 2010].

Several new classes of embedded objects were inferred and modeled, based on often faint and initially obscure patterns seen to come and go. Mini-jets (small spikes poking out of the central strand) were catalogued and understood as caused by large embedded objects (meters or tens of meters in size perhaps) colliding at low (few m/sec) speeds within the dense central ring strand [Charnoz 2009; Murray et al. 2008; Esposito et al. 2008; Beurle et al. 2010; Albers et al. 2012; Meinke et al. 2012; Attree et al. 2012, 2014]. Fans or localized regular brightness fluctuations were shown to be due to small embedded objects on slightly eccentric orbits relative to the F-ring [Murray et al. 2008]. Some of these fans were localized to parts of the ring where Prometheus compressed ring material, perhaps actually forming new small moonlets [Beurle et al. 2010].

RSS occultations only detected the F-ring's very narrow (< 1 km) true core of cm-and-larger-size particles about 1/3 of the time, showing it had to be azimuthally broken and discontinuous. Using these observations, a new theory was developed in which the stability of the true core, in the presence of strong orbital chaos driven locally by Prometheus, seems to be due to longitudinal confinement into separated clumps or arcs by a corotational resonance in which the stable clumps never encounter Prometheus at its apoapse where strong chaos-inducing perturbations can result [Cuzzi et al. 2018c], see also Albers et al. [2012]; Cooper et al. [2013]. The reason why only this one of many nearby corotational resonances is occupied remains unclear. This arrangement of incomplete arcs of macroscopic particles must occasionally make small

adjustments, given the occasional chaotic changes in Prometheus' orbit to which the clumps must readjust. Hedman et al. [2011b] observed variations in crystalline ice band depth due to variations in the relative abundance of macroscopic bodies and dust, which have yet to be correlated with the RSS clumping. Large objects forming in fans, and usually outside the very narrowly defined stable true core orbit [Cuzzi et al. 2014, 2018c], can become strongly perturbed by Prometheus and evolve into 2004S6-like objects, ultimately recolliding with the F-ring at high speeds. Indeed, while 2004S6 was tracked in 2006–2008 as it collided with the F-ring several times and then lost, similar objects have since appeared. Different frequencies and intensities of such big eruptions as seen by Cassini and by Voyager observations underline the sporadic nature of these variations [French et al. 2012, 2014].

Ring age and origin (RN1a)

Constrains the origin and age of the rings by: a) direct determination of the ring mass; and b) of the composition of ring ejecta trapped on field lines.

Over the years the ring composition has emerged as perhaps the best gauge of ring age and clue to ring origin. While ring composition is powerfully addressed using traditional remote sensing techniques (see section entitled Ring Particle Composition and Size), this objective focused on in situ measurements that were only achievable during Cassini's RG and GF orbits.

Determination of ring mass

It was not known, when Cassini was initially planned, that we would be able to obtain a direct measurement of the ring mass; this only became possible in the CSM GF orbits when the spacecraft was able to fly between the rings and the planet 22 times. The original AO mission plan was to constrain the ring mass by measuring the ring optical depth and particle size distributions together, and sample all available spiral density waves, using stellar and radio occultations. However, because of the possible ambiguities associated with hidden mass in the B-ring that arose during the prime mission (see section entitled Gravitational Processes), six complete close passes were allocated in the GF orbits, during which the spacecraft remained quiet while RSS transmitted a carrier signal to Earth, to allow the small gravitational effects of the rings to be separated from those of Saturn; a mini-Juno mission. The details of the technique, and difficulties encountered, are described by Iess et al. [2019] and in this volume. Unexpected and probably azimuthally variable internal properties of the planet (very unlike those of Jupiter) contaminate the gravitational signature of the rings, increasing the measurement uncertainty to perhaps 50% of the signal. It is puzzling that, if the RSS variance is interpreted as internal mass irregularities, the amplitude of these seems considerably larger than would be

It was not known, …, that we would be able to obtain a direct measurement of the ring mass; this only became possible …, when the spacecraft was able to fly between the rings and the planet 22 times.

inferred from the dozen or so spiral density and bending waves currently seen in the rings that have been identified as being driven by mass fluctuations inside the planet (see section entitled Gravitational Processes). Nevertheless, it can be concluded with confidence that the ring mass is probably less than the Voyager-era estimate to within the uncertainty, see Section 3.2 Instruments Science Results chapter entitled RSS, and Iess et al. [2019]. A total ring mass even as large as 0.8 Mimas masses is regarded as unlikely, and the nominal value is 0.4 Mimas masses. While RSS has been as yet unable to obtain a radial profile of surface mass density, there is a clue from CIRS thermal models that the central B-ring region called B3 (105000–110000 km) is actually a quite sharply bounded annulus containing 2–3 times the surface mass density of the rest of the B-ring [Reffet et al. 2015].

Composition of Rings from Ring Ejecta

The AO mission provided for no direct, in situ measurement of main ring particle composition; it was planned to rely on remote observations by VIMS and CIRS, and eventually RADAR 2.2 cm radiometry, sensing the non-icy component of ring material (see section entitled Ring Particle Composition and Size). Unfortunately, no unambiguous compositional signatures of any materials besides water ice were seen by VIMS, UVIS, or ISS; and other instruments such as CIRS and RADAR could only constrain the amount of non-icy material in a nonspecific way. Fortunately, in the GF orbits, when Cassini crossed the ring plane inside of the D-ring (and indeed skimmed through the planet's tenuous upper atmosphere) synergistic, dedicated in situ observations by CDA, INMS, MIMI, and RPWS hit pay dirt.

CDA detected grains at a variety of vertical distances above the rings, with varying silicate/ice fraction [Hsu et al. 2018]. The Fe/Si ratio suggested low-Fe silicates. The order-unity silicate/ice ratio in material detected by CDA (primarily at high latitudes) is far higher than seen in the main rings or even the more polluted C-ring, and suggests that detected grains have been stripped of most of their ice before detection, perhaps by photosputtering [Hsu et al. 2018], but this remains an active area of research. No evidence was found for free iron or FexOy compounds (candidates for reddening the rings)—see section entitled Composition (Remote Sensing) and Cuzzi et al. [2009] for a review and discussion—even though their presence had been suggested in true interstellar grains detected by CDA [Altobelli et al. 2016]. CDA observations of organics are expected to be limited to large grains, which were rare because the dust abundance at the radii of ring plane crossings was much lower than had been (conservatively) estimated from spacecraft hazard studies, and most of the detected grains were too tiny to get good mass spectra in the presence of known carbon contamination of CDA. For the larger grains, CDA can say that the concentration of organics is low in any single detected grain, compared to the amount of ice or silicate. Nevertheless, the data are still being analyzed and new results along these lines are anticipated—see, for instance, Hsu et al. [2018], and Section 3.2 Instruments Science Results chapter entitled CDA.

MIMI detected an equatorial layer of 4–5 nm radius grains with vertical thickness of a few thousand km [Mitchell D. et al. 2018] blending into the very rare upper atmosphere of Saturn. These

tiny grains plausibly derive from the even flatter D-ring and drift inwards under gas drag while spreading vertically. They are too small to pick up much charge, so orbit at nearly Keplerian speeds, obtaining their few-thousand km vertical thickness by scattering collisions with differentially rotating exospheric H atoms. MIMI could not determine the composition of these grains directly, but estimates their mass flux into the atmosphere at 5 kg/s [Mitchell et al. 2018] (and Section 3.2 Instrument Science Results chapter entitled MIMI).

Meanwhile, as Cassini skimmed through the very rarified upper atmosphere on the GF orbits closest to Saturn, INMS detected strong signals due to a very wide range of masses, up to their limit at 100 amu [Waite et al. 2018; Perry et al. 2018]. The abundance of these molecules actually decreased downwards into Saturn, so they are entering from above, not diffusing up from depth. The overall pattern observed is roughly dominated by multiples of carbon atoms, up to C6, but given the likelihood that large molecules fragment into smaller ones within the INMS chamber prior to actually being sampled, detailed inferences require a complex deconvolution process [Waite et al. 2018; Miller et al. 2019]. INMS is unable to detect nonvolatile material like iron or silicates, and is even subject to underestimation of H_2O. The good agreement between the INMS latitudinal signal strength and the thickness of the MIMI 4–5 nm particle layer suggests that the INMS compositions refer to impact fragments of the MIMI particles. Also seen in the INMS spectra are N and O; however, the complexity of the deconvolution leaves some ambiguity about whether the O, N (and even some of the C) were carried as part of the organics or in smaller molecules like NH_3 or CH_4 [Waite et al. 2018; Perry et al. 2018; Miller et al. 2019]. For comparison, Cassini VIMS observations see no CH_4 or CO_2 [Cuzzi et al. 2009] and STIS spectra see no NH_3 [Cuzzi et al. 2018b]. INMS estimated a total flux of these materials into Saturn's upper atmosphere, over a latitudinal band of 5–10° wide, that is about 1000 times larger than the MIMI estimate [Perry et al. 2018], and propose that it must be carried dominantly by particles of 1–2 nm radius, too small for MIMI to detect, but following roughly the same vertical distribution. This flux is so high that INMS suggests it is probably due to a flareup in the D-ring, perhaps due to recent activity in the D68 ringlet [Hedman et al. 2014b; Hedman and Showalter 2016; Hedman 2019].

Ring origin and age

The age of the rings has been debated since the Voyager era, when two general lines of argument arose suggesting they may be much younger than the solar system. These are described in more detail in several recent review chapters [Cuzzi et al. 2009, 2018a; Charnoz et al. 2009]. First, angular momentum transfer by spiral density waves between the rings and the inner moons should quickly collapse the A-ring and spin the close ringmoons outwards, a tidal effect like our own Earth-moon tidal interaction [Goldreich and Tremaine 1982], see also Poulet and Sicardy [2001] or Charnoz et al. [2009] for loopholes. Second, pollution of the dominantly icy A-ring and B-ring, more than 90% ice, as known since pre-Voyager [Esposito et al. 1984; Orton et al. 2009], by dominantly non-icy meteoroid infall should darken them in much less than the age of the solar system [Doyle et al. 1989; Cuzzi and Estrada 1998; Elliott and Esposito 2011]. It had been argued, however, that the ring mass could be much larger than generally accepted during the Voyager era, because gravitational clumping and lack of sampling by spiral density waves of the most massive B-ring

might allow most of the mass to escape detection (see section entitled Gravitational Processes). Also, the meteoroid mass flux was very poorly known, and if it had been overestimated by an order of magnitude or so, the rings could remain unpolluted for the age of the solar system.

The combination of ring mass determined by RSS [Iess et al. 2019], and the extrinsic meteoroid mass flux measured by CDA [Kempf et al. 2019] (see section entitled The Extrinsic (Interplanetary) Mass Flux) at last allows us to constrain the ring age to be less than 250 million years or so (observational and model-based uncertainties remain), i.e., no older than the dinosau [O'Donoghue et al. 2019]. If we must reluctantly relinquish our otherwise physically plausible primordial ring origin scenarios, at least there is one plausible recent origin scenario, related to a dynamical instability incurred 100 million years ago by a stably evolving Saturn inner moon system [Cuk et al. 2016]. There are many current issues associated with connecting such an instability (near Rhea's orbit) and actual formation of a massive ring inside the Roche zone. However, it offers both an independently derived, recent age and also an indication why Saturn is the only giant planet to sport such a young, massive, icy ring. Constraints from cratering of icy moon surfaces and internal evolution will play an important role in testing the idea. There are also several Titan-related puzzles pointing to short timescales [Nixon et al. 2018]. A possibly important constraint is that the D/H ratio in the rings is similar to the regular icy moons and terrestrial values, while that of Phoebe is more comet-like [Clark et al. 2019]. The current implications that the rings are colored by organics, that there may be a silicate-rich rubble belt buried within the C-ring (see section entitled Composition (Remote Sensing)), and even the dark, enigmatic G-ring parent Aegaeon [Hedman et al. 2011a] provide important constraints as well.

Ring composition (RN1b) - ringmoons

Determines the composition of the close-in ringmoons as targets of opportunity. This is discussed in detail in Section 3.1 Discipline Science Results chapter entitled Icy Satellites.

Ring structure (RN1c) – high resolution and composition

Determines structural and compositional variations at high resolution across selected ring features of greatest interest, using remote and in situ observations.

A substantial number of new, dedicated observations were prioritized, integrated, and implemented to make use of the unique, up-close-and-personal geometry of Cassini's RG and GF orbits to address radial structure, meaning on scales larger than the vertical thickness. Also, a large number of ISS 8–15 filter color scans with 3–5 km radial resolution were integrated and successfully implemented well before the RG and GF orbits, to address compositional variations, over a large range of illumination and viewing angles, as well as different solar hour angles to assess the role of Saturnshine and the wavelength variation of ring particle phase functions.

Much higher spatial resolution is needed to assess fine scale structural variations. Recall that the unique SOI observations (400 m resolution) were sparsely sampled, were of the unlit face, and were taken at a large relative velocity requiring short exposures and producing noisy images. On

the other hand, the RG and GF orbits provided similar 100–300 m resolution on the lit face as well as of the unlit face, and at low phase angles, with the opportunity to use smear removal tracking. Moreover, one new kind of observation was enabled during the RG and GF orbits; active radar backscattering. Radar observations (from the ground) opened the modern era of Saturn's Rings research 40 years ago, but their sensitivity decreases as distance to the fourth power, so they only became feasible for Cassini in these very close-in geometries. The Radar team did carry out three active radar backscattering radial profiles with the potential to reach several km radial resolution, but reduction of this sort of data has not been previously done by the team and is still in progress (see Section 3.2 Instruments Science Results chapter entitled RADAR). Indeed, as of this writing, a number of observations taken on the RG and GF orbits remain in the early stages of analysis. However, an overview of high resolution observations by ISS, VIMS, UVIS, and CIRS may be found in Tiscareno et al. [2019].

Ring microstructure (RN2a)

Conducts in-depth studies of ring microstructure such as self-gravity wakes, which permeate the rings.

Microstructure has the connotation of structure comparable in scale to the ring vertical thickness (see section entitled Gravitational Processes). During the CSM, a number of exceptionally high radial resolution scans were implemented of the lit and unlit faces, using smear removal tracking (the so-called SUPERHRES scans) and targeted observations of, for instance, the Keeler gap in the vicinity of Daphnis, the C-ring plateaus, and other specific regions of interest. Spatial clumping, of several different types and on scales still larger than the expected self-gravity wakes, is widely seen in images with these sub-km resolutions [Tiscareno et al. 2019a]. A number of specially designed Turnaround stellar occultations were prioritized and included; these are chord occultations in which the path of the star becomes tangent to the orbital direction at some radius. The implication is that radial stellar velocity vanishes and ultra-high radial resolution can be obtained, along with very good tangential resolution. Finally, the technique of variance analysis 4 has been widely applied and a variety of interesting differences seen from place to place. This sort of analysis is only getting underway [Colwell et al. 2018].

New ring structures (RN2b)

Performs focused studies of the evolution of newly discovered propeller objects. Extend to studies of streaky plateau structure.

A dedicated campaign to image selected giant propellers (> 1 km size) as often as possible was conducted over the last five years of the mission. This campaign yielded several hundred images that successfully targeted propellers, with rich sampling in time. Ongoing analysis of these images—for example, see section entitled Ring-Satellite Interaction) finds excursions from Keplerian orbit of diverse kinds, including both gradual trends and sharp changes of direction. In the RG orbits, three giant propellers were specifically targeted for close-flyby imaging, which

successfully revealed their detailed structure. Also in the RG orbits, high-resolution images of the Propeller Belts yielded the first full view of a size distribution in which the largest propellers are 4× to 5× larger than the smallest [Tiscareno et al. 2019a]. In the GF orbits, images of the plateaus spectacularly confirmed previous suspicions of streaky texture, and further revealed sharp-edged belts of textures (some streaky, some clumpy) at other locations in the main rings [Tiscareno et al. 2019b]. Most of these data encompass both the lit and unlit faces of the rings, and are still under reduction and analysis.

Saturn System Science Results

The possibility of young rings now has broadened to the possibility of a young inner icy moon (and ring) system. The evection resonance theory of Cuk et al. [2016] not only independently arrives at a similar timescale as ring ages, but also points to Saturn as the most likely planet to incur such a fate. More studies of the icy moon surfaces (especially cratering statistics) are needed to constrain the validity of this hypothesis, and the composition of the moons and rings needs to be taken into account together.

Along these lines, results obtained through the study of rings have led us to a new understanding of the deep interior of Saturn. The discipline, now known as Kronoseismology, is in its infancy, and has led to the suggestion of a diffuse core boundary and rapidly changing internal structure at Saturn, see section entitled Gravitational Processes. Recent results have even shown that the elusive deep interior rotation period of the planet can be determined very precisely by matching internal structure predictions with spiral waves seen in the C-ring [Mankovich et al. 2019].

CDA also detected 46 grains coming from the Interstellar Flux stream (its velocity apex or ram direction is known from the velocity of the solar system through the local diffuse Interstellar medium) and constrained their composition [Altobelli et al. 2016]. This profoundly important in situ determination of the composition of interstellar medium (ISM) grains complements and informs often ambiguous remote sensing determinations, see section entitled Ring Age and Origin. The grains populating the diffuse ISM; those detected here and the most easily studied by remote sensing, include Mg-rich silicates and, perhaps, iron metal or oxides, but are depleted in sulfur. By comparison, the silicates detected by CDA during the GF orbits were also Mg-rich, but showed no evidence of companion Fe metal or oxides. The ISM grains were quite homogeneous, probably by repeated processing in the ISM by shocks and radiation. As these grains become embedded in the dark, dense, presolar parent cloud; they accumulate more volatile organics and ices (apparently some sulfur-bearing ices) before flowing into the forming solar system. However, their very refractory mix of silicates and metal would not be expected to change at the low temperatures of these clouds.

Non-Saturn-System Science Results

Cassini ISS took nearly 1200 images of the Jovian ring system during its 6-month encounter with Jupiter … .

Cassini ISS took nearly 1200 images of the Jovian ring system during its 6-month encounter with Jupiter [Porco et al. 2003]. These observations constitute the most complete data set on the ring taken by a single instrument, both in phase angle (0.5°–120° at seven angles) and wavelength (0.45–0.93 μm through eight filters). The optical depth and radial profile of the main ring are consistent with previous observations. No broad asymmetries within the ring were seen, but possible hints of 1000 km-scale azimuthal clumps were detected. Throop et al. [2004] combined the Cassini ISS and VIMS observations with those from Voyager, HST, Keck, Galileo, and groundbased telescopes, and fit the entire dataset using a photometric model including microscopic silicate dust grains and larger, long-lived parent bodies. Main ring optical depths for the large bodies, and the dust, of about 1–5 × 10^{-6}, respectively, were obtained, and the grains appear to be nonspherical. The larger bodies must be very red between 0.4–2.5 μm wavelengths, and may have absorption features near 0.8 and 2.2 μm.

Unsolved Problems Suitable for Ongoing Research and Future Missions

Figure RINGS-2 shows a montage of views displaying Saturn's main rings structure.

Why is the interior of Saturn different from that of Jupiter (as seen by the RSS gravity passes) and, why are the mass irregularities inferred so different and so much larger than what are inferred from Kronoseismology spiral density and bending waves in the rings? Are these differences tied to the faster tidal evolution rates seen for the Saturnian moons than for the Jovian moons (the so-called larger Q for Jupiter than for Saturn)? What are the embedded mass concentrations responsible for the tesseral spiral density waves that rotate at harmonics of Saturn's spin rate, and moreover change with time?

The ring mass and in particular its radial distribution were not as well constrained as hoped, because of unexpected internal structure within Saturn. Only a total ring mass could be determined, and the B-ring component inferred by backing out the already very well-known A-ring and C-ring masses (from spiral density waves). This remaining uncertainty provides an opportunity for a future mission to use repeated close gravitational flybys to separate out and fully understand the apparently unusual and intriguing internal structure of the planet, from the radial mass distribution within the rings, hopefully at a few hundred km radial resolution even, and to determine which parts of the opaque B-ring actually hold how much of the mass. Better radial mass resolution would be useful in the C-ring also, because the possibility that the middle C-ring hides a fossil silicate rubble belt has implications for ring origin; it is currently constrained by a small handful of surface mass densities. There is some evidence that the visual wavelength

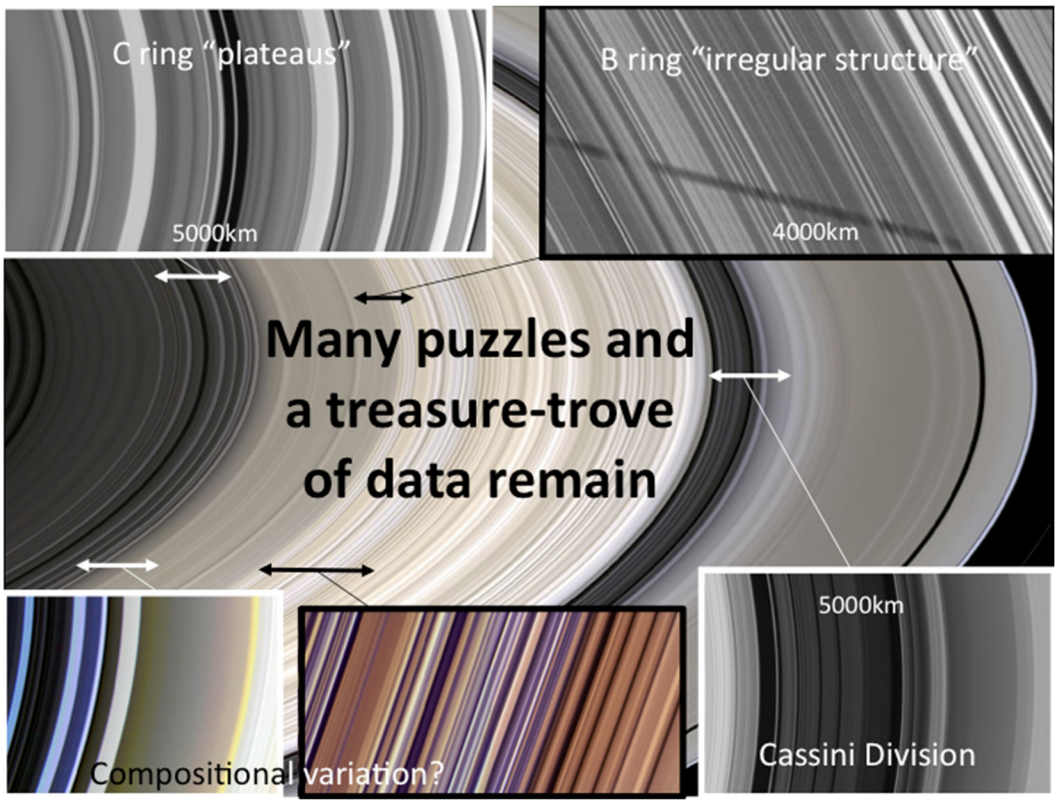

Figure RINGS-2: A montage of still-puzzling structure. A mosaic view of Saturn's main rings is shown in the central panel. Certain selected regions are indicated by double-header arrows, and by close-up images shown as insets.

spectra of the central C-ring differ from the otherwise similar Cassini Division; might this be another clue regarding a buried silicate belt?

The smooth, undulating 80 km scale irregular structure in the inner B-ring may be related to ballistic transport, but the array of finer-to-coarser scale structure in the middle and outer B-ring seems to be something different. Could it be some form of viscous overstability, operating at longer wavelengths than models show, and possibly coupling to the even larger scale azimuthal B-ring edge variations? In the region between 100,000–104,500 km, radio and stellar occultations both see successions of very sharp transitions between large and very large optical depth, for which no explanations exist. At the time of this writing, RSS occultations of the very densest B-ring regions, taken at the largest ring opening angles where they would be most likely to be even partially transparent, have not been analyzed or released, but are eagerly anticipated.

The outer C-ring hosts a series of 5–8 plateau features in optical depth, nearly symmetrically arrayed about the Maxwell gap which is now known to be caused by a 2:1 resonance with the strongest planetary internal vibration mode [Marley and Porco 1993; French et al. 2016b; Fuller 2014]; the reason why a dense, elliptical m = 1 ringlet dominates the gap, apparently caused by an m = 2 resonance, is not understood. A similar situation occurs at a Titan resonance in the C-ring, but that is an m = 1 resonance. The plateaus do not have any special association with resonances

from known or predicted planetary internal modes [Marley 2014]. They are odd in that their appearance as features is due primarily to locally abrupt changes in particle size distribution rather than surface mass density, see section entitled Size Distribution, and the following paragraphs. Moreover, ultra-high resolution Cassini images reveal a novel and unique streaky structure in the plateaus that is not understood [Tiscareno et al. 2019a].

Why is there a Cassini Division and why are there no embedded moonlets clearing its several empty gaps? It has been suggested that weak perturbations from the fluctuating B-ring edge might play a role [Hedman et al. 2010b]. Presumably the Cassini Division was originally cleared by a powerful Mimas 2:1 spiral density wave, at a time when the rings were continuous through the region [Baillié et al 2019] , but how did that early, vigorous evolution lead to today's quiet, banded structure? And, how are the moonlet-free C-ring gaps formed?

In the A-ring, a million propeller objects populate three distinct radial belts. Are these objects transient clumps that emerge from the background material with low, but finite probability and then disperse again? Giant propellers (found only outside the Encke gap) seem especially hard to create by spontaneous, or triggered formation. Gravitational encounters with smaller masses seem to explain their wandering behavior, but the mass clumps needed are larger than the largest ring particles and even typical self-gravity wakes. There are a few propeller objects in the B-ring, but their locations and abundances have not been well characterized. What else could be hiding in the densest parts of the B-ring? What causes the ghost gaps in the C-ring and outer Cassini Division?

In the F-ring, telltale signatures of embedded, relatively large objects are seen preferentially in strands where they are maximally compressed by Prometheus. If the semi-major axes of these newly created objects lie outside the stable true core (see section entitled F-ring), they will develop chaotic orbital perturbations, diffusing away from their formation location as their eccentricity increases, and ultimately recolliding sporadically with the F-ring core. Cycles of such activity may be expected (and there is some evidence from comparing Voyager and Cassini), but no systematic assessment has been obtained. Meanwhile, even the most recent hypothesis for the stability of the F-ring true core cannot explain the stable precession of dozens of separated arcs as a single, well defined ellipse. Could the (mostly unconstrained) mass of the F-ring be playing a role?

The systematic increase of the redness of the rings inwards across the B-ring remains a puzzle. In situ observations (albeit in the D-ring) seem to favor large organic molecules, polycyclic aromatic hydrocarbons (PAHs) or fragments of tholins, possibly containing N and maybe even O, as the UV absorber responsible for the ring redness. These red organics seem to be intrinsic to the dominant icy material. Whether or not organics also explain the weaker UV absorption seen in most of the icy moons will be an important clue regarding ring origin scenarios; such as recent ones that connect their origin to a moderately recent collisional erosion/destruction of pre-existing, mature, differentiated icy moons. Can organic material remain associated with liquid water when a moon differentiates, and remain with it when it freezes?

Unexplained microstructure is seen in many places across the rings, at optical depths large and small, in late, high-resolution images which have resolution even better than those taken at SOI, … .

Color and brightness variations within the rings on tens to hundreds of km scale have been interpreted as small-scale, optical-depth dependent regolith grain size variations, but models capable of treating the difficult ring radiative transfer problem have yet to be deployed in compositional analyses. That is, secondary optical-depth dependent effects (like collisional packing or smoothing of particle surfaces) may change the particle phase functions, or volume density effects may change the layer scattering function. Much more analysis needs to be done with more sophisticated, nonclassical radiative transfer models, fitting observations over wide ranges of illumination and viewing geometry, as well as assessing wider ranges of wavelength simultaneously, to understand the situation before compositional implications can be derived with confidence. Shadowing on the surely very ragged ring particle surfaces needs to be studied [Cuzzi et al. 2017]. Also on the subject of radiative transfer models, Cassini's three high-radial-resolution active radar backscattering scans require new models for their interpretation that can adequately treat coherent backscattering.

Unexplained jumps in particle size distribution are seen at a number of places in the rings where sharp edges appear in optical depth, but across these edges there are only small (or no) contrasts in surface mass density. Basically, this means the features are caused by abrupt changes in particle size distribution. The inner edge of the A-ring, where it transitions to the Cassini Division, is one such place. The series of C-ring plateaus, nearly symmetrically surrounding the Maxwell gap (which is known to be associated with a 2:1 resonance with a mode inside Saturn) are like that as well. What causes this effect? Why do the slopes and minimum or maximum sizes in generally powerlaw size distributions of ring particles vary from place to place? Are most particles porous throughout or do they conceal dense, solid cores?

Unexplained microstructure is seen in many places across the rings, at optical depths large and small, in late, high-resolution images which have resolution even better than those taken at SOI, as well as combinations of lit and unlit face geometries, lower smear, and higher signal to noise ratio [Tiscareno et al. 2019a]. The texture can change rather quickly with radius and is not always related to optical depth changes.

The process actually responsible for the initial formation of spokes; whether it be bursts of ionizing radiation from planetary superstorms, magnetic field instabilities, or impacts, remains unclear.

The Ballistic transport process usually believed to explain the sharp inner edges of the A-ring and B-ring, and hypothesized to explain the C-ring plateaus, has been modeled assuming the boundaries of these features manifested jumps in surface mass density without particle size changes, and we now know the underlying surface mass density is only slowly varying while the particle size changes abruptly. How do these new realizations affect the models? Could the ejection

velocity change from place to place, depending on the nature of the local particle regoliths? How will the results change under new assumptions about meteoroid impact flux and dynamical population? The theory of ring pollution and restructuring by meteoroid bombardment and ballistic transport needs to be tested more carefully against other structures and compositional profiles, and revised to capture more realistic impact outcomes and newly constrained incoming meteoroid fluxes. Matching radial scans of ring color and spectral reflectance with models of compositional evolution must incorporate new understanding about ring surface mass density, particle size, and viscosity. Inclusion of regolith thermal inertias would provide another handle on how particle surfaces respond to meteoroid bombardment.

More sophisticated models of impact chemistry and radiation chemistry are needed; both in micrometeoroid impacts on ring particles, possibly resulting in some C-O chemistry, and by nm-size grain impacts into the INMS entry chamber. INMS sees a variety of molecules (CH_4, CO_2, and NH_3 in particular) that are not evident in VIMS or HST-STIS spectra of the rings. Are some of these created in hypervelocity impacts, transforming absorbing carbon compounds into volatiles or transparent ices? If so (or if not) this would have implications for ring pollution and inferred ring age. How does the water ice throughout the rings remain crystalline given constant radiation and meteoroid bombardment? VIMS spectral and occultation observations strongly support crystalline ice.

Explanation for the geologically recent formation of the rings: We now have a new set of constraints, and even an appealing theoretical hypothesis to explore; however, we are still lacking a complete understanding as to how the rings formed in their current location, within Saturn's Roche limit, from a differentiated icy object with a trace, intimately mixed organic component, 250 million years ago, even given disruptive collisions near the current orbit of Rhea. Observations and interpretation of icy moon surfaces can contribute meaningful constraints.

CONCLUSION

This short review can in no way capture the depth and complexity of the analysis that has gone into every one of the incomplete list of ~200 publications cited here, each of them several years work for multiple scientists. Each of these papers has contributed one critical and unique stone to the edifice of knowledge we now possess about the rings of Saturn; stones all formed from bits returned by Cassini's spectacular 13-year mission. Nor can it adequately convey the even larger and deeper, still unanalyzed and uninterpreted amount of data so thoughtfully conceived, passionately argued for, painstakingly planned, obtained, carefully calibrated, and stored in the Planetary Data System that awaits the attention of future generations of ring scientists. However, we hope it can provide an idea of the scope of where we stand today, and hints at future directions of research. Even this summary would be different if it were written a year from now. The Cassini Rings Discipline Working Group has nothing but admiration and deep appreciation for the dedication of the hundreds of engineers and dozens of managers at Jet Propulsion Laboratory (JPL) who made this mission possible, some of whom may be lucky enough to return to Saturn on a future mission and help answer these outstanding questions.

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AO	Announcement of Opportunity
CAPS	Cassini Plasma Spectrometer
CDA	Cosmic Dust Analyzer
CIRS	Composite Infrared Spectrometer
CSM	Cassini Solstice Mission
FOV	field-of-view
GF	Grand Finale
HST	Hubble Space Telescope
INMS	Ion and Neutral Mass Spectrometer
IR	infrared
ISM	interstellar medium
JPL	Jet Propulsion Laboratory
KBO	Kuiper Belt object
MAPS	Magnetospheres and Plasma Science
MIMI	Magnetospheric Imaging Instrument
NIR	near-IR
PAH	polycyclic aromatic hydrocarbon
PDS	Planetary Data System
RADAR	Titan Radar Mapper
RG	Ring-Grazing
RSS	Radio Science Subsystem
RWG	Ring Working Group
SED	Saturn Electrostatic Discharge
SKR	Saturn Kilometric Radiation
SOI	Saturn Orbit Insertion
STIS	Space Telescope Imaging Spectrograph
TM	Traceability Matrix
UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph
VIMS	Visual and Infrared Imaging Spectrometer
WP	water products

SATURN

Before Cassini, scientists viewed Saturn's unique features only from Earth and from a few spacecraft flybys. During more than a decade orbiting the gas giant, Cassini studied the composition and temperature of Saturn's upper atmosphere as the seasons changed there. Cassini also provided up-close observations of Saturn's exotic storms and jet streams, and heard Saturn's lightning, which cannot be detected from Earth. The Grand Finale orbits provided valuable data for understanding Saturn's interior structure and magnetic dynamo, in addition to providing insight into material falling into the atmosphere from parts of the rings.

Cassini's Saturn science objectives were overseen by the Saturn Working Group (SWG). This group consisted of the scientists on the mission interested in studying the planet itself and phenomena which influenced it. The Saturn Atmospheric Modeling Working Group (SAMWG) was formed to specifically characterize Saturn's uppermost atmosphere (thermosphere) and its variation with time, define the shape of Saturn's 100 mbar and 1 bar pressure levels, and determine when the Saturn safely eclipsed Cassini from the Sun. Its membership consisted of experts in studying Saturn's upper atmosphere and members of the engineering team.

EXECUTIVE SUMMARY

The Executive Summary is organized into the 10 major discoveries that Cassini made about the planets during its 13 years at Saturn and its months-long flyby of Jupiter.

The planets themselves were an important scientific objective of the Cassini mission, and they are the focus of this Saturn Discipline Working Group (DWG) science results. The Executive Summary is organized into the 10 major discoveries that Cassini made about the planets during its 13 years at Saturn and its months-long flyby of Jupiter. Measurements for the future, after Cassini, are given at the end. The main parts are organized by objectives listed in the Cassini Announcement of Opportunity (AO) and the Traceability Matrix (TM) of the Cassini Solstice Mission (CSM). The bold items in parenthesis that appear with the 10 major discoveries in the Executive Summary refer to the sub-sections in the Saturn DWG Science Results and Saturn DWG Non-Saturn Science Results sections. Figures are found in these sub-sections.

1. **Great Storm on Saturn – (Storms (SN1b, SN2a))**

    a. **Storm Evolution.** Saturn's weather is generally quieter and blander than Jupiter's and Earth's, but every few decades a latitude band erupts with turbulent clouds, high winds, and lightning. Typically the disturbed region spreads eastward or westward around the planet and fades after a few months of violent activity. Five such eruptions, sometimes called great white spots, were observed from Earth during the period 1876–1990. Cassini was fortunate to be in orbit, routinely taking images and searching for radio signals from Saturn lightning, when the great storm of 2010–2011 began. The storm appeared on December 5, 2010 as a small dot in an Imaging Science Subsystem (ISS) image and a sudden start of lightning activity recorded by the Radio and Plasma Wave Science (RPWS) instrument. Within a few days, amateur astronomers were tracking its progress from Earth, and within a month a new set of observing commands had been uploaded onto the Cassini spacecraft to bring its powerful instruments to bear on the new target. Figure SATURN-7 shows an ISS image of the storm on February 25, 2011, after the storm's head, trailing westward, had wrapped around the planet and caught the tail. The giant storm of 2010–2011 is extensively reviewed by Sanchez-Lavega et al. [2018].

    b. **Lightning.** For months or years at a time, Saturn does not emit the broad-band radio signals called atmospherics (sferics) that are produced by lightning. In contrast, the great storm of 2010–2011 was emitting constantly, often faster than the RPWS counting rate of ten per second. The ISS is only ON when the shutter is open, for about 0.1 second depending on the filter, but sometimes it detects lightning. Figure SATURN-8 shows a color image, a superposition of three ISS

images in different filters taken in rapid succession. The blue filter happened to capture a lightning flash, which shows up as a blue dot near the right edge of the image. Further to the right, a second color image taken 30 minutes later at the same location failed to capture a lightning flash. The size of the observed flash is comparable to the depth from the tops of the clouds down to the light source, which is probably in the water cloud. This data could give an estimate of the amount of water on Saturn, and the analysis is ongoing.

c. **Ammonia Precipitation.** The great storm affected all levels in the atmosphere. Figure SATURN-9 [Janssen et al. 2013] shows images from 2009, 2010, and 2011 taken by the Cassini Titan Radar Mapper (RADAR) with its transmitter turned OFF. Operated this way, the instrument sees thermal radiation coming up through dry spots, which are gaps in the otherwise uniform distribution of ammonia vapor. The gaps show up as bright areas, and on March 20, 2011 the great storm, at 30–40° planetocentric latitude, shows up as a low-ammonia band [Sromovsky et al. 2016]. This tells us something about the updrafts and downdrafts, since the vapor falls out when the air is rising. The first models of this process have been published [Li and Ingersoll 2015], and the research is ongoing.

d. **Upward-Propagating Waves.** The great storm sent waves propagating up into the stratosphere, where they break and deposit their energy. The heating is strong enough to cause chemical changes of the stratospheric gases, which are still somewhat of a mystery. Figure SATURN-10 [Fletcher et al. 2011] shows an Earth-based image, left, and two infrared images taken by Cassini Composite Infrared Spectrometer (CIRS) on January 19, 2011. The center image records temperature in the upper troposphere, at the 200–500 mbar level, and the right image shows temperatures at the 1–10 mbar level. The stratospheric beacon stands out in the right image.

e. **Temperatures, Molecular Hydrogen, and Heat Budget.** Figure SATURN-11 [Achterberg et al. 2014], from Cassini CIRS, shows evidence of air being dredged up from below. The top two panels show tropospheric temperature before and after the storm, and the band from 30–40° planetographic has warmed by several degrees. The bottom two panels show the two chemical states (nuclear spins parallel and nuclear spins anti-parallel) of molecular hydrogen H_2 before and after the great storm. The 30–40° band shows a low para fraction, which indicates that the air has risen from below cloud base. Figure SATURN-4 [Li et al. 2015] shows the thermal emission of the planet, in units of W m^{-2}, also from Cassini CIRS. Comparing the years before and after 2011, it is clear that the storm increased the thermal emission by 5–10% in the 30–40° latitude band, and that the anomaly persisted for several years. These details are important for understanding why Saturn erupts and are a necessary test of atmospheric models.

2. Saturn's Rotation and Interior – (Saturn's Rotation Rate (SN1a))

a. **Rotation.** The giant planets reveal their rotation in several ways—from cloud motions in the atmosphere, from the wobble of the internally-driven magnetic field, from radio waves, from the equatorial bulge, and for Saturn at least, from internal oscillations revealed in slight eccentricities in the orbits of ring particles. Cloud motions have two problems. Different latitudes give different periods ranging from about 10 h 12 m to about 10 h 40 m, and the atmosphere can slide relative to deeper levels. Saturn's internally-driven magnetic field is aligned within 0.06° of the rotation axis [Cao et al. 2011], so it does not wobble. As a random event, such alignment is highly improbable, given that the other giant planets are misaligned by tens of degrees and the probability goes as the area on the surface of the sphere rather than the angle from the pole. Voyager detected radio waves with a period of 10 h 39 m 22 s, but the radio periods turned out to vary over the years in ways that strongly suggested they originated in the upper atmosphere and magnetosphere.

b. **Gravity.** The other methods, involving gravity, are being developed and tested. Rotation causes the planet to bulge at the equator, but to interpret the shape it is necessary to know the equation of state to high accuracy. The shape of the atmosphere just gives the rotation of the atmosphere. The axisymmetric components of the gravity field indicate that the zonal winds extend 9000 km down into the fluid interior [Iess et al. 2019; Galanti et al. 2019]. The depth is greater than that for Jupiter, and that is consistent with the greater depth on Saturn at which magnetic drag reduces the winds to zero. The method involves tracking the orbit of the spacecraft using the Doppler shift of the craft's radio signal, which is observed to high precision.

c. **Ring seismology.** The orbits of Saturn's ring particles are exquisitely sensitive to non-axisymmetric (tesseral) harmonics of the gravity field. These could be due to normal mode oscillations in Saturn's interior or masses floating in the interior and rotating with it. Figure SATURN-15 [Hedman and Nicholson 2014] shows observed periods that are close to the atmospheric periods and are therefore likely be the signature of floating masses. The observed periods are just as diverse as those derived from cloud motions, which may indicate floating masses moving at different speeds. The frequencies of the normal modes depend on the planet's rotation. The implied rotation period turns out to be intermediate between the shortest and longest atmospheric periods defined from cloud motions at different latitudes [Mankovich et al. 2019]. Although the possibility of using the rings as a seismometer was predicted before Cassini, there was no guarantee that the irregularities inside the planet would be large enough.

3. **Energy for the Zonal Jet Streams – (Atmospheric dynamical processes (S_AO2))**

    a. **Mean Zonal Winds.** The eastward-flowing and westward-flowing jet streams are an iconic feature of giant planet atmospheres. They are remarkably fast and remarkably steady in time by terrestrial standards. Figure SATURN-18 [Porco et al. 2003] shows the zonal jet streams for Jupiter. The black curve is from Cassini ISS data in late 2000, and the red curve is from Voyager data in mid-1979. The jets are remarkably steady over this interval of 21 years. Figure SATURN-5 [Garcia-Melendo et al. 2011b] shows Saturn data from Cassini ISS. The black curve represents data from the 350 to 700 mbar levels, and the red curve represents data from 100 to 200 mbar. The differences are small except for a latitude band within ±15° of the equator. This could be part of a 15-year periodicity that resembles the quasi-biennial oscillation in the stratosphere of Earth. We have more to say about that oscillation in the section entitled Saturn DWG Non-Saturn Science Results.

    b. **Eddy Input.** Figure SATURN-13 [Del Genio and Barbara 2012] and Figure SATURN-19 [Salyk et al. 2006] show how eddies are pumping energy and momentum into the jets for Saturn and Jupiter, respectively. Both studies use Cassini ISS data. An eddy in this context is a departure of wind from the zonal mean. The eddy eastward wind u′ is the residual after the mean zonal wind has been subtracted off, and similarly for the eddy northward wind v′. The zonal means of u′ and v′ are zero by definition, but the mean of their product, $\overline{u'v'}$, may be non-zero. Multiplied by the density, this quantity is the northward flux of eastward momentum. If this quantity has the same sign as $\partial\bar{u}/\partial y$, which is the increase of the mean eastward wind with latitude, then the eddies are putting energy into the jets and not the reverse. Figures SATURN-13 and SATURN-19 show that this is the case. The data are less noisy for Jupiter because Jupiter has more small-scale features with which to measure winds from a series of images. This type of eddy mean-flow interaction is an important topic in fluid dynamics and atmospheric science, and the giant planets provide the best examples.

4. **Elemental Abundances and Chemical Tracers – (Composition and chemistry (SN1c); Saturn Formation and Evolution (S_AO5))**

    a. **Helium.** For the Sun, the abundances of major elements relative to hydrogen are known to better than ±10%. Jupiter and Saturn come close to solar composition, but the actual ratios range from less than 1 to at least 10. Each element tells its own story of how and when it was incorporated into the giant planet when it was forming and how the atmospheric ratio has evolved since then. Helium, being the second most abundant element after hydrogen, has special relevance. Direct detection by mass spectrometry when the spacecraft is dipping into the

exosphere on its final proximal orbits is possible, but the determination of the planet's He/H ratio involves extrapolating down to the well-mixed troposphere and is difficult. Remote sensing is difficult because helium has no spectral signature at visible or infrared wavelengths, so one has to use its effect on the molecular mass. Traditionally this is done by finding temperature as a function of pressure from infrared radiometry and then finding density as a function of altitude by preforming an occultation. Hydrostatic equilibrium then gives density as a function of pressure. With T, P, and density, one can solve for the molecular mass. Another approach uses the difference between He and H_2 in their effects on the infrared spectrum of hydrogen itself. The most recent estimate [Koskinen and Guerlet 2018] uses Cassini UVIS for the occultations and CIRS for temperature versus pressure. They get a helium mass fraction Y of 0.16−0.22, which is about 70% of the protosolar mass fraction of 0.27, implying that a certain amount of settling has occurred in Saturn's interior.

b. **Carbon.** The C/H ratio is perhaps the most accurately known ratio of all elements beyond helium. This is because its molecular form, methane, does not condense at Saturn temperatures and is not readily destroyed in chemical reactions. Cassini CIRS probes the far-infrared rotational lines of the molecule and has determined a volume mixing ratio of $(4.7 \pm 0.2) \times 10^{-3}$, corresponding to a C/H enrichment relative to solar of 10.4. This is more than a factor of 2 greater than that for Jupiter and points to a fundamental difference between the gas giants' origin and evolution. The O/H ratio is largely unknown because its molecular form, water, condenses out at the 15–20 bar level, which is well below the levels reachable by remote sensing. CO and H_2O, which are observed in trace amounts in the upper atmosphere, are probably supplied by comets. Without direct observation, the best one can do is to assume that the enrichment factor relative to solar of O/H is the same as that of C/H.

c. **Phosphorus, Arsenic, and Nitrogen.** Although phosphine, PH_3, is also enriched relative to solar by a factor of ~10, its abundance is highly variable and is often used as tracer of vertical motion. The standard view is that PH_3 is brought up from below on updrafts and is destroyed by sunlight in the upper troposphere and stratosphere. Arsine (AsH_3) is supposed to work the same way, and so is ammonia, although it is removed from the upper troposphere by precipitation rather than destruction by sunlight. However, Figure SATURN-2, from Cassini Visual and Infrared Mapping Spectrometer (VIMS) [Fletcher et al. 2011], does not tell a consistent story according to this picture. NH_3 shows a high mole fraction at the equator, consistent with upwelling there and downwelling on either side at 10–12° latitude, but PH_3 and AsH_3 show low abundances at the equator. Low para fraction, discussed in connection with Figure SATURN-11, also implies upwelling at the equator—an observation dating back to Voyager. On the other hand, the Cassini CIRS data [Fletcher et al. 2009a] show a maximum of PH_3 at the equator, which seems to contradict the Cassini VIMS data (Figure SATURN-

2). All the data are good, and the resolution may be that there are two circulations, one on top of the other, with rising motion at high altitude and sinking motion deeper down. This is compatible with all the data, since VIMS is sensitive to deeper levels, 1.3 to 4 bars, where the equatorial downwelling might occur, and CIRS is sensitive above the 1.3 bar level, where the equatorial upwelling might occur. These complications are one of the surprises of the Cassini mission, and tell us important things about how atmospheres work. Upwelling and downwelling are what drive atmospheric circulations and give energy to the winds.

5. **Hexagon and Polar Vortex – (Storms (SN1b, SN2a); Atmospheric dynamical processes (S_AO2))**

a. **Discovery.** Saturn has five or six eastward jets in each hemisphere, but only the one at 75° meanders in latitude, forming a six-lobed pattern. Small clouds within the jet move eastward along the hexagonal pattern at 100 m s^{-1}, but the pattern stays stationary in a reference frame close to Saturn's radio emissions. There is no consensus on why only this jet meanders, although there are numerical models and laboratory experiments that can simulate the phenomenon, given the right boundary and initial conditions. The hexagon was discovered in images taken by the two Voyager spacecraft as they flew past Saturn in 1980 and 1981. It was re-discovered in infrared VIMS images in 2006. ISS images had to wait until the start of spring in the northern hemisphere when the North Pole was in full sunlight. Figure SATURN-12 shows a false color image taken on November 27, 2012. The MT3 and MT2 images, which are dark where the light is passing through methane gas, are projected as blue and green, respectively. The CB2 image, which is not sensitive to methane absorption, is projected as red. The color balance is chosen to make the planet's atmosphere look realistic. The rings look bright blue because there is no methane gas between the rings and the spacecraft.

The hexagon was discovered in images taken by the two Voyager spacecraft as they flew past Saturn in 1980 and 1981.

b. **Polar Cyclone.** The red spot in the center of Figure SATURN-12 extends from the pole to a latitude of 88–89°. It looks red in the false-color image because the clouds are deep and methane gas absorbs the sunlight before it can reflect off the clouds and reach the spacecraft. There is a similar zone in the south, and there the clouds just outside the zone appear to cast shadows, either because they are 50–70 km higher than the clouds inside [Dyudina et al. 2009] or because there is a step-wise poleward decrease in optical depth of the overlying haze [Sromovsky et al. 2019]. The outer ring of clouds circulates counterclockwise around the pole at a speed of 100 m s^{-1}. In these respects the structure is like a

tropical cyclone on Earth—a hurricane—but it is not in the tropics and it is not drawing energy from an ocean underneath. It is known that cyclonic vortices drift poleward, but how they originate and why there is only one on Saturn is still being investigated.

6. **Equatorial Oscillation – (Saturn's Winds (SC1b))**

   a. **Quasi-biennial oscillation.** On Earth, waves generated by storms in the troposphere propagate into the stratosphere and break, depositing energy and momentum there. A symmetry-breaking instability develops in which the eastward waves break preferentially at altitudes where the mean zonal wind is eastward, and similarly for the westward waves and the westward wind. The result is that the mean zonal wind forms an oscillation with altitude that propagates downward with time. The amplitude of the waves sets the period, and on Earth it averages out to 22 months and is known as the quasi-biennial oscillation (QBO). The period of the oscillation on Jupiter is ~4 years, and on Saturn it is ~15 years. Figure SATURN-6 [Fouchet et al. 2008], from Cassini CIRS, documents the oscillation in greater detail, as reflected both in the temperature field, upper panel, and its associated zonal velocity, lower panel. The wave generation mechanism is still uncertain, but presumably the longer period as one moves out in the solar system is due to the lower energy flux available to drive the waves.

7. **Upper Atmosphere – (Seasonal Variations (SC1a); Upper atmosphere (SC2a); Aurora (SC2a); (SN1c))**

   a. **Stratosphere.** Upwelling and downwelling in the stratosphere are detected by chemical tracers as in the troposphere. For both Saturn and Jupiter, the best tracers are probably ethane and acetylene, C_2H_6 and C_2H_2, respectively. Both gases are formed from photodissociation of methane at mbar levels and are destroyed in the troposphere where they revert back to methane. Thus an enhancement at the 200 mbar level is indicative of downwelling.
   Figure SATURN-20 [Nixon et al. 2007] shows the picture for Jupiter, as derived from Cassini CIRS data. C_2H_2 has a shorter lifetime once it is formed than C_2H_6 does, so it decays on the downdrafts faster than C_2H_6. Thus the lower panel of Figure SATURN-20 shows downdrafts at the pole and updrafts at the equator. The upper panel shows that the time constant of this circulation is longer than the lifetime of the C_2H_2 molecule, because it has decayed before reaching the 200 mbar level.

   b. **Thermosphere.** An ongoing mystery is why the thermosphere is so warm outside the polar auroral zones. The problem is illustrated in Figure SATURN-16 [Koskinen et al. 2015], which compares Cassini Ultraviolet Imaging Spectrograph (UVIS) observations with Voyager observations and with a 3-D general

circulation model. The model result is represented by the smooth dot-dashed line, and it is significantly low (colder) equatorward of ±60° in both hemispheres. The problem is that the air from the polar regions, heated by auroral currents, cools before it reaches the lower latitudes. One proposal is that drag forces due to atmospheric gravity waves, which are often overlooked in the models, could speed up the pole-to-equator circulation [Müeller-Wodarg et al. 2019]. The Cassini data confirm that the observations are good and not restricted to the Voyager era.

8. **Seasonal Change, Energy Budget and Temperatures – (Temperature and clouds (S_AO1); Saturn Formation and Evolution (S_AO5))**

   a. **Radiation.** Seasonal change begins with the changing distribution of sunlight falling on the two hemispheres. The rings amplify this effect by putting the winter hemisphere in shadow, but the effect on temperatures is moderated by the large heat capacity of Saturn's deep atmosphere and the small radiative fluxes far out in the solar system. Figure SATURN-4 [Li et al. 2015], which we have already discussed in connection with the great storm, also shows the reduction of emitted long-wave radiation in the south and increase in the north as the latter changed from early winter in 2004 to late spring in 2013.These changes in the emitted radiation reflect changes in temperature at the emitting levels, but they also could reflect changes in gaseous and cloud opacity.

   b. **Temperature Change.** The emitted radiation of Figure SATURN-2 includes the radiation at all wavelengths. Radiation at specific wavelengths allows one to probe to different levels and deduce temperature as a function of latitude and altitude. Figure SATURN-3 [Fletcher et al. 2010] shows this for years 2005 and 2008, also using CIRS data. The south is warmer than the north in both years, although most of the hemispheric contrast and most of the difference between 2005 and 2008 is confined to high altitudes. There the sunlight is strongest and the atmospheric density is low, so the seasonal effect on temperature is greatest.

   c. **Chemical Change.** The other seasonal effect is on the chemistry of the atmosphere. Figure SATURN-1 was taken by the ISS in 2004 as Cassini was approaching Saturn. It was summer in the south, and the sunlight was driving a rich hydrocarbon chemistry, resulting in an orange haze of small particles. The north was mostly shielded from sunlight, and the skies were blue, as shown by the sliver of atmosphere visible above the ring. Toward the end of the mission, the colors reversed. The rate of the shift reveals much about the photochemical processes that produce the haze.

9. **Lightning – (Saturn Lightning Sources and Morphology (S_AO6, SN2a))**

    a. **Quiet Times.** We have already mentioned that the Cassini RPWS recorded lightning strikes from the 2010–2011 great storm at rates exceeding 10 s^{-1}. But normally Saturn is a quiet place, with no lightning storms at all, which contrasts starkly with Earth's average of 2000 storms per day. Figure SATURN-14 [Dyudina et al. 2007] shows the Saturn electrostatic discharge counts, SED's, which are roughly equivalent to lightning strikes, over a 2-year period starting in 2004. The SED's are detected by the RPWS instrument, which is ON continuously. The lower panel shows ISS coverage of latitudes −34° to −36°, where all the storms were occurring, and it is clear that no storms were present when the RPWS was detecting nothing.

10. **Jupiter Colors and Movies – (Jupiter atmospheric dynamics (J_AO1))**

    a. **Chromophores.** The agent that colors the particles in Jupiter's clouds has been a mystery for decades. The principal cloud-forming gases are NH_3, H_2S, and H_2O, but they form particles that are white. Disequilibrium species involving phosphorus, sulfur, and/or hydrocarbons have been suggested, and it is difficult to choose one candidate over another. A new, Cassini-era candidate, a red (blue-absorbing) chromophore made from ammonia reacting with acetylene has been proposed [Carlson et al. 2016; Baines et al. 2019]. It seems to account for almost all of the color variation on the planet [Sromovsky et al. 2017]. Figure SATURN-17 shows the highest-resolution, full-disk color mosaic of Jupiter ever taken.

    b. **Movies.** With its powerful imaging system, Cassini took images continuously during its 70-day approach to Jupiter at the end of year 2000. A 70-day movie shows the clouds in motion at all longitudes and latitudes up to within ~10 degrees of the poles. The movie can be seen at these site(s): https://photojournal.jpl.nasa.gov/catalog/PIA03452; https://photojournal.jpl.nasa.gov/catalog/PIA03453; https://photojournal.jpl.nasa.gov/catalog/PIA03454. It is a modern sequel to the successful Voyager approach movie and an important research tool for measuring winds and the evolution of cloud features.

11. **For the Future, the Next Generation**

    a. **Water.** Measure the global water abundance and determine its role in bringing heat to the surface. Determine the role of moist convection in maintaining the large-scale motions. A Saturn probe to the base of the water cloud is a challenging but possible objective. Juno-type microwave remote sensing, in addition, is potentially valuable.

b. **Ammonia.** Determine the global ammonia abundance, and map its distribution with depth over the planet. Currently available data are good down to only about 3 bars, which do not necessarily represent the deep well mixed abundance of ammonia. A Saturn probe to 10 bars could make this measurement, and microwave remote sensing is potentially valuable.

c. **Noble Gases.** Determine Saturn's noble gas abundances including helium, and their isotopic ratios, as done for Jupiter by the Galileo probe. A Saturn probe could measure noble gases to exquisite precision.

d. **Interior Motions.** Determine Saturn's rotation period if such a number exists, or determine the spread of periods if differential motions persist into the interior. Document the time dependence of motions in Saturn's interior.

e. **Weather Layer.** Determine the vertical profiles of temperature, winds, clouds, condensable gases, longwave and shortwave radiation, and turbulence levels. A cloud-resolving model like those used in tropical meteorology, but tailored to the giant planets, is both timely and valuable. Again, a Saturn probe is needed.

f. **Interior.** Using the power of ring seismometry and gravity sounding, improve the understanding of Saturn's internal equation of state, mass distribution, composition, and temperature distribution. Develop a fully coupled interior/weather-layer model as done for Earth's oceans and atmosphere.

SATURN DWG SUMMARY

Cassini's Saturn science objectives were overseen by the Saturn DWG. This group consisted of the scientists on the mission interested in studying the planet itself and phenomena which influenced it. Leadership consisted of Interdisciplinary Scientists (IDS). The Saturn DWG would meet roughly three times a year at the Project Science Group (PSG) meetings and occasionally via telecon to discuss the executed and upcoming planned Saturn science, in addition to any high-priority science issues that the Project Scientist would request. This group would participate in tour selection (Prime, Equinox, and Solstice, and Grand Finale), define campaigns for focused Saturn science and define activities that eventually become the highest-priority observations—Pre Integration Event (PIE) and Cassini Apoapses for Kronian Exploration (CAKE)—to be negotiated with other Cassini DWGs.

The day-to-day work of the Saturn DWG was carried out by the Saturn Target Working Team (TWT). The Saturn TWT consisted of a subset of Saturn scientists who were interested in negotiating on a weekly basis with other scientists to layout a timeline of observations to be conducted in Saturn-centric windows of time (segments) within the constraints of the

Cassini's Saturn science objectives were overseen by the Saturn DWG.

spacecraft and of the mission. Its leadership consisted of an appointed Saturn scientist, a supporting Investigation Scientist, and one or more Science Planning Engineers. This group would implement both individual stand-alone team observations and campaign templates involving multiple of Cassini's instruments. Most issues were nicely negotiated and resolved during the weekly (and ultimately monthly) telecons. Where there were major science conflicts to be resolved amongst the scientists, the Saturn DWG would offer recommendations for their resolution.

The SAMWG was formed by the Project Scientist to specifically answer the following three questions: 1) characterize Saturn's uppermost atmosphere (thermosphere) and its variation with time; 2) define the shape of Saturn's 100 mbar and 1 bar pressure levels; and 3) determine when the Saturn safely eclipsed Cassini from the Sun. Its membership consisted of experts in studying Saturn's upper atmosphere and members of the engineering team. The SAMWG reported to the Saturn DWG on a periodic basis.

SATURN KEY OBJECTIVES

Cassini's Saturn and Jupiter science objectives originate from those spelled out in the AO and CSM TMs. They are briefly called out here.

- **Saturn Temperature, Clouds, Composition (S_AO1)**
  - **Temperature and clouds (S_AO1)** – Determine temperature field, cloud properties, and composition of the atmosphere of Saturn.
  - **Composition and chemistry (SN1c)** – Measure the spatial and temporal variability of trace gases and isotopes.
- **Saturn Winds and Weather (S_AO2)**
  - **Seasonal Variations (SC1a)** – Observe seasonal variations in temperature, clouds, and composition in three spatial dimensions.
  - **Saturn's Winds (SC1b)** – Observe seasonal changes in the winds at all accessible altitudes coupled with simultaneous observations of clouds, temperatures, composition, and lightning.
  - **Storms (SN1b, SN2a)** – Observe the aftermath of the 2010–2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon. Monitor the planet for new storms and respond with observations when they occur.
  - **Atmospheric dynamical processes (S_AO2)** – Measure the global wind field, including wave and eddy components; observe synoptic cloud features and processes.

  - **Saturn Lightning Sources and Morphology (S_AO6, SN2a)** – Investigate the sources and the morphology of Saturn lightning—Saturn Electrostatic Discharges (SED)—lightning whistlers.
- **Saturn Interior Structure and Rotation (S_AO3)**
  - **Saturn's Rotation Rate (SN1a)** – Determine Saturn's rotation rate and internal structure despite the planet's unexpected high degree of axisymmetry.
  - **Saturn Formation and Evolution (S_AO5)** – Provide observational constraints (gas composition, isotope ratios, heat flux, …) on scenarios for the formation and the evolution of Saturn.
- **Aurora, Chemistry, and Upper Atmosphere (SC2a)** – Observe the upper atmosphere and the aurora as it changes on all time scales—minutes to years—and is affected by seasonal and solar cycle forcing.
- **Jupiter atmospheric dynamics (J_AO1)** – Extend the time for studies of atmospheric dynamics beyond the period accessible to the Galileo nominal mission.
- **Jupiter Global Atmospheric Structure and Composition (J_AO2)** – Infer global atmospheric thermal structure and composition with instrumentation not carried by the Galileo Orbiter, complementing the local in situ measurements of the Galileo Probe.
- **Venus atmosphere observations** – No specific objectives were called out.
- **Cruise Planetary and Stellar Internal Oscillations (C_AO5)** – Attempt to detect internal oscillations of Saturn, Jupiter, and some stars.
- **Saturn Ionosphere-Magnetospheric Interaction (S_AO4)** – Study the diurnal variations and magnetic control of the ionosphere of Saturn.

Saturn Science Assessment

Table SATURN-1 is an assessment of data collected to satisfy an objective. It is not as assessment of the status of data analysis/publications.

Table SATURN-1. Science Assessment.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

Saturn DWG Science Objectives	AO and TM Science Objectives	Saturn DWG Assessment	Comments (if yellow, partially fulfilled)
Saturn Temperature, Clouds, Composition	S_AO1		
– Temperature and clouds	S_AO1		
– Composition and chemistry	SN1c		
Saturn Winds and Weather	S_AO2		
– Seasonal variations	SC1a		

Table SATURN-1. Science Assessment.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

Saturn DWG Science Objectives	AO and TM Science Objectives	Saturn DWG Assessment	Comments (if yellow, partially fulfilled)
– Saturn's winds	SC1b		
– Storms	SN1b, SN2a		
– Atmospheric dynamical processes	S_AO2		
– Saturn lightning	S_AO6, SN2a		
Saturn Interior Structure and Rotation	S_AO3		
– Saturn's rotation rate	S_AO3, SN1a		
– Saturn formation and evolution	S_AO3, S_AO5		
Aurorae, Chemistry, and Upper Atmosphere	SC2a		
– Upper atmosphere	SC2a		
– Aurora	SC2a		
Jupiter Atmospheric Dynamics	J_AO1		
– Dynamics observations	J_AO1		
– Dynamics modeling and theory	J_AO1		
Jupiter Global Atmospheric Structure and Composition	J_AO2		
– Thermal and cloud structure	J_AO2		
– Composition and chemistry	J_AO2		
Venus Atmosphere Observations	N/A		
Cruise Planetary and Stellar Internal Oscillations	C_AO5		NOTE: Planetary and stellar cruise observations were not conducted.
Saturn Ionosphere-Magnetosphere Interaction	S_AO4		NOTE: This is primarily a MAPS WG objective. See their objectives MN1b, MN1c, MN2a, and MC1a. The green assessment reflects the status of both WG's data analysis.

SATURN DWG SCIENCE RESULTS

Saturn Temperature, Clouds, Composition (S_AO1)

- **Temperature and clouds (S_AO1)** – Determine temperature field, cloud properties, and composition of the atmosphere of Saturn.

The temperature field, cloud properties, and composition are an interacting system that controls the energy budget of the planet and the clouds and haze that we see in the planet's atmosphere (Figure SATURN-1). Clouds are a tracer of the motion. They form on updrafts, which are part of the energy cycle that controls the zonal winds. Also, clouds interact with the temperature field through condensation and evaporation. Cassini, with its comprehensive array

of instruments and unique perspective from different positions in the orbit, has contributed critical data on all of these objectives. In addition, Cassini has spawned exploration of Saturn from Earth-based telescopes.

Timed with the start of Cassini's exploration of the Saturn system, Beebe [2005] presented the case for comparative study of the outer planets. Papers on the Cassini instruments and their ability to measure clouds and haze include: Baines et al. [2005] on VIMS; Porco et al. [2005] on ISS; Flasar et al. [2005] and Jennings et al. [2017] on CIRS; and Janssen et al. [2013] on the Cassini RADAR radiometer. Schinder et al. [2015] give the techniques for probing the electron density and temperature structure with radio occultations.

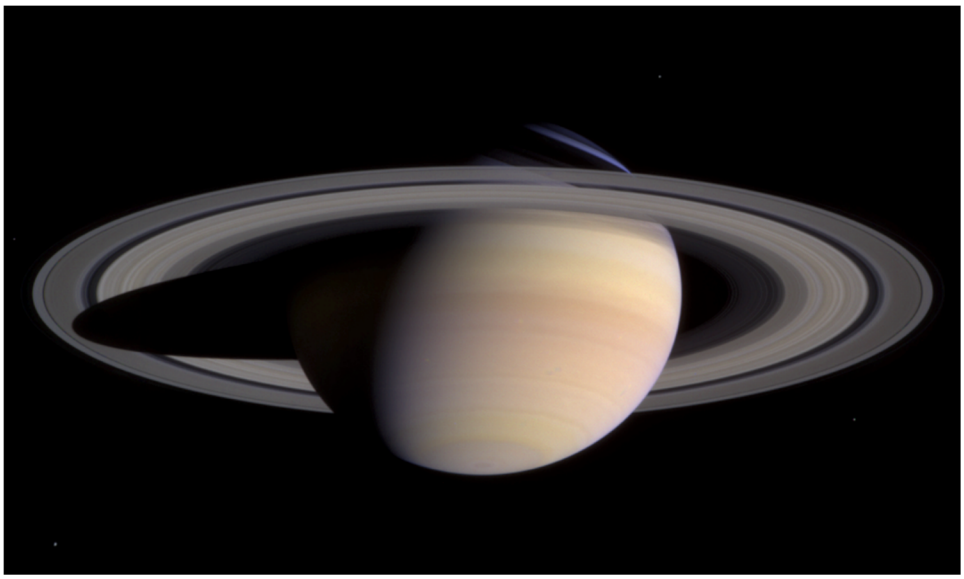

Figure SATURN-1. Image taken by the ISS in 2004 as Cassini was approaching Saturn. It was summer in the south, and the sunlight was driving a rich hydrocarbon chemistry, resulting in an orange haze of small particles. The north was mostly shielded from sunlight, and the skies were blue, as shown by the sliver of atmosphere visible above the ring (PIA05389).

Banfield et al. [1998] described the use near-infrared (IR) spectroscopy from the 5-m Hale telescope at Palomar, California, to measure the altitudes and scattering properties of clouds and haze. Similarly, Sanchez-Lavega et al. [2004] described Hubble Space Telescope observations of cloud morphology in Saturn's atmosphere. Temma et al. [2005] used Earth-based telescopic observations to probe the vertical structure of Saturn's cloud layers. Using Hubble Space Telescope (HST) data, Perez-Hoyos et al. [2006] documented short-term variability (weeks to months) associated with cloud reflectivity of the belts and zones. West et al. [2009] gives a comprehensive survey of clouds and haze in Saturn's atmosphere as inferred from Cassini VIMS and ISS, as well as HST and other Earth-based telescopes. Ingersoll et al. [2018] present images taken during the last few months of the mission at resolutions down to 0.5 km per pixel. The interesting features include filamentary clouds coherent over 20,000 km and puffy clouds resembling terrestrial cumulus.

Fletcher et al. [2007b] used Cassini CIRS data to probe the vertical and horizontal temperature structure and its relation to the belt and zone cloud structure. Roman et al. [2013] used ISS data to probe the layered cloud structure from the haze layers at 40 mbar to tropospheric clouds at 2.5 bar. Laraia et al. [2013] used Cassini RADAR radiometer data to probe the vertical distribution of NH_3 to depths below its nominal cloud base. Barstow et al. [2016] used Cassini VIMS to document a photochemical origin for the stratospheric haze and either NH_3 or NH_4SH for the deeper tropospheric cloud. Using Cassini ISS data, Dyudina et al. [2016] and Perez-Hoyos et al. [2016] quantified the way the atmosphere scatters light, including the phase function and the spherical and Bond albedos.

Del Genio et al. [2009] give a comprehensive review of Saturn's atmospheric structure and dynamics. The early data come from the Voyager flybys and Earth-based telescopes and then from the remote-sensing instruments on Cassini. The review covers the deep atmosphere, the troposphere, the stratosphere, and dynamical features such as the jets, waves, discrete features. Del Genio and Barbara [2016] provide a classification scheme based on cloud morphology for revealing the underlying dynamics.

- **Composition and chemistry (SN1c)** – Measure the spatial and temporal variability of trace gases and isotopes

The gaseous composition of a giant planet atmosphere varies due to several processes: condensation and precipitation that remove the particles from the gas, updrafts and downdrafts that alter the chemical equilibrium of the various reacting species, and photochemical reactions that lead to dissociation and/or ionization (Figure SATURN-2). The reacting species include CH_4, NH_3, PH_3, and their chemical byproducts like C_2H_2 and C_2H_6. In addition, the upper atmosphere may receive molecules and solid particles from the rings and satellites.

Fouchet et al. [2009] give a comprehensive review of Saturn composition and chemistry. Fletcher et al. [2011a] review the elements that appear in simple compounds that are detectable in VIMS spectra, including PH_3, NH_3, AsH_3, GeH_3, CO, CH_3D, and $^{13}CH_4$. Howett et al. [2007] and [Guerlet et al. 2009] focus on C_2H_2, C_2H_6, and C_3H_8, which are produced in the stratosphere by photodissociation of methane. They use Cassini CIRS data to infer a stratospheric circulation from south to north during the southern summer. Guerlet et al. [2010] added C_3H_8 and CH_3C_2H to the list of tracers and again found evidence of upwelling in the south and downwelling in the north. Fletcher et al. [2007a] also used CIRS data, focusing on phosphine, PH_3. It is in chemical equilibrium below the cloud tops and is destroyed by photolysis in the stratosphere. The altitudes of sources and sinks are opposite to that of C_2H_2 and C_2H_6, but the inferred circulation is similar.

Cassini CIRS data stimulated photochemical modeling in order to quantify the inferred circulations [Dobrijevic et al. 2011; Hue et al. 2015]. The data also stimulated laboratory measurements [Auwera et al. 2007; Devi et al. 2014] to refine the infrared absorptions of these gases. Gases like CH_4, C_2H_2, and C_2H_6 absorb and emit in the infrared, and their spatial and temporal variations create temperature variations, which in turn affect the circulation. These

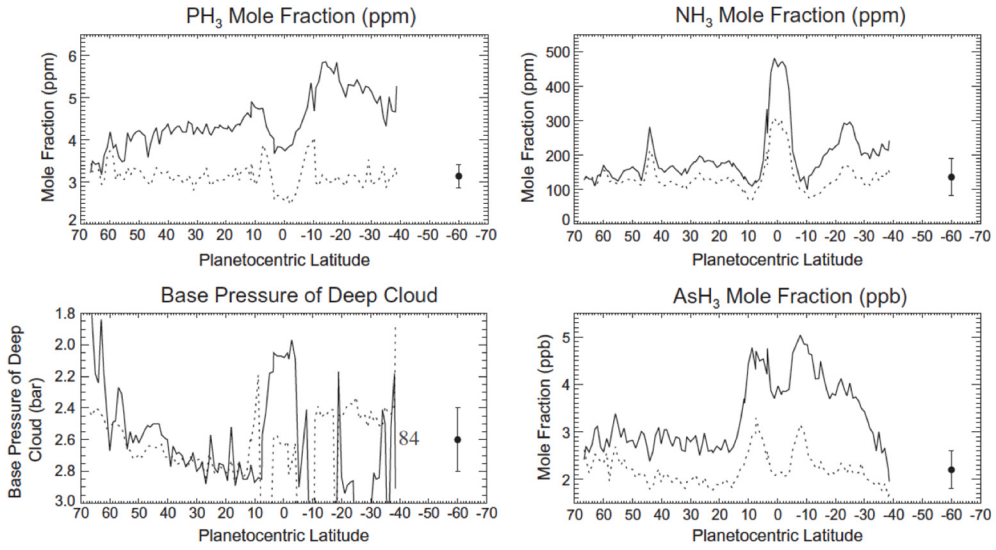

Figure SATURN-2. Tropospheric chemical abundances from Cassini VIMS. The profiles do not tell a consistent story according to this picture. NH_3 shows a high mole fraction at the equator, consistent with upwelling there and downwelling on either side at 10–12° latitude, but PH_3 and AsH_3 show low abundances at the equator, consistent with downwelling. The data may be indicating a double Hadley cell, with rising motion at the higher altitudes at the equator and sinking motion deeper down [Fletcher et al. 2011a].

interactions are studied with 2-D photochemical models, which have been another desirable outgrowth of Cassini observations [Hue et al. 2016].

Intensified Earth-based observations are a further desirable result of Cassini's mission to Saturn. Some of the observations immediately preceded the outpouring of Cassini data [Kim and Geballe 2005; Tejfel 2005], both to extend the range of temporal variability and to compare inferences based on different data sets. For instance, microwaves are sensitive to ammonia vapor at deeper levels than those probed by infrared radiation. The Cassini RADAR used in passive mode collects thermal radiation at 2.2 cm wavelength. With laboratory measurements of the ammonia opacity [Hanley et al. 2009], the Cassini 2.2 cm data were used to infer depletion of ammonia below the expected base of the ammonia cloud [Janssen et al. 2013; Laraia et al. 2013]. This depletion is observed on Jupiter as well and has not been fully explained. The NH_3 abundance is controlled mostly by condensation and evaporation, which is more tied to the cloud structure, so it reveals different aspects of the circulation [Hurley et al. 2012b] than that of the hydrocarbons.

In giant planet atmospheres, the principal oxygen-bearing molecules are H_2O and CO, with the latter in equilibrium at higher temperatures and pressures than the former. However, water is frozen out at high altitudes, so the presence of CO_2 at the 1 mbar level suggests a source outside the planet. Cassini CIRS observations were used to show that the source is probably interstellar dust grains [Abbas et al. 2013].

Saturn Winds and Weather (S_AO2)

- **Seasonal Variations (SC1a)** – Observe seasonal variations in temperature, clouds, and composition in three spatial dimensions.

Two opposing effects control the amplitude of seasonal variations on Saturn (Figure SATURN-3). The obliquity is 26.73°, which is larger than that of Earth, and is tending to produce large seasonal variations in incident sunlight. These variations are augmented by the rings, which block sunlight from reaching large parts of the winter hemisphere. On the other hand, Saturn's troposphere is massive, with clouds of water down to the 20-bar level, assuming the enrichment of water relative

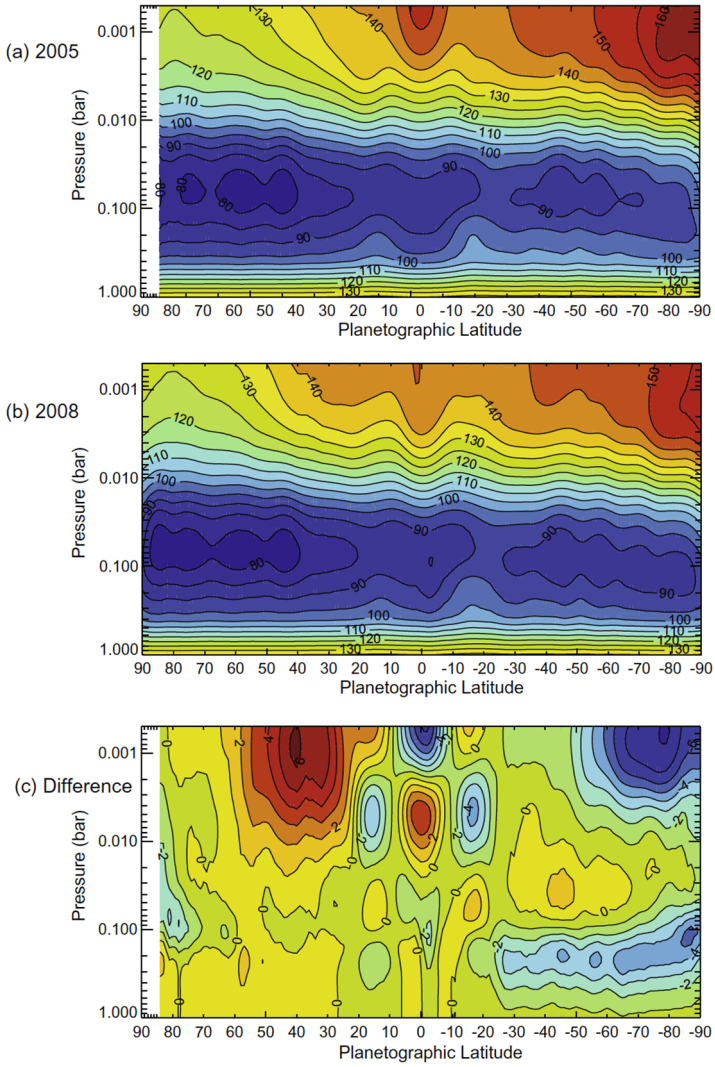

Figure SATURN-3. Temperature as a function of latitude and altitude from Cassini CIRS. In 2005 the season was early winter in the north, and in 2008 the season was mid-winter. The south is warmer than the north in both years, although most of the hemispheric contrast and most of the difference between 2005 and 2008 is confined to high altitudes [Fletcher et al. 2010].

to solar composition is the same as that of methane, whose abundance can be measured spectroscopically. Further, the high specific heat of hydrogen gives the troposphere a huge thermal inertia, so the atmosphere tends to average over the seasonal cycle rather than respond to it. Seasonal averaging is reduced in the stratosphere, because it has less thermal inertia than the troposphere. Seasonal change is reflected in the emitted power as a function of latitude [Li et al. 2015], as the northern hemisphere season changed from winter to late spring over the period 2004-2013 (Figure SATURN-4).

Using Cassini CIRS data Fletcher et al. [2010] showed that the stratosphere has a greater range of temperatures than the troposphere, which is consistent with the greater thermal inertia of the latter. They point out that a photochemical haze develops in the spring/summer hemisphere (Figure SATURN-1). Fletcher et al. [2015] observed polar cooling and depletion of acetylene in the southern hemisphere during fall and winter. Tropospheric temperature variations are small [Fletcher et al. 2016] and show a substantial seasonal lag time, as expected. These seasonal changes are superposed on a general upwelling in the tropics and downwelling at the poles, as revealed by the two states (ortho and para) of the H_2 molecule [Fletcher et al. 2016, 2017]. Sinclair et al. [2013] and Sylvestre et al. [2015] compare CIRS observations of temperature, C_2H_2, C_2H_6, and C_3H_8 with a static photochemical model and find substantial effects of circulation and transport in addition to variations due to chemistry. Seasonal change of thermal structure, composition and aerosol is extensively reviewed by Fletcher et al. [2018].

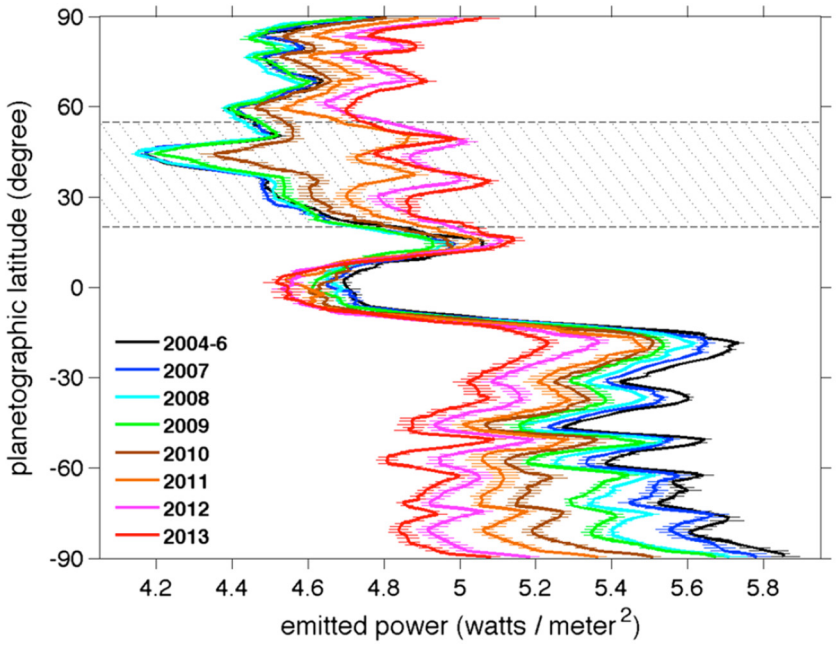

Figure SATURN-4. Thermal emission of the planet in units of W m^{-2} from Cassini CIRS. In the south the season was early summer in 2004 and mid fall in 2013. The decrease in thermal emission in the south was due to cooling of the atmosphere. Comparing the years before and after 2011, it is clear that the great storm increased the thermal emission by 5–10% in the 30–40° latitude band, and that the anomaly persisted for several years [Li et al. 2015].

- **Saturn's Winds (SC1b)** – Observe seasonal changes in the winds at all accessible altitudes coupled with simultaneous observations of clouds, temperatures, composition, and lightning.

Tracking small clouds in sequences of images is the principal way of measuring the winds (Figure SATURN-5). Both ISS and VIMS can measure the winds directly. CIRS can measure the gradient of the wind with respect to altitude by measuring the horizontal gradient of temperature and applying the thermal wind equation. Except at the equator, the mean zonal winds—the

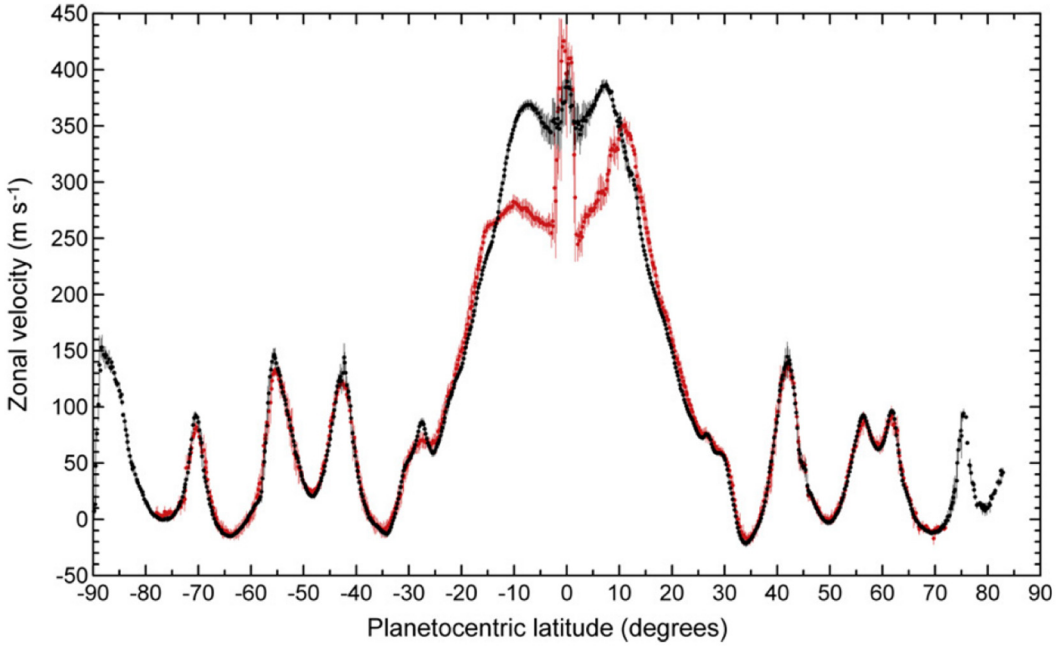

Figure SATURN-5. Atmospheric zonal velocity for Saturn from Cassini ISS. The black curve is data from the 350 to 700 mbar levels, and the red curve is data from 100 to 200 mbar. The differences are small except for a latitude band ±15° from the equator [Garcia-Melendo et al. 2011b].

eastward winds averaged with respect to longitude—are remarkably steady. This conclusion follows, in part, by comparing the mean zonal winds during Voyager times with those measured by Cassini 25–30 years later [Antunano et al. 2015; Choi et al. 2009; Li et al. 2011, 2013; Vasavada et al. 2006]. Images taken at wavelengths where methane is a strong absorber tend to sample higher altitudes than those where methane is transparent. Vertical shears show up in the eastward jets [Garcia-Melendo et al. 2009, 2011], which is consistent with the horizontal temperature gradient and the thermal wind equation.

At the equator, the speed of the zonal wind in the upper troposphere and stratosphere oscillates with a 15-year period [Fouchet et al. 2008] (Figure SATURN-6). Similar oscillations occur in the stratospheres of Earth and Jupiter. On Earth the period is about 22 months, and the oscillation is called QBO. On Jupiter, the period is about four years. On Earth, the mechanism is feedback between the wind profile and the altitude where waves propagating up from the troposphere deposit their zonal momentum. The period is inversely related to the intensity of the waves. A similar

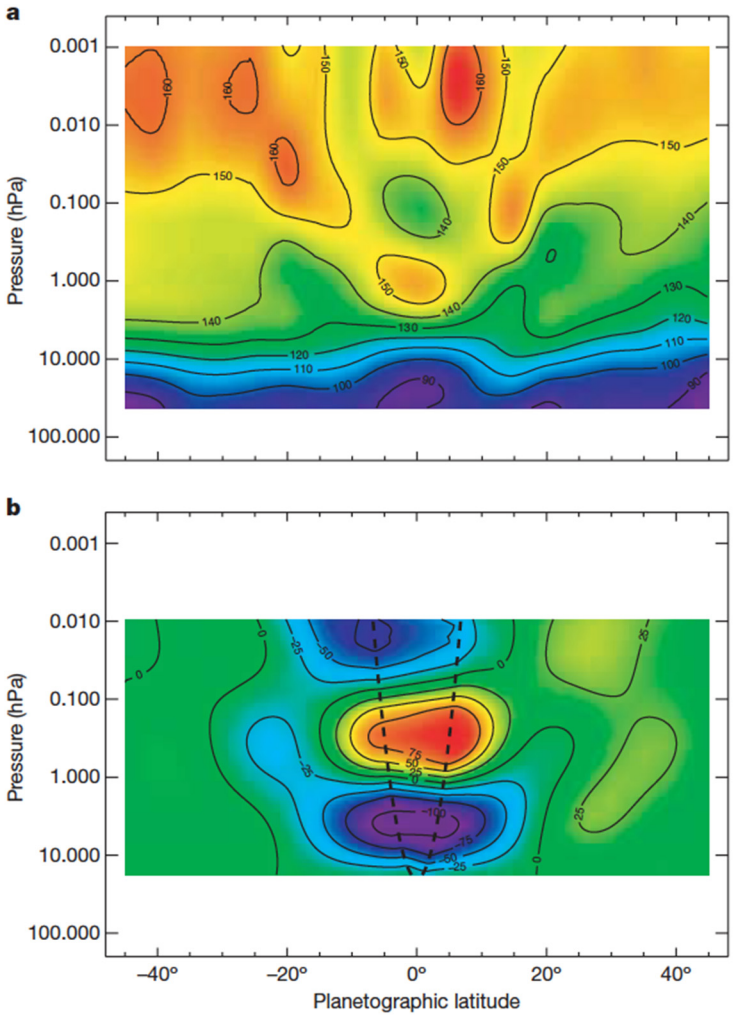

Figure SATURN-6. Oscillation of temperature (upper panel) and mean zonal wind (lower panel) at the equator from Cassini CIRS. The pattern moves down with time and has a ~15-year period. A similar pattern on Earth has a ~22 month period and is known as the QBO. The period of the oscillation on Jupiter is ~4 years. The longer period as one moves out in the solar system is probably due to the lower energy available to drive the oscillation [Fouchet et al. 2008].

mechanism is likely to operate on Jupiter and Saturn. Since vertical shear in the zonal wind is related to horizontal gradients of temperature through the thermal wind equation, the oscillation reveals itself in the temperatures on either side of the equator.

In preparation for the Cassini encounter, Voyager and Hubble Space Telescope observations were used to document the variability of the zonal wind in the equatorial stratosphere [Perez-Hoyos and Sanchez-Lavega 2006; Sanchez-Lavega et al. 2000]. Sanchez-Lavega et al. [2007] and Garcia-Melendo et al. [2010] used Cassini ISS images in the methane bands to further document the vertical wind shear and its temporal variability. Li et al. [2008] used Cassini CIRS data, where the oscillation is revealed in stratospheric temperatures, and Li et al. [2011] showed that the temperatures and cloud-tracked winds are consistent with the QBO oscillation mechanism.

Schinder et al. [2011] used radio occultations by the Cassini spacecraft to measure temperature and showed that the zonal wind profile propagates downward as on Earth, consistent with the wave forcing mechanism of the QBO. Downward propagation also shows up in the thermal infrared maps based on CIRS data [Fouchet et al. 2008; Guerlet et al. 2011]. Sanchez-Lavega et al. [2016] used ISS data to track individual features in the upper haze and clouds and further demonstrated the intense vertical shears and temporal variability.

- **Storms (SN1b, SN2a)** – Observe the aftermath of the 2010–2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon. Monitor the planet for new storms and respond with observations when they occur.

Saturn is prone to large-scale eruptions (Figure SATURN-7). They start with a small cloud that grows rapidly during its first week and expands zonally, until after two or three months the

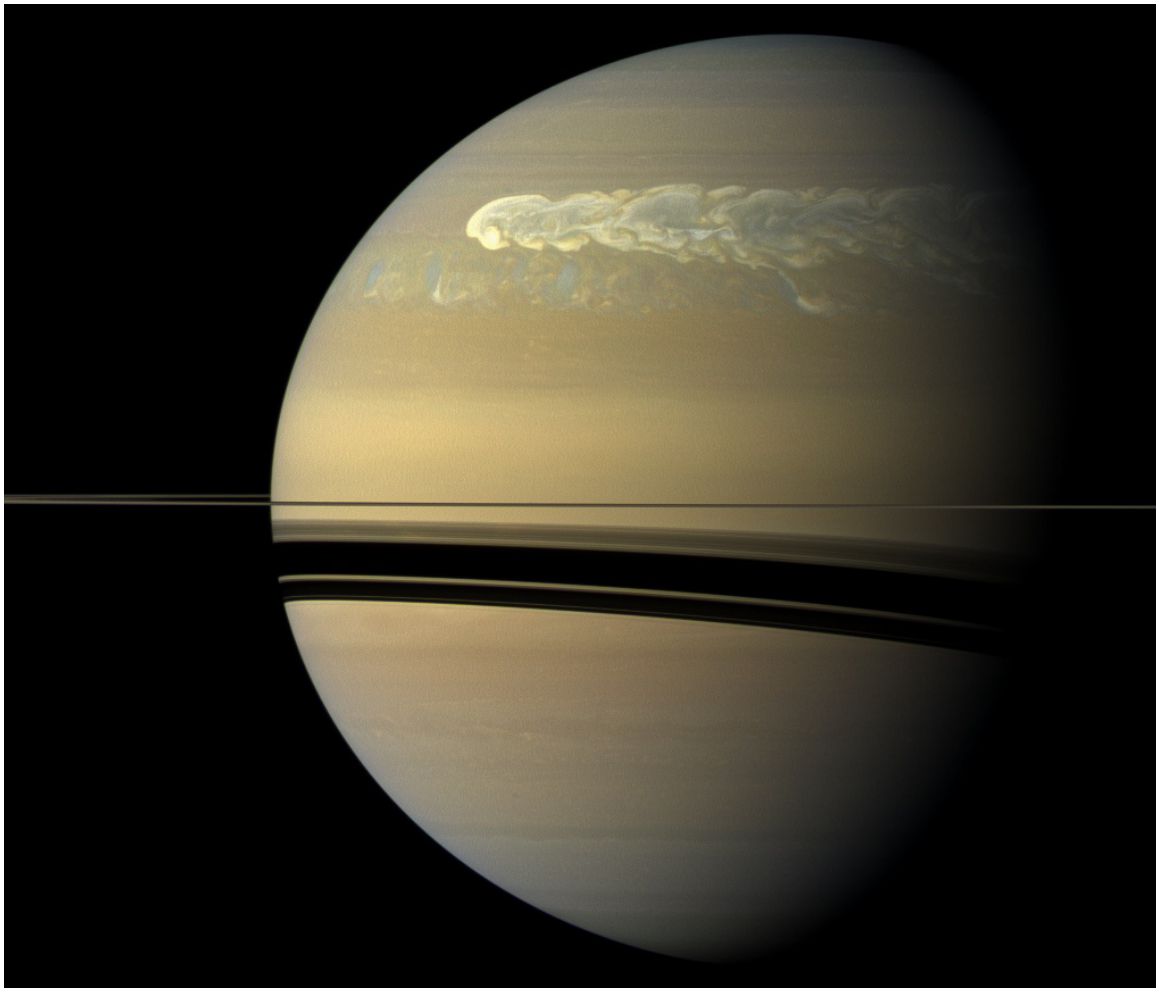

Figure SATURN-7. Saturn imaged by Cassini ISS on February 25, 2011. The great storm of 2010–2011 is clearly visible in a band centered at 30–40° latitude. Since its appearance on December 5, 2010, the head of the storm had drifted west and overtaken the tail.

disturbance has fully encircled the planet within its latitude band. The paper by Sanchez-Lavega [1994] is the definitive pre-Cassini review of these phenomena. He calls them Great White Spots, and he lists five of them before the Cassini era: 1876, 1903, 1933, 1960, and 1990. This gives an average periodicity of 28.5 Earth years, which is close to Saturn's year of 29.46 Earth years. The corresponding latitude bands of these storms are 8 ±3°, 36 ±2°, 2 ±3°, 58 ±1°, and 12 ±1°, all in the northern hemisphere. Whether the disturbances are in a unique class or just the largest in a continuous distribution of sizes is uncertain. And whether the disturbances are locked in phase to Saturn's year is also uncertain, because within each latitude band the period is much longer than a Saturn year. And the great storm of 2010–2011 came 10 years too early to satisfy the annual cycle hypothesis.

Saturn's great storm of 2010–2011 was a singular event in Cassini's 13 year tour of the Saturn system [Sanchez-Lavega et al. 2018]. It began as a small (~1000 km) spot captured in a routine ISS image on December 5, 2010. Cassini RPWS had been detecting lighting discharges (Figure SATURN-8) from the storm for a few hours when the image was taken [Fischer et al. 2011]. The lightning continued for the ~7 month lifetime of the storm as the westward-moving head left behind a tail that eventually wrapped around the planet. In its mature phase, the storm filled a latitude band 10,000 km wide that was centered at a planetocentric latitude of 35°. Earth-based telescopes were following the storm within days of its appearance [Sanchez-Lavega et al. 2011], and systematic Cassini imaging began in January 2011.

Visible-light images of clouds in the troposphere [Sanchez-Lavega et al. 2012; Sayanagi et al. 2013] showed that the head spawned large (10,000 km diameter) anticyclones that drifted off to the east and became part of the tail. The storm seems to have originated from a feature called the string of pearls, a train of cyclones at the latitude of the great storm [Sayanagi et al. 2014]. Garcia-Melendo et al. [2013] are able to reproduce many of the observed morphological features of the storm with a prescribed heat source moving at a prescribed velocity. Li and Ingersoll [2015] present a theory that reproduces the observed drying (low mixing rate of ammonia) of the storm's latitude band (Figure SATURN-9) [Janssen et al. 2013; Laraia et al. 2013] as well as the multi-decadal

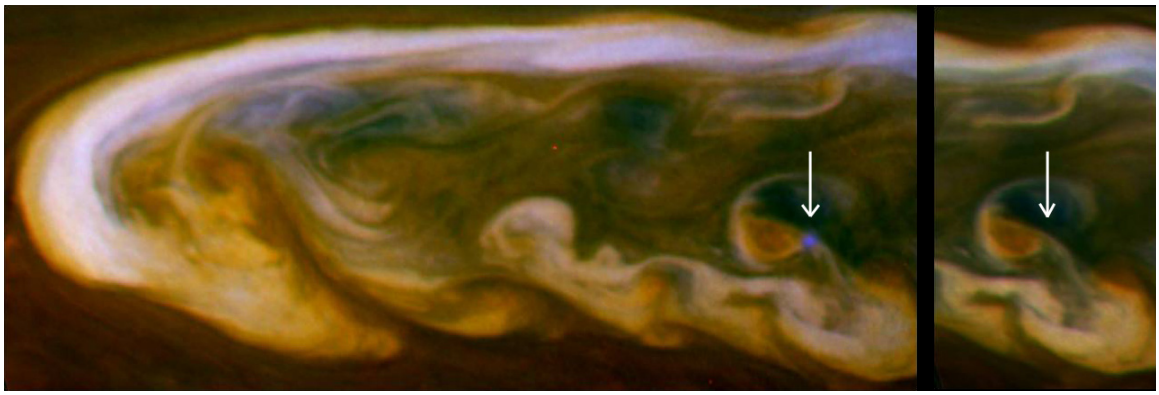

Figure SATURN-8. Lightning flash in Saturn's great storm of 2010–2011. The color composite consists of three images taken in rapid succession at three different wavelengths. A lightning flash occurred while the blue-filtered image was taken, making a blue spot in the composite image, left. The same region was imaged 30 minutes later and did not see a lightning flash, right (PIA14921).

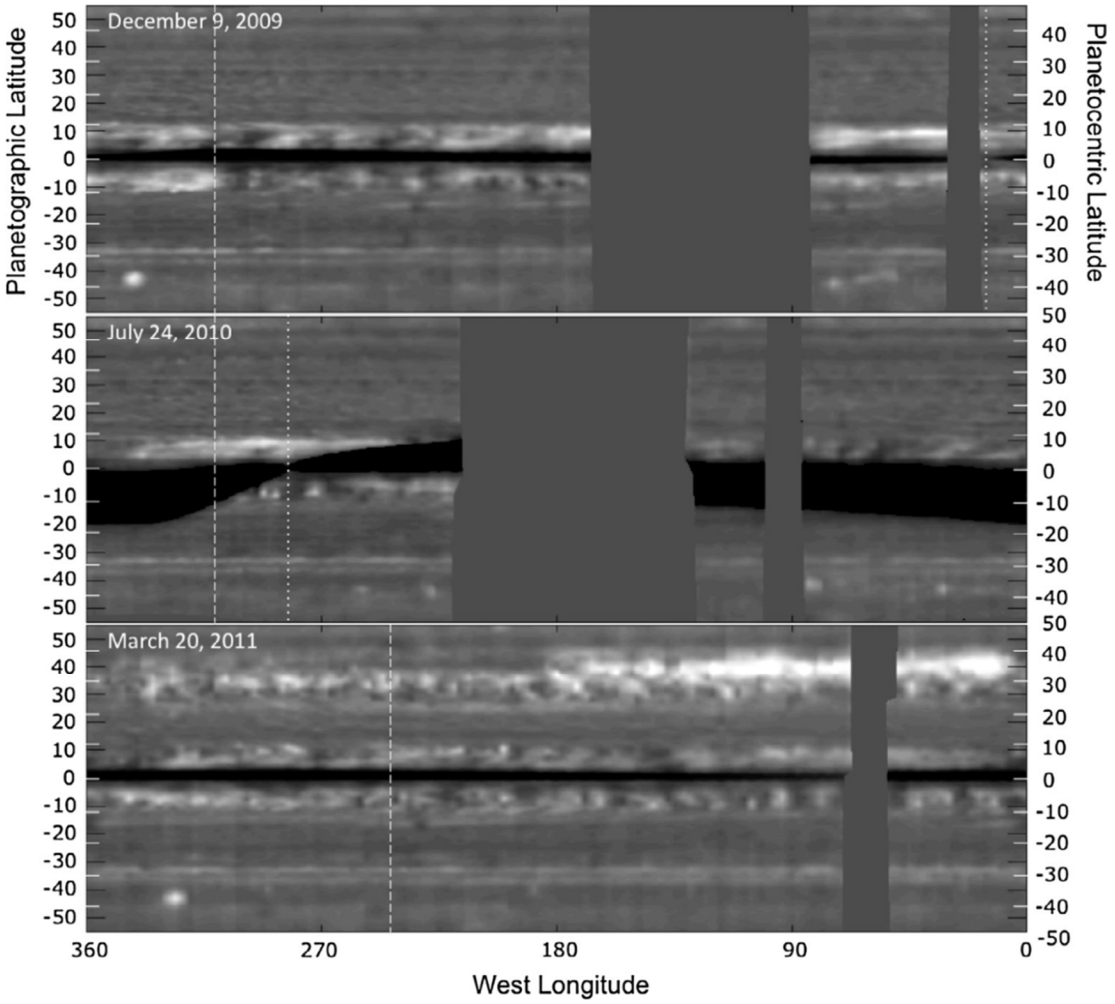

Figure SATURN-9. Cylindrical projection of Jupiter thermal emission at 2.2 cm wavelength, obtained by the Cassini RADAR in passive (non-transmitting) mode. The dark band at the equator is due to the rings, which are colder than the planet itself. The top two panels show the planet before the great storm. The lower panel shows warm emission at the location of the storm. Ammonia is the principal absorber at 2.2 cm wavelength, so the warm emission is due to ammonia depletion allowing radiation from deeper levels to reach the detector [Janssen et al. 2013].

interval between great storms. The latter is tied to mass loading, i.e., the stabilizing effect of water and ammonia condensation in a low molecular weight (H_2 and He) atmosphere. Above a critical abundance of the condensates, the atmosphere becomes stable after a convective event, and the time needed to destabilize the atmosphere is decades. Based on the C/H ratios for Jupiter and Saturn, assuming the same enrichment factors relative to solar for O/H, Saturn is above the critical value and Jupiter is below it, which could explain why only Saturn has these great storms.

Thermal infrared spectroscopy by Cassini CIRS revealed effects of the storm that penetrated into the stratosphere to the 1 mbar level [Fletcher et al. 2011b]. Subsidence of air in the stably-stratified stratosphere produced beacons as much as 16 K warmer than their surroundings

(Figure SATURN-10). By May 5, 2011, the beacons had reached temperatures of 226 K, about 80 K warmer than the surrounding stratosphere [Fletcher et al. 2012; Fouchet et al. 2016]. The storm produced a 100-fold increase of ethylene in the stratosphere near the beacon [Hesman et al. 2012]. Photochemical models cannot explain this increase, so some dynamical mechanism must be at work [Cavalie et al. 2015; Moses et al. 2015]. Temperatures in the troposphere at the latitude of the storm increased by 3 K, and the para fraction of H_2 decreased by about 0.4, indicating warm air upwelling from below (Figure SATURN-11) [Achterberg et al. 2014].

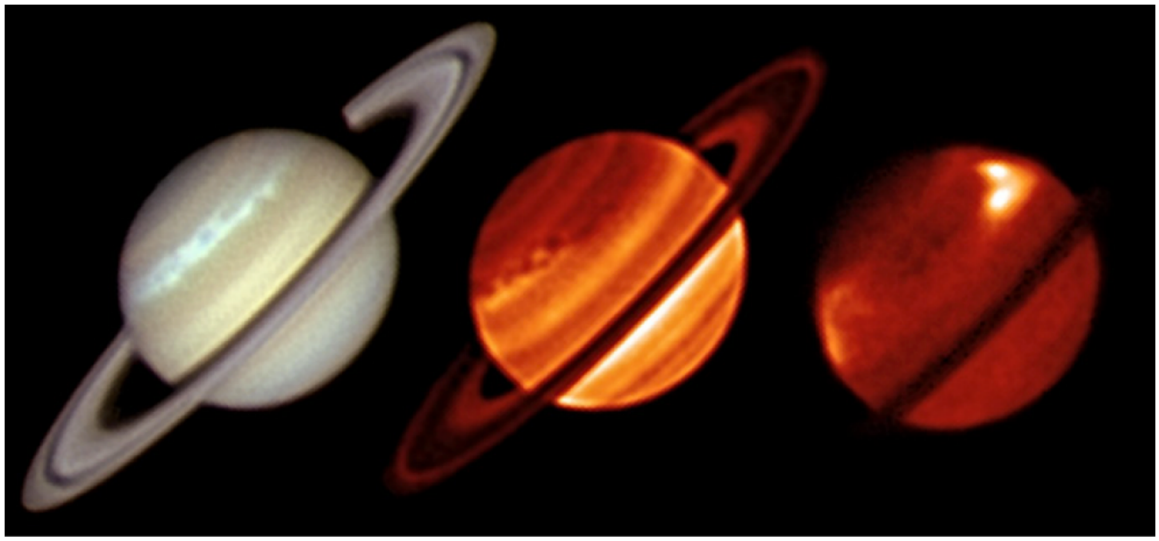

Figure SATURN-10. Earth-based image, left, and two infrared images taken by Cassini CIRS on January 19, 2011. The center image records temperature in the upper troposphere, at the 200–500 mbar level, and the right image shows temperatures at the 1–10 mbar level. The stratospheric beacon stands out in the right image [Fletcher et al. 2011b].

The 2010–2011 storm seems to have affected clouds and haze, both at the latitude of the storm and farther away. Sromovsky et al. [2013] used VIMS spectra to study the composition of the cloud particles lofted by the storm, and found evidence of ammonia ice, water ice, and ammonium hydrosulfide. This is the first spectroscopic evidence of water ice in Saturn's atmosphere and indicates upwelling from 200 km below the tops of the ammonia clouds. Further study of the aftermath of the storm reveals clearing of the ammonia cloud with some residual particles of other species [Sromovsky et al. 2016]. According to an analysis of VIMS data, a residual haze layer persisted in the upper troposphere and lower stratosphere as well [Oliva et al. 2016]. The great storm seems to have caused a 10 K warming of the middle atmosphere (0.5-5 mbar) at the equator, providing evidence of teleconnections between latitudes [Fletcher et al. 2017].

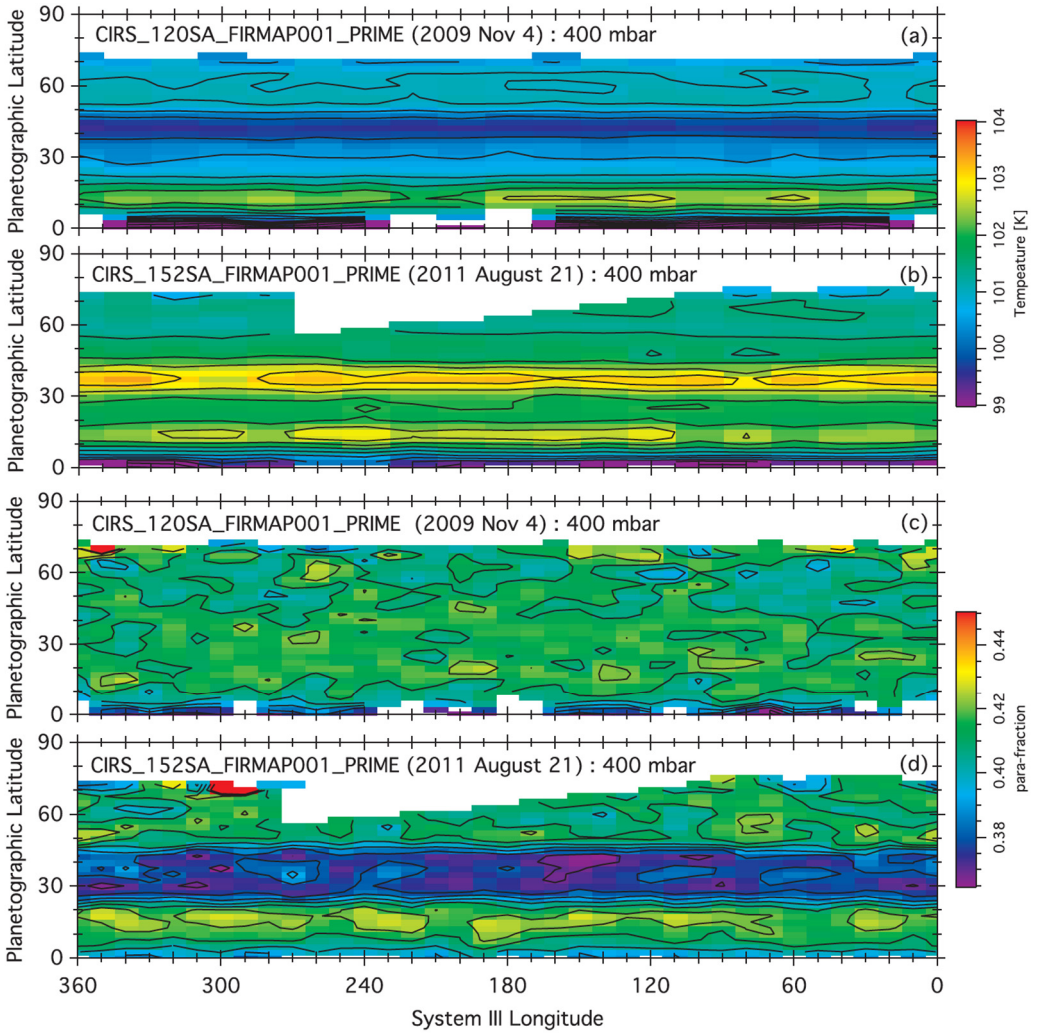

Figure SATURN-11. Cassini CIRS cylindrical projections showing evidence of air being dredged up from below. The top two panels show tropospheric temperature before and after the storm and the band from 30–40° planetographic has warmed by several degrees. The bottom two panels show the two chemical states (nuclear spins parallel and nuclear spins anti-parallel) of molecular hydrogen H_2 before and after the great storm. The 30–40° band shows a low para fraction, which indicates that the air has risen from below cloud base [Achterberg et al. 2014].

Saturn's hexagon is a six-lobed meandering pattern in an eastward jet centered at 75° north latitude (Figure SATURN-12). The excursions in latitude are approximately ±1°, which gives the structure its polygonal shape. Larger excursions would give it a more sinusoidal, wave-like shape. The hexagon was discovered in Voyager images taken in 1980 and was discovered again by Cassini VIMS, before the spring equinox when the North Pole was still in darkness [Baines et al. 2009b]. Its effects extend into the stratosphere to altitudes of 0.5 mbar [Adriani et al. 2015]. Based on ISS and VIMS imaging, the clouds on either side of the jet move slowly or not at all relative to the nominal rotation rate for Saturn, which was defined following the Voyager encounter [Desch and Kaiser 1981]. Relative to these clouds and to the hexagon pattern, the jet's speed is

~125 m s^{-1}. Thus the hexagon is like a road fixed in the Voyager reference frame, and the clouds in the jet move along it. Based on the hexagon's long-term stability, Sanchez-Lavega et al. [2014] argue that it is a deep-seated feature that could reveal the true rotation of the planet.

Each pole of Saturn is occupied by a single isolated cyclonic vortex with peak winds of ~150 m s^{-1} [Dyudina et al. 2008, 2009; Sanchez-Lavega et al. 2006]. The latitude of the peak winds

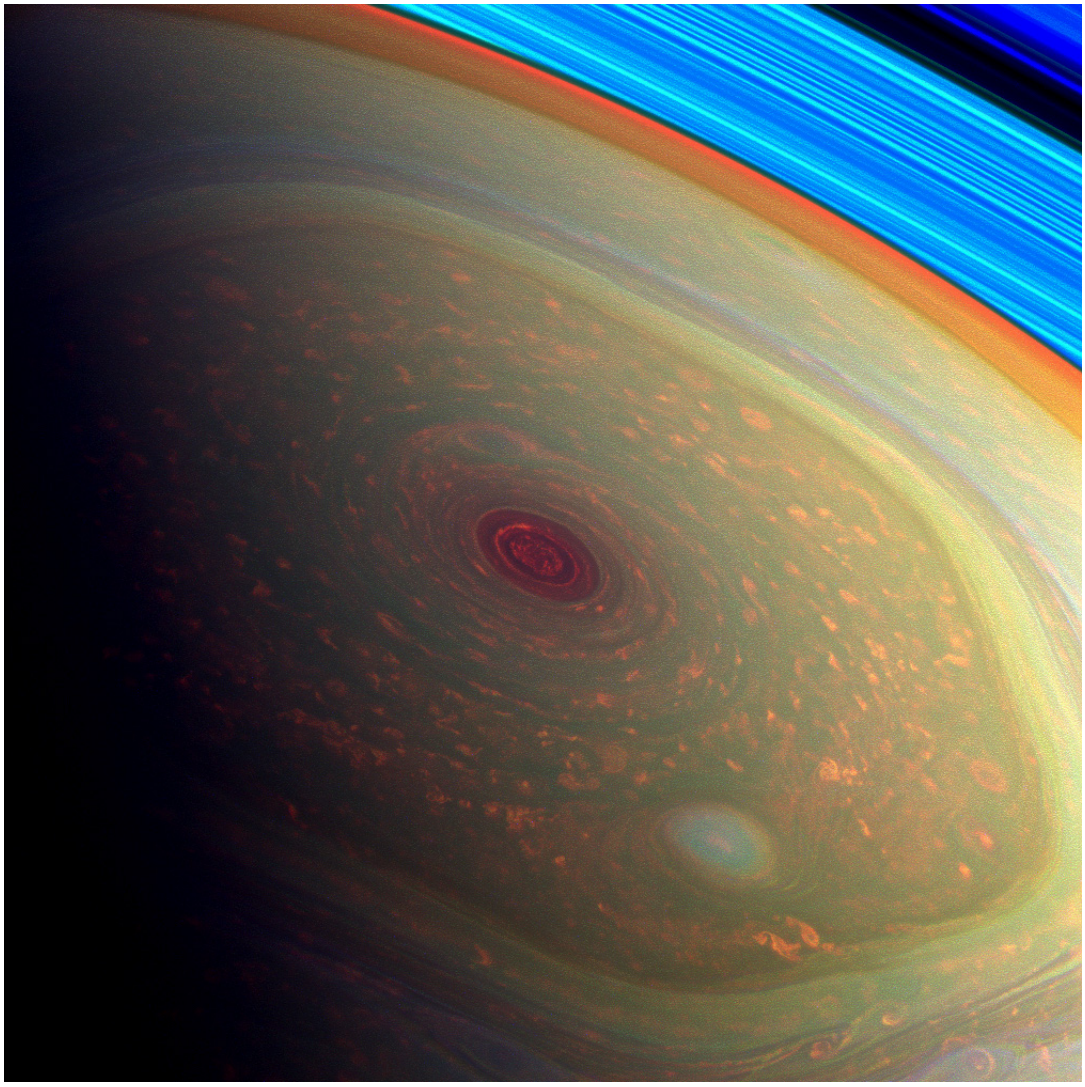

Figure SATURN-12. Saturn's north polar hexagon and polar cyclone. This false color image was taken on November 27, 2012 by the Cassini ISS. The MT3 and MT2 images, which are sensitive to absorption by methane gas in the atmosphere, are projected as blue and green, respectively. The CB2 image, which is not sensitive to methane absorption, is projected as red. The color balance is chosen to make the planet's atmosphere look realistic. The rings look bright blue because there is no methane gas between the rings and the spacecraft. The red spot in the center extends from the pole to a latitude of 88–89°. It looks red in the false-color image because the clouds are deep and methane gas absorbs the sunlight before it can reflect off the clouds and reach the spacecraft. The spot is a cyclone with winds of ~100 m s^{-1}.

is ~88°, which means that the average relative vorticity within 2° of the poles is equal to 0.4 times the local planetary vorticity. Based on Cassini ISS, VIMS, and CIRS data, Dyudina et al. [2008] and Dyudina et al. [2009] interpreted the vortex as a hurricane-like eye with eyewall clouds at 88° extending 20–70 km above the clouds at the pole. Sromovsky and Fry [2019] argued that an abrupt change of optical thickness could mimic the apparent eyewalls. The region has a 4–7 K warm core extending from the upper troposphere into the stratosphere [Achterberg et al. 2018]. The warm core and stable stratification implies downwelling, which is consistent with low phosphine abundance in the core [Fletcher et al. 2008]. Outside the eyewall are numerous anticyclonic vortices suggesting a convective origin [Dyudina et al. 2009]. Sayanagi et al. [2017] compared the north and south polar cyclones and attributed the differences to seasonal effects. Polar phenomena are extensively reviewed by Sayanagi et al. [2018].

- **Atmospheric dynamical processes (S_AO2)a**

Giant planet atmospheres are a superb laboratory for studying the dynamics of rotating fluids. Cloud tracking provides estimates of the winds, and the lack of continents and oceans provides a simpler setting than on Earth. The Cassini mission advanced this field, not only by providing 13 years of observations of Saturn but also by providing a 3-month flyby of Jupiter with an upgraded suite of instruments compared with those on the Voyager flybys. The Jupiter observations are discussed in the section entitled Saturn DWG non-Saturn science results. Here we focus on observations and models of the jets and vortices in Saturn's atmosphere. Saturn's atmospheric dynamics is extensively reviewed by Showman et al. [2018].

The zonal wind profile is a fundamental observation. ISS provided the first data at the start of the Cassini mission [Garcia-Melendo et al. 2011b; Porco et al. 2005; Vasavada et al. 2006] and a valuable comparison with Voyager 25 years earlier. The second fundamental observation is the eddy momentum flux (Figure SATURN-13). Eddies are the time- and longitude-dependent motions that carry heat and momentum across latitude circles. Using ISS data, Del Genio et al. [2007] and Del Genio and Barbara [2012] found a clear positive correlation between eddy momentum fluxes and meridional shear of the zonal wind, implying that eddies supply eastward momentum to the eastward jets and westward momentum to the westward jets. Similar correlations are found on Jupiter and Earth, although the energy supply for Earth's eddies could be different from that for Saturn and Jupiter.

> The eddies north and south of the equator supply positive angular momentum to the equator, so the meridional circulation replaces it with air from higher latitudes on both sides, implying convergence.

Since the eddies supply positive angular momentum to the eastward jets, the meridional circulation must replace it with low angular momentum air, which is found at higher latitudes. Conversely, the westward jets must have flow from lower latitudes. The result is that the meridional circulation diverges in the latitude bands that have westward jets on their poleward sides and eastward jets on their equatorward sides. These are the cyclonic shear zones—called belts on Jupiter.

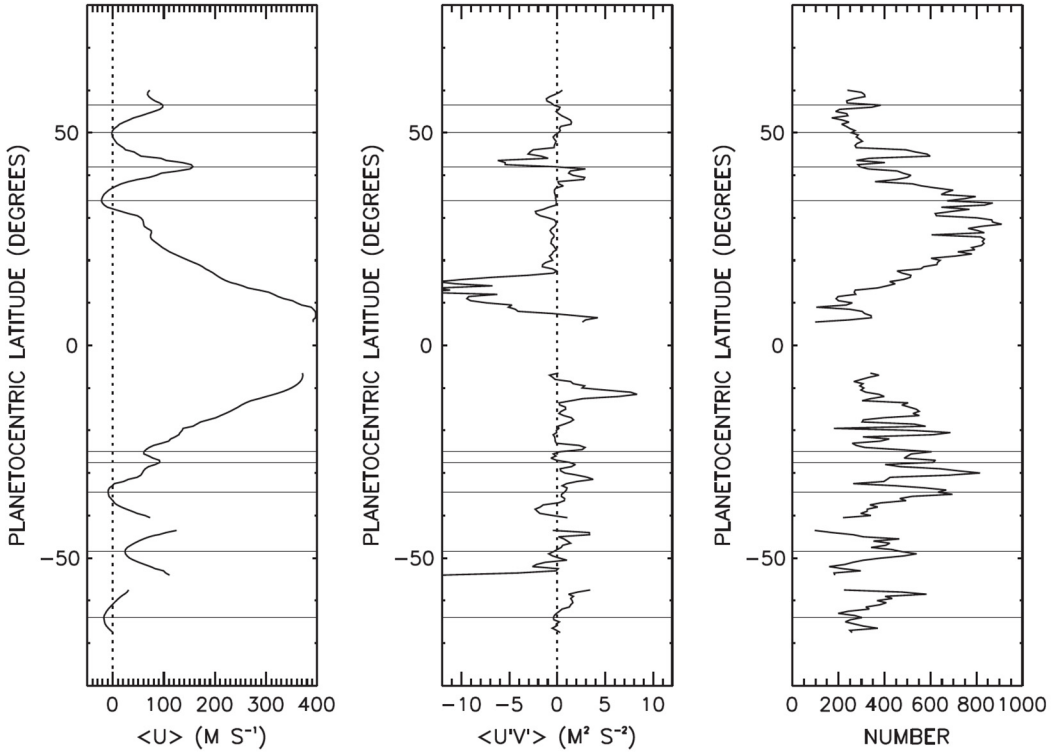

Figure SATURN-13. Eddy momentum transport for Saturn from Cassini ISS. The eastward and northward eddy winds u′ and v′ are the departures from the zonal means. Their product $\overline{u'v'}$ averaged over longitude and multiplied by density is the northward eddy flux of eastward momentum. The fact that this quantity has the same sign as $\partial\bar{u}/\partial y$, which is the increase of the mean eastward wind with latitude, says that the eddies are putting energy into the jets and not the reverse [Del Genio and Barbara 2012].

Anticyclonic shear zones—called zones on Jupiter—are the reverse, so they have convergence. The eddies north and south of the equator supply positive angular momentum to the equator, so the meridional circulation replaces it with air from higher latitudes on both sides, implying convergence. Horizontal convergence implies vertical divergence—either upwelling into the stratosphere or downwelling into the deep troposphere, or both. Using CIRS data Fletcher et al. [2009a] observed phosphine (PH_3), which is destroyed by photochemistry in the upper troposphere, to infer upwelling at the equator above the 0.5 bar level. However using VIMS data, which is sensitive to deeper levels, Fletcher et al. [2011a] inferred downwelling at the equator below the 1.3 bar level. Zuchowski et al. [2009] showed how this pair of stacked, oppositely-directed Hadley cells could arise from a balance between the effects of radiative heating and eddy momentum flux convergence. There is evidence of stacked Hadley cells on Jupiter as well [Gierasch et al. 2000; Ingersoll et al. 2000, 2017; Showman and de Pater 2005], but the subject of upwelling and downwelling is still open.

Zonal jet stability is the third important observation. Stability depends on the potential vorticity [Antunano et al. 2019], which depends on vertical structure, both of temperature and wind, but a simple but relevant criterion is that the flow is stable if the curvature of the zonal wind profile with respect to latitude does not exceed β, which is twice the planet's angular velocity times the cosine

of latitude divided by the planetary radius. Interestingly, this stability criterion is violated on Saturn near the peaks of the westward jets, especially at high latitudes, indicating that the zonal jets could be unstable [Antunano et al. 2015; Read et al. 2009a]. That does not mean the flow is unstable, however, as there are other stability criteria that involve vertical structure [Dowling 1995]. Liao et al. [2007] argue that a statistical equilibrium occurs as the zonal flow saturates. In their global vortex analysis, Trammell et al. [2014] find a correlation between the number of vortices and the westward jet peaks, implying at least some degree of instability at those latitudes.

Waves and vortices are another important feature of giant planet atmospheres. Saturn currently has nothing like the Great Red Spot, which has endured for over 100 years, but it has similar structures. Generally, anticyclones last longer than cyclones, but del Rio-Gaztelurrutia et al. [2010, 2018] document a cyclone that lasted for four years. Convective storms can generate waves that transport westward momentum away from their source regions, helping to accelerate eastward jets at the latitudes of the convection [Gunnarson et al. 2018; Liu and Schneider 2015; Sayanagi and Showman 2007]. This acceleration must be balanced somewhere, and [Schneider and Liu 2009] argue that the balance occurs through magneto-hydrodynamic drag at 0.3 to 1.4 Mbar where the atmosphere becomes electrically conducting [Liu et al. 2014; Liu and Schneider 2015].

Saturn's north polar hexagon at 75° latitude has inspired several modeling studies, both in the laboratory [Aguiar et al. 2010] and on the computer [Morales-Juberias et al. 2011, 2015]. Saturn's ribbon at 47° latitude is a less dramatic relative of the hexagon [Sayanagi et al. 2010] since both seem to represent a steady meandering pattern on an eastward jet stream. The models do not explain why the conditions necessary for a long-lived meandering jet stream exist only at certain latitudes on Saturn or why there are no such jet streams on Jupiter. O'Neill et al. [2015, 2016] propose a model of Saturn's polar cyclones in which convection at mid latitudes produces a vortex that is cyclonic at the bottom and anticyclonic at the top. The two halves separate, and the cyclonic vortex drifts to the pole and merges with other cyclonic vortices to make a single polar vortex. Brueshaber et al. [2019] one-layer shallow-water simulations also show that poleward drifting cyclonic vortices merge to form polar vortices, and also revealed a mechanism that separates the polar dynamical regimes of Jupiter, Saturn, and Uranus/Neptune. On the other hand, Antunano et al. [2018] report no meridional migration in the region north of the hexagon, and suggest that mergers do not contribute to the maintenance of the polar vortex. Sanz-Requena et al. [2018, 2019] describe the haze and cloud structure in the north pole and hexagon region.

Saturn's great storm has also inspired modeling studies. One model uses an imposed heat pulse and studies its interaction with the ambient zonal flow [Garcia-Melendo and Sanchez-Lavega 2017]. Another model studies how precipitation of water, which has a high molecular mass relative to hydrogen, from the troposphere, can inhibit convection for decades due to the long radiative time constant of Saturn's atmosphere [Li and Ingersoll 2015]. A third model uses a long-term numerical integration of moist convection in a giant planet atmosphere [Sugiyama et al. 2014]. The simulations are conducted using a two-dimensional cloud-resolving model that explicitly represents the convective motions and microphysics of NH_3, NH_4SH, and H_2O. It produces intermittent cumulonimbus activity. The time scale is ~60 days, although it is proportional to the water abundance and is therefore likely to be greater for Saturn than for Jupiter.

Numerical models of Saturn's jets and vortices fall into two categories. One is the conventional general circulation model (GCM), which uses hydrostatic balance in the vertical and is valid for large horizontal scales and small vertical scales [Friedson and Moses 2012; Garcia-Melendo et al. 2007; Trammell et al. 2016]. The other is the fluid sphere model in which the vertical and horizontal scales are comparable and the flow takes place in thick spherical shells [Aurnou et al. 2008; Heimpel and Aurnou 2007; Liu et al. 2014]. Computational limitations make it difficult to develop a single model that includes both small and large vertical scales, although the effort is being made [Heimpel et al. 2016]. More often, the practitioners divide in separate camps and work with different tools.

- **Saturn Lightning Sources and Morphology (S_AO6, SN2a)** – Investigate the sources and the morphology of Saturn lightning SED, lightning whistlers.

The Cassini RPWS detects the radio waves from lightning at frequencies starting at 1.3 MHz and ranging up to 40 MHz [Fischer et al. 2006a; Fischer et al. 2006b; Fischer et al. 2007; Fischer et al. 2008]. A single flash is called a SED, and it lasts for less than the 35.2 ms integration time of the RPWS instrument (Figure SATURN-14). Fundamentally, the duration of an SED is unknown [Farrell et al. 2007]. An SED is not a whistler; it is a freely-propagating radio wave that follows a straight-line path from the source. Although the RPWS is listening virtually all the time, sometimes it detects nothing for months. SED activity is often from a single storm, with SEDs every few seconds for a 5-hour ON period followed by a 5-hour OFF period, when the storm is hidden behind Saturn. Often the storm itself is visible, both in ISS images [Dyudina et al. 2007] and in the images gathered by amateur astronomers at Earth. Criteria used to identify the storm are that it appeared within a day or two after the onset of SED activity and it was always on the side of the planet facing the spacecraft when the RPWS was detecting signals. Thus the number of lightning storms at any one time is likely to be either 0 or 1. In contrast, Earth has ~2000 lightning storms over the globe at all times, and Jupiter has dozens of storms at all times [Little et al. 1999].

Cassini ISS eventually detected the lightning flashes [Dyudina et al. 2010], even on the day side despite the bright background of clouds in sunlight. The secret is to take many short exposures, since a short exposure reduces the background but not the lightning; it does reduce the probability of capturing a flash, so one needs to take many exposures. The diameter of the illuminated spot is about 200 km, indicating that the lightning is 125–250 km below cloud tops. This depth is above the liquid H_2O–NH_3 cloud and may be either in the NH_4SH cloud or the H_2O ice cloud.

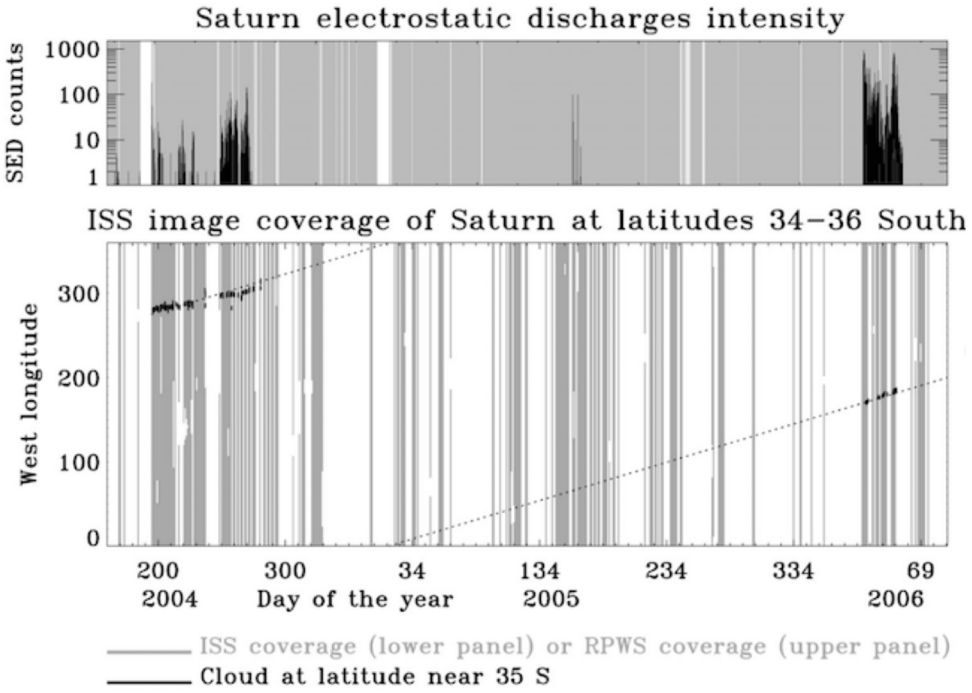

Figure SATURN-14. Saturn electrostatic discharge counts, SEDs, which are roughly equivalent to lightning strikes, over a 2-year period starting in 2004. The SEDs are detected by the RPWS instrument, which is ON continuously. The lower panel shows ISS coverage of latitudes −34° to −36°, where all the storms were occurring, and it is clear that storms were seen only when the RPWS was detecting SED's [Dyudina et al. 2007].

The great northern storm of 2010–2011 was a copious lightning emitter [Dyudina et al. 2013; Fischer et al. 2011]. The RPWS recorded flashes every 0.2 s. The optical energy per flash was about equal to that of the radio energy [Dyudina et al. 2013], although there is considerable uncertainty in both. The optical energy in single flashes ranged up to 8×10^9 J. The flash rate and total power were hundreds of times greater than those of the smaller southern storms that had been appearing intermittently since the start of Cassini observations. Fischer et al. [2014] proposed that the northern storm could account for a change in the Saturn kilometric radiation (SKR) frequency through its effect on thermospheric winds.

The Saturn lighting results stimulated two reviews of planetary lightning [Yair et al. 2008; Yair 2012]. Lightning is an agent of chemical change. Based on VIMS observations, Baines et al. [2009a] proposed that the dark and spectrally featureless clouds associated with giant planet thunderstorms represent small particles of elemental carbon. The particles are postulated to arise from atmospheric methane exposed to high temperatures during the lightning discharge, but Sromovsky et al. [2018] argue that the dark features are more likely regions of reduced optical depth. Dubrovin et al. [2014] studied the effect of lightning on the lower ionosphere of Saturn finding that H_3^+ ions are rapidly produced from the parent H_2^+ ion. On the other hand [Hurley et al. 2012a] searched for but found no correlation between acetylene and thunderstorm activity on Saturn. The Saturn results also

stimulated lightning searches throughout the solar system and on exoplanets from Earth-based radio telescopes and from spacecraft [Hodosan et al. 2016; Zarka et al. 2008].

Saturn Interior Structure and Rotation (S_AO3)

- **Saturn Formation and Evolution (S_AO5)** – Provide observational constraints (gas composition, isotope ratios, heat flux, …) on scenarios for the formation and the evolution of Saturn

The internal heat coming out of the planet is a fundamental quantity relevant to formation and evolution. Because giant planets in our solar system are massive and their surfaces are cold, they cool off slowly. Their interiors are still warm, and they are still releasing some of their heat of formation. To measure the internal power one takes the difference between the emitted infrared power and the absorbed solar power, which is the difference between the incident and reflected sunlight. Using Voyager data, Hanel et al. [1983] estimated the effective emission temperature as 95.0 ±0.4 K, corresponding to an average emitted heat flux of 4.62 ±0.8 W m^{-2}, and the ratio of emitted power to absorbed power as 1.78 ±0.09. Thus the internal power divided by the absorbed solar power is 0.78. Using data from Cassini CIRS, Li et al. [2010] estimated the emitted heat flux as 4.952 ±0.035 W m^{-2} during 2004–2009, although it decreased by 2% during that time and was 16% higher in the southern hemisphere than in the northern hemisphere. These were likely seasonal changes associated with the approach of vernal equinox in 2009. Li et al. [2015] measured the emitted power vs. latitude from 2004 to 2013 and documented the 2010 great storm's effect, which was to increase the global emitted power by 2% and the power at the latitude of the storm by 9% (Figure SATURN-4). These changes were in addition to a seasonal warming of the north and cooling of the south from 2004 to 2013.

The settling releases gravitational potential energy, which affects the cooling history and planetary evolution.

The helium to hydrogen ratio in the atmosphere reflects the value in the solar nebula when the planets were forming as well as the degree to which helium has settled toward the core. Settling is thought to happen because helium becomes immiscible in metallic hydrogen, which is the dominant constituent at megabar pressures. The settling releases gravitational potential energy, which affects the cooling history and planetary evolution. In principle, helium is detected by remote sensing through its effect on the molecular weight of the gas. One uses occultation data to get density vs. altitude, and from the hydrostatic equation one gets density vs. pressure. Then one uses infrared data to get temperature vs. pressure, and with the equation of state one can solve for the molecular weight. The method was used for Jupiter and Saturn using Voyager data [Conrath et al. 1984], but the Galileo probe gave a different result for Jupiter and forced a reanalysis for Saturn [Conrath and Gautier 2000]. Cassini has collected excellent data using CIRS for the temperature and occultations by several instruments—radio science, VIMS, and UVIS, but getting a consistent estimate of the helium abundance is difficult. The occultation result depends on the ray path, and that depends on unknown winds and temperatures above the

occultation point. The most recent estimate [Koskinen and Guerlet 2018] uses Cassini UVIS for the occultations and CIRS for temperature versus pressure. They get a helium mass fraction Y of 0.16−0.22, which is about 70% of the protosolar mass fraction of 0.27, implying that a certain amount of settling has occurred in Saturn's interior.

Before Cassini reached Saturn, the C/H abundance ratio was known to be higher on Saturn than on Jupiter, which was known to be higher than that on the Sun [Atreya et al. 1999, 2003; Owen and Encrenaz 2003]. The C/H ratio is perhaps the most accurately known ratio of all the heavy elements because its molecular form, methane, doesn't condense at Saturn temperatures and isn't readily destroyed in chemical reactions. Cassini CIRS probes the far-infrared rotational lines of the molecule and has determined a volume mixing ratio of $(4.7 \pm 0.2) \times 10^{-3}$, corresponding to a C/H enrichment relative to solar of 10.4 [Fletcher et al. 2009b]. This is more than a factor of 2 greater than that for Jupiter but consistent with conventional models of the formation and evolution of the giant planets, which predict increasing ratios to H of the heavy element abundances relative to the Sun from Jupiter to Neptune [Atreya et al. 2019].

Saturn's greater enrichment is also qualitatively consistent with the masses and radii of the two giant planets. These, coupled with the gravitational moments, rotation rate, and an equation of state, give information about the core mass and amount of heavy elements in the molecular envelope [Guillot 1999; Nettelmann et al. 2013]. Chemical models preceding the arrival of Galileo and Cassini listed many gases that were potentially observable in the atmospheres of Jupiter and Saturn [Fegley and Lodders 1994].

The high C/H ratio is taken as evidence of heavy element enrichment in general and has implications for possible differential sedimentation in the planet's interior over its lifetime [Mousis et al. 2006]. Measurements of NH_3, PH_3, C_2H_2, C_2H_6, and CH_4 all are consistent with these gases trapped as clathrate hydrate in the feeding zone of Saturn as the planets were forming [Hersant et al. 2008]. Clathrate hydrates require water, and our lack of knowledge of the oxygen abundance allows for a number of interior models with a range of values for the C/O ratio [Lunine 2011]. Cassini CIRS measurements suggest that Saturn's D/H ratio is less than that for Jupiter, which mostly reminds us that our understanding planetary formation and evolution is incomplete [Pierel et al. 2017].

Although ammonia is the main carrier of nitrogen on Jupiter and Saturn, the isotopic ratio $^{15}N/^{14}N$ can reveal insights into the molecular carrier (N_2 versus NH_3) in the protoplanetary nebula. The Saturnian and Jovian isotopic ratios appear indistinguishable [Fletcher et al. 2014; Fouchet et al. 2004a]. That result favors accretion of primordial N_2 on both planets, either in the gas phase from the solar nebula or as ices formed at very low temperature [Fletcher et al. 2014].

- **Saturn's Rotation Rate (SN1a)** – Determine Saturn's rotation rate and internal structure despite the planet's unexpected high degree of axisymmetry.

The periodic variation of the dynamo field has been used to estimate the interior rotation rates of Jupiter, Uranus, and Neptune. However, Saturn's magnetic field axis is so closely aligned with its rotation axis that is has no periodic variation. Taking the misalignment of the other three giant

planets, 10° for Jupiter, 60° for Uranus, and 47° for Neptune, the 0.1° upper bound for Saturn is highly improbable (1 chance in 10^4 or 10^5), given that the probability of the magnetic axis aligning with the rotation axis goes as the square of the angle between them [Dougherty 2017]. The close alignment means that there is no detectable wobble in the field as the planet rotates and therefore no periodic signal with which to estimate the rotation period of the planet's interior. The SKR radio emissions are tied to currents in the magnetosphere and ionosphere, and the period is variable from year to year [Fischer et al. 2014], which rules out a direct tie to the interior of Saturn.

There have been various attempts to use the atmospheric periods to estimate the interior rotation rate. They use the data in different ways, but they all derive a period that is near the midpoint of the atmospheric periods. Smith et al. [1982] use cloud tracking and choose a reference frame that minimizes the variance of the cloud-tracked zonal wind with respect to latitude, with 10 h 31 m 30 ±30 s as the result. Anderson and Schubert [2007] chose the reference frame that minimizes the measured shape of the 100 mbar surface from an equipotential, with 10 h 32 m 35 ±13 s as the result. Read et al. [2009b] use the reference frame in which the atmosphere is marginally stable with respect to Arnol'd's second stability criterion, with 10 h 34 m 13 ±20 s as the result. Their method uses ISS and CIRS wind and temperature data to estimate potential vorticity in the range 2–270 mbar. The problem with these approaches is that they ignore the thermal wind equation, which allows vertical shear in the zonal winds. Thus the speed at depth might not match the average speed at the tops of the clouds where the winds and temperatures are measured. Read et al. [2009b] argue that the stability criterion depends on the speed of the longest Rossby waves, which are deeply rooted, but still the problem remains. For instance, the midpoint of the wind distribution at Earth's upper troposphere would give a period between 22 hours and 23 hours for the rotation of the planet, because the average wind at the top of the troposphere is to the east.

Saturn is a fluid planet, and if it were in equilibrium only the zonal harmonics with even *n* would be present.

The gravity field [Jacobson et al. 2006] also has information about the rotation rate of the interior [Hubbard 2009]. As with all planets, Saturn's gravitational potential can be expanded into spherical harmonics, the leading term of which is the spherically symmetric potential −GM/R, followed by the zonal harmonics and the tesseral harmonics. The zonal harmonics are axially symmetric, and each term is proportional to a Legendre polynomial of degree n and a dimensionless amplitude factor J_n. The tesseral harmonics are the longitudinally-varying part of the gravitational potential. Saturn is a fluid planet, and if it were in equilibrium only the zonal harmonics with even n would be present. The J_n reflect the response of the planet to its own rotation, so one could use them to infer the interior rotation rate if the interior structure were known. Conversely, one could infer the interior structure, e.g., core mass, metallic hydrogen, degree of helium separation, heavy elements in the molecular envelope, etc., if the rotation rate were known [Helled and Guillot 2013; Helled et al. 2015; Hubbard 2009]. Further information about the interior could come from the tidal Love number—the magnitude of the planet's response to tidal forces [Lainey et al. 2017]. The observations are astrometric data on the orbits of Saturn's moons spanning more than a century and include a large set of Cassini data. The study indicates significant tidal

dissipation inside the planet. In all cases, an independent measure of the rotation rate is important for probing the internal structure.

The tesseral harmonics have an effect on the rings, which are a sensitive seismometer for detecting the non-zonal gravity field [Hedman and Nicholson 2013, 2014]. The harmonics are of two types. One type has pattern speeds ranging from 807 to 834 degrees per day, for which the corresponding periods are 10 h 42 m to 10 h 22 m, respectively (Figure SATURN-15). These nearly bracket the periods derived from tracking the clouds at various latitudes in Saturn's atmosphere, and could be due to non-zonal structures rotating with the planet. The large range of periods prevents improving on cloud tracking estimates alone. The other types of tesseral harmonics have pattern speeds near five hours and are thought to be due to normal mode oscillations inside the planet. The precise frequencies of these normal modes depend both on the interior structure and the interior rotation rate, but as with the zonal harmonics, it is difficult to separate the two effects. This is an ongoing effort.

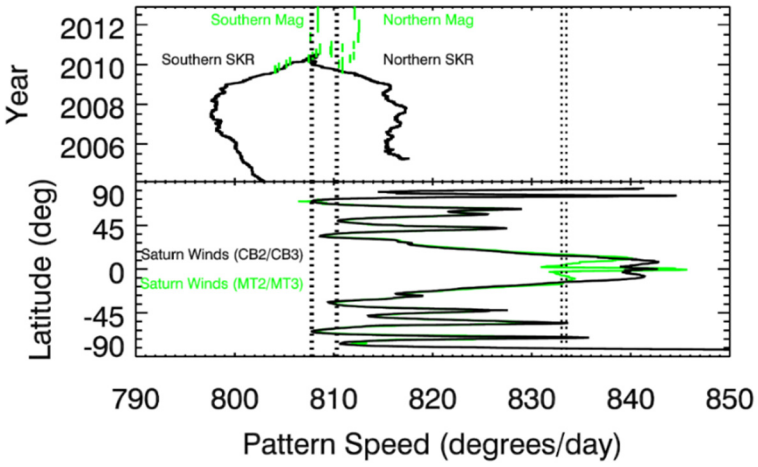

Figure SATURN-15. Ring seismology. The vertical dotted lines are the speeds of non-axisymmetric patterns in Saturn's rings. Only the patterns that match the planet's rotation are shown. They could be due to floating masses in the interior of Saturn. For comparison, periods of exterior magnetic fields, radio emissions, and clouds in the atmosphere are shown. Other patterns with speeds twice as fast are likely due to normal mode oscillations of the planet [Hedman and Nicholson 2014].

The precise frequencies of the normal modes depend both on the interior structure and the interior rotation rate. Parameters of the interior structure include the mass of the core, the helium mass fraction and the heavy-element mass fraction in the metallic and molecular envelopes, and the pressure at the metallic-molecular transition [Mankovich et al. 2019]. For a given rotation rate, the interior parameters are adjusted to give the observed values of J_2 and J_4. The rotation rate is varied to give the best fit to the observed frequencies of the ~20 normal modes whose resonant effect on the ring orbits makes them detectable. The planet's rotation affects the frequencies through the Coriolis and centrifugal forces and the ellipticity of level surfaces. The distribution of rotation periods resulting from a broad sample of interior models can be summarized as $10^h\ 33^m\ 38s^{+1m52s}_{-1m19s}$ [Mankovich et al. 2019]. The residuals of the fit do not exhibit any strong evidence of differential rotation inside the planet, but differential rotation cannot be ruled out. The rotation period

is consistent with predictions by Militzer et al. [2019] who combined interior models, which were constrained by Cassini's gravity measurements, with observations of the planet's oblateness by the Voyager spacecraft. Based on this analysis, a rotation period of 10:33:34 ±55 s is predicted for the planet's deep interior.

The even zonal harmonics, especially n = 6 and above, can be used to detect differential rotation inside the planet [Galanti and Kaspi 2017; Kaspi 2013]. This method is being used both with Cassini at Saturn and with Juno at Jupiter. The odd harmonics have been used only at Jupiter. The software to analyze these data was developed to be used on both planets [Galanti and Kaspi 2016; Galanti et al. 2017; Kaspi et al. 2016]. Cassini produced its best gravity data during six dives between the planet and the innermost ring during the final five months of the mission [Iess et al. 2019]. On these dives the spacecraft skimmed 2600–3900 km above the cloud tops while the radio link to Earth was monitored to determine the gravitational field of the planet and the mass of the rings. The gravity measurements yielded unexpectedly large values of the even zonal harmonics J_6, J_8 and J_{10}. These values do not match any interior model that assumes uniform rotation and makes reasonable assumptions about the equation of state and helium rain [Iess et al. 2019]. Galanti et al. [2019] confirmed that an acceptable solution can only be found for J_2 and J_4.

One can fit all the even harmonics J_2-J_{10} with a model where unknown winds extend through the planet on cylinders. The best fit is where the atmosphere at the equator rotates 4% faster than the deep interior, but the models also require a region that rotates more slowly than the deep interior, which is surprising because it is not seen in the cloud tracking data. One can also fit the harmonics by assuming the observed cloud-top winds extend to a finite depth. The best fit is with a finite depth of 9000 km. Qualitatively the two results are the same, since the cloud-top winds are fastest at the equator. The depth of the winds for Saturn is 2–3 times deeper than that for Jupiter, but the difference is explained by the more rapid increase of electrical conductivity with depth on Jupiter and the shallower point where magnetic drag suppresses differential rotation [Guillot et al. 2018].

Once the gravity signal of the deep winds is adequately incorporated into models for Saturn's interior, reasonable structures are obtained: The conditions of helium rain are compatible with predictions from ab initio computer simulations. Cores of heavy elements with 15–18 Earth masses are compatible with the core-accretion hypothesis, which requires a ~8 Earth mass core to trigger run-away gas accretion. The enrichment of heavy elements in the planet's molecular envelope of 1–3 times solar is lower than expected but still reasonable. This contrasts with the persistent conundrum for Jupiter, for which the inferred heavy abundances are near or subsolar.

A puzzling feature of this analysis is that the same model of the gravitational field cannot fit all of the six passes in a combined, multi-arc orbital solution [Iess et al. 2019]. The residuals represent unmodeled accelerations acting on Cassini over time scales of 20–60 min and could be due to time-varying tesseral harmonics. Convection in Saturn's interior is one possible source. Normal modes varying in amplitude and frequency is another. The data were eventually fit by assuming random accelerations of 10 minute duration acting within ±1 hour from pericenter [Iess

et al. 2019]. The hope is that these high-frequency accelerations do not significantly affect the determination of the even harmonics J_2-J_{10}.

Aurora, Chemistry, and Upper Atmosphere (SC2a)

Observe the upper atmosphere and the aurora as it changes on all time scales—minutes to years—and is affected by seasonal and solar cycle forcing.

- **Upper atmosphere (SC2a)**

The stratosphere entered in the discussion in the sections entitled Composition and chemistry, Seasonal variations, and Saturn's winds. To reduce the overlap between those sections and this one, we focus here on theoretical models and on the parts of the atmosphere above the stratosphere. The entire subject, upper atmosphere and ionosphere, is reviewed in the book chapter by Nagy [2009]. Species like C_2H_2 and C_2H_6 have chemical lifetimes in the stratosphere that are comparable to a season on Saturn, so they can be used as tracers of the meridional circulation and its annual reversal from north to south. At the equator the zonal winds in the stratosphere exhibit a 15-year oscillation that is accompanied by an oscillation of the temperature distribution symmetric about the equator to maintain thermal wind balance.

The simplest chemical model is a diurnally averaged 1D photochemical model with eddy diffusion chosen to represent dynamical processes. Moses et al. [2000a] developed a model that couples hydrocarbon and oxygen photochemistry, molecular and eddy diffusion, radiative transfer, and condensation to better constrain the chemical species and to identify the important physical processes that control the abundances. Moses et al. [2000b] consider the role of oxygen by comparing their model results with the observed abundances of H_2O and CO_2. They find that an external source of oxygen is necessary, and they estimate its magnitude. They mention micrometeoroid ablation and ring particle diffusion as likely sources.

In particular, electrostatic charging could lead to ejection of nanograins out of the ring plane and into the atmosphere by the electromagnetic force [Ip et al. 2016]. Further evidence of ring rain is seen in enhanced H_3^+ emissions at latitudes tied to magnetic field lines that cross the equatorial plane at the locations of the inner edges of the A-ring and B-ring and at the orbit of Enceladus [O'Donoghue et al. 2013, 2017].

Hesman et al. [2009] compare the output of the static photochemical model with observations of C_2H_2 and C_2H_6, and they find evidence of a meridional circulation. Guerlet et al. [2014] compare the temperatures computed from a radiative equilibrium model with temperatures observed by Cassini CIRS, and they find evidence that other processes, presumably related to dynamics, control Saturn's stratospheric thermal structure. Teanby et al. [2006] place new upper limits on halides in Saturn's stratosphere, but they advise that the abundances in the troposphere could be much larger. Sinclair et al. [2014] compare temperatures and gaseous abundances from Cassini with those from Voyager exactly one Saturn year later. They find that most of the change is due to the opposite phase of the 15-year oscillation and that other types of interannual variability are small.

Above the stratosphere, diffusive separation takes over and each gas's density falls off with altitude at its own individual scale height, which depends on its molecular weight. The altitude of the transition is called the homopause. Below the homopause, one finds gaseous hydrocarbons ranging in molecular weight at least up to benzene [Koskinen et al. 2016; Vervack and Moses 2015]. These hydrocarbons are the source of stratospheric haze particles at non-auroral latitudes [Moses et al. 2000a; Kim et al. 2012]. Above the homopause the major constituent is H_2, which continues into the exosphere where the molecules don't collide with each other except at the exobase [Koskinen et al. 2013]. The relatively high (380 K to 590 K) exospheric temperature at low to mid latitudes is a long-standing mystery [Shemansky and Liu 2012; Stallard et al. 2012b]. Despite the changing seasons, the high temperatures have persisted from the period of the Voyager flybys through the Cassini era [Koskinen et al. 2015]. High temperatures do occur in the auroral zones, but dynamical models strongly suggest that the upper atmosphere is geostrophically balanced and cannot convey the high-temperature air to lower latitudes (Figure SATURN-16). One possibility is that atmospheric gravity waves, which are often overlooked in models, could supply enough torque to overcome the Coriolis force and allow enough meridional overturning to warm the equatorial thermosphere [Müeller-Wodarg et al. 2019].

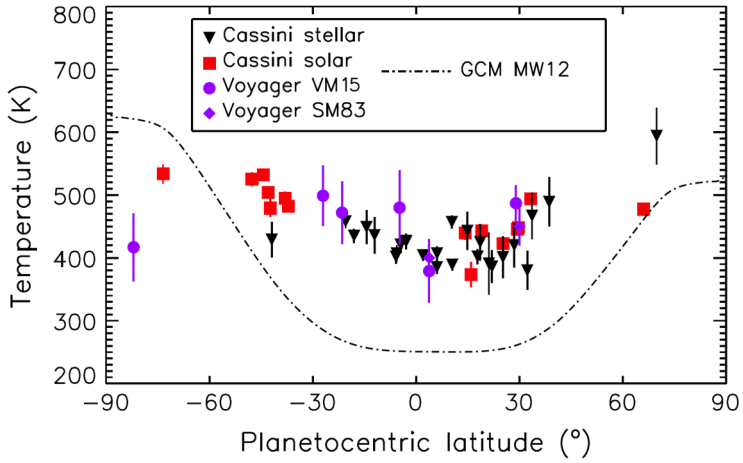

Figure SATURN-16. Comparison of Cassini UVIS observations with Voyager observations and with a 3-D general circulation model. The model result is represented by the smooth dot-dashed line, and it is significantly low (colder) equatorward of ±60° in both hemispheres. The problem is that the air from the polar regions, heated by auroral currents, cools before it reaches the lower latitudes. What keeps it warm is an ongoing mystery [Koskinen et al. 2015].

The first in situ measurements of the equatorial thermosphere occurred during the final month of the Cassini mission, when the spacecraft skimmed through the upper atmosphere on four periapses and also during the final plunge. The Ion Neutral Mass Spectrometer (INMS) measured the profiles of temperature and composition [Yelle et al. 2018]. The best fit to the exospheric temperature is in the range 340 to 370 K, with a value during the final plunge of 354 K. The helium profiles are consistent with diffusive equilibrium, but the methane profiles are not. Even well above the homopause, the CH_4/H_2 ratio is nearly constant with height. This points to an external source, the most likely being Saturn's rings [Yelle et al. 2018].

- **Aurora (SC2a)**

The aurora is caused by precipitating electrons striking the upper atmosphere. The source of the electrons is in the magnetosphere, and the subject is covered mainly in the section entitled Magnetospheres and Plasma Science (MAPS) Discipline Science Results. Some of the questions involve the energy and source of the electrons, how deep they penetrate into the atmosphere, and what effects they have on the temperatures, chemistry, and electromagnetic emissions associated with the aurora.

The aurora is observed in the ultraviolet [Gerard et al. 2013; Gustin et al. 2009, 2010, 2017], visible [Dyudina et al. 2016], infrared [Melin et al. 2011, 2016; O'Donoghue et al. 2014; Stallard et al. 2012a], and radio wavelengths [Lamy et al. 2009, 2013; Ye et al. 2016]. The currents associated with the electrons can be observed when the spacecraft flies through an auroral flux tube [Bunce et al. 2014]. And although the magnetosphere of Saturn is much less energetic than that of Jupiter, the footprint of the Enceladus flux tube has detectable emissions [Pryor et al. 2011], though not so bright as those of the Jovian moons: The geysers of Enceladus are weaker than the volcanoes of Io, and the magnetic field of Saturn is weaker than the magnetic field of Jupiter.

For a short, broad-brush summary of the magnetosphere, ionosphere, and atmosphere, we recommend Gombosi and Ingersoll [2010].

- **Ionosphere (S_AO4)** – Study the diurnal variations and magnetic control of the ionosphere of Saturn.

This science objective is captured in detail in the Magnetospheres and Plasma Science (MAPS) Discipline Science Results under the following AO and TM science objectives: **MN1b:** Conduct in situ studies of Saturn's ionosphere and inner radiation belt; **MN1c:** Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the SKR periods are imposed from close to the planet (3–5 R_S) out to the deep tail; **MN2a:** Determine the coupling between Saturn's rings and ionosphere; and **MC1a:** Determine the temporal variability of Enceladus' plume (relevant to the Enceladus auroral footprint).

Further Science Objectives for Saturn Science

- **Water.** Measure the global water abundance and determine its role in bringing heat to the surface. Determine the role of moist convection in maintaining the large-scale motions. A Saturn probe to the base of the water cloud is a challenging but possible objective.
- **Rotation.** Determine Saturn's rotation period if such a number exists, or determine the spread of periods if differential rotation persists into the interior.
- **Noble gases.** Determine Saturn's noble gas abundances including helium, as done for Jupiter by the Galileo probe. A Saturn probe could measure noble gases to exquisite precision.

- **Weather layer.** Determine the vertical profiles of temperature, winds, clouds, condensable gases, longwave and shortwave radiation, and turbulence levels. A cloud-resolving model like those used in tropical meteorology, but tailored to the giant planets, is both timely and valuable. Again, a Saturn probe is needed.
- **Interior.** Using the power of ring seismometry and gravity sounding, improve the understanding of Saturn's internal equation of state, mass distribution, composition, and temperature distribution. Develop a fully coupled interior/weather-layer model as done for Earth's oceans and atmosphere.

SATURN DWG NON-SATURN SCIENCE RESULTS

- **Jupiter atmospheric dynamics (J_AO1)** – Extend the time for studies of atmospheric dynamics beyond the period accessible to the Galileo nominal mission.

Jupiter has a photogenic atmosphere; its colorful clouds provide ideal tracers of the winds (Figure SATURN-17). The light and dark bands—the zones and belts—and their associated jet streams have been observed from Earth for more than 100 years. The Great Red Spot (GRS) and its smaller cousins have been observed for just as long. Thus Jupiter is an atmospheric dynamics laboratory, where dynamical phenomena like waves, jets, eddies, and vortices can be studied without the complications of continents, oceans, and large seasonal swings. As it approached and flew past Jupiter in late 2000, Cassini provided three months of valuable data about the atmosphere. A 70-day movie shows the clouds in motion at all longitudes and latitudes up to within ~10 degrees of the poles. That movie in cylindrical and polar projections is PIA03452, PIA03453, and PIA03454, and is available at https://photojournal.jpl.nasa.gov/.

The GRS is at least 150 years old, although it could be much older. The three white ovals to the south of the GRS formed in the late 1930s and merged into one oval named BA in the late 1990s. All of these features are anticyclones with circumferential winds greater than 100 m s^{-1}. They drift slowly in longitude but stay fixed in latitude. Combined with Hubble Space Telescope and Galileo data, Cassini data were used to show that the GRS shrank by 15% from 1996 to 2006, both in terms of its visible appearance and its ring of circumferential winds [Asay-Davis et al. 2009; Shetty and Marcus 2010].

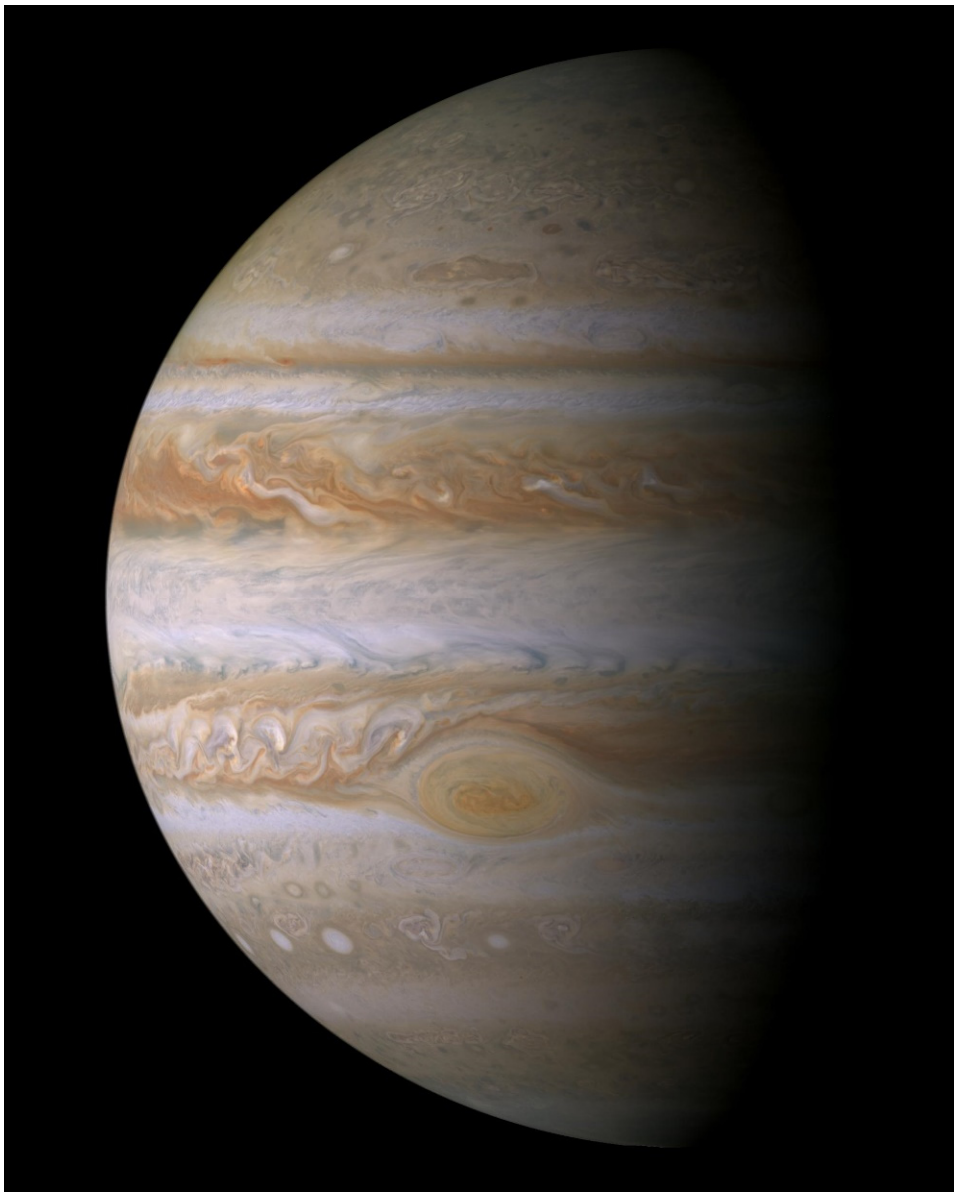

Figure SATURN-17. The highest-resolution, full-disk color mosaic of Jupiter ever taken. Jupiter more than filled the field of view of the ISS, so the mosaic was assembled from over 30 individual images, allowing for the planet's rotation as the images were taken.

The white ovals occupied a single latitude band with anticyclonic vorticity. They avoided each other for 60 years because they were separated by cyclonic regions encroaching into the band from the equatorward side [Youssef and Marcus 2003]. When the cyclonic regions got pushed out, the ovals merged. Peak velocities around oval BA remained steady while the color changed from white to red several years later. Using different techniques to measure winds and different definitions of the oval's edge, different groups have documented small changes in the properties of

BA over similar time periods [Hueso et al. 2009; Choi et al. 2010; Sussman et al. 2010]. The combination of Cassini ISS data and Hubble methane band data was used to understand the changes in vertical cloud structure as BA changed from white to red [Wong et al. 2011]. Using ISS data from the Cassini flyby [Li et al. 2004; Choi et al. 2013] and amateur telescopic data [Rogers et al. 2006], several authors have documented the life cycles—formation, shape, lifetime, mergers—of the more numerous smaller spots on Jupiter.

Jupiter's zonal jets are remarkably steady in comparison with Earth's jet streams, which change on time scales of one or two weeks (Figure SATURN-18). Cassini ISS documented only one latitude outside the equator, near 21° planetocentric, where the jet speed had changed by a modest amount from Voyager in 1979 to Cassini in 2000 [Porco et al. 2003; Asay-Davis et al. 2011]. Most of the observed variability is at the equator [Garcia-Melendo et al. 2011a] and is part of a regular ~4-year oscillation similar to the QBO on Earth [Simon-Miller et al. 2007; Simon-Miller and

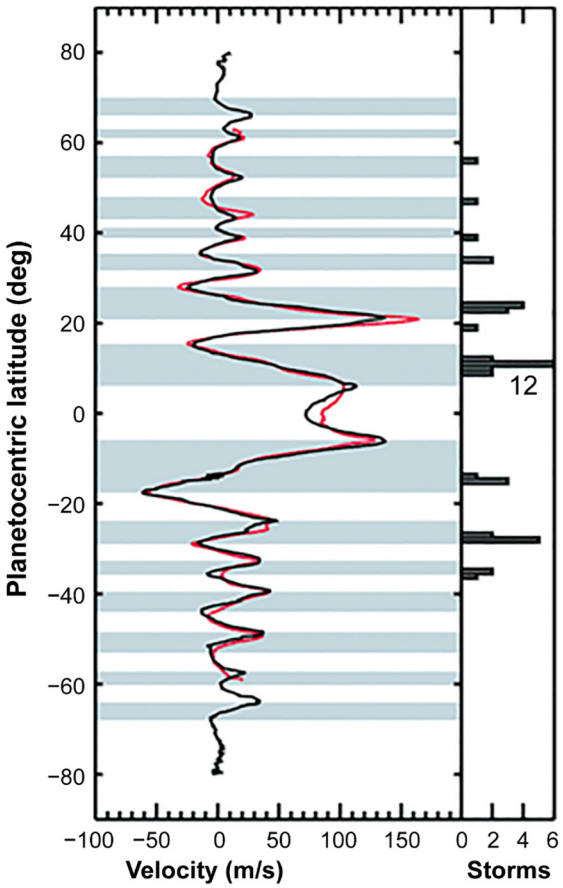

Figure SATURN-18. Atmospheric zonal velocity for Jupiter. The black curve is from Cassini ISS data in late 2000, and the red curve is from Voyager data in mid1979. The jets are remarkably steady over this 21-year interval [Porco et al. 2003].

Gierasch 2010]. Meridional transport is inferred indirectly from Cassini CIRS data that give the latitudinal distribution of C_2H_2 and C_2H_6, which have known chemical lifetimes and thereby track

the age of air masses in the stratosphere [Liang et al. 2005; Zhang et al. 2013b]. Vertical wind shear of the zonal winds is studied by tracking features at different wavelengths that probe different altitudes [Li et al. 2006c].

Waves in a planetary atmosphere provide information about the medium in which they propagate and also about the sources that excite them. Mesoscale waves—wavelengths ~100 km—are visible from space if the crests and troughs are marked by clouds. The thunder following a lightning strike and the sonic boom following a meteor impact are examples of intense sound waves. Cassini could not detect sound waves, but it did detect thunderstorms and lightning [Dyudina et al. 2004; Porco et al. 2003; Baines et al. 2007]. Voyager, Galileo, and New Horizons detected mesoscale wave trains with crests and troughs aligned north-south and wavelengths of ~300 km. Cassini apparently did not detect mesoscale waves [Arregi et al. 2009]. They may have been absent at the time of the Cassini flyby or perhaps the waves were unobservable due to lack of cloud tracers. One theory says the mesoscale waves are propagating gravity waves [Flasar and Gierasch 1986], and another theory says they are shear instabilities [Bosak and Ingersoll 2002]. The measured phase velocities seem inconsistent with both models [Simon et al. 2015] given reasonable assumptions about the vertical wind shears, so the nature of the mesoscale waves is uncertain.

Cassini also detected large scale periodic patterns with wavelengths ranging up to 20,000 km. Circumpolar waves have wavelengths and phase speeds that suggest they are Rossby waves [Barrado-Izagirre et al. 2008, 2009]. Simultaneous observations by ISS, UVIS, and CIRS allow one to probe the vertical structure and opacity sources of the waves [Li et al. 2006b]. Radio observations allow one to study how the passage of a wave affects the distribution of ammonia [Cosentino et al. 2017]. Cassini observations have been used to support various theories of wave-like features in the South Equatorial Belt—that they are either inertia-gravity waves or Rossby waves [Simon-Miller et al. 2012] or a pattern associated with baroclinic instability at that latitude [Rogers et al. 2016].

Wave mean-flow interactions and cascades of energy from one scale to another are fundamental processes in the dynamics of planetary atmospheres. One theory says that the zonal mean flow forms into a potential vorticity (PV) staircase. PV is a conserved dynamical tracer and the staircase consists of latitude bands with constant PV and sharp boundaries in between. However, quantitative analysis of the Cassini 70-day movie shows that the PV gradient reverses sign and is not zero as the staircase model predicts [Li et al. 2004; Read et al. 2006; Shetty and Marcus 2010]. The 70-day movie was also used to show that the eddy momentum transport is into the jets from neighboring latitudes, meaning that the eddies are supplying energy to the jets and not the reverse (Figure SATURN-19) [Salyk et al. 2006]. The eddies could be getting their energy from convection [Li et al. 2006a] or the latitudinal gradient of radiative heating, or both [Schneider and Liu 2009]. Fourier spectra of the 70-day movie data generally reveal an inverse energy cascade, where kinetic energy flows from intermediate scales to large scales [Choi and Showman 2011; Galperin et al. 2014; Hadjighasem and Haller 2016], but there is evidence of a forward cascade from intermediate scales down to small scales, which has been interpreted as energy input at the intermediate scales, perhaps associated with the radius of

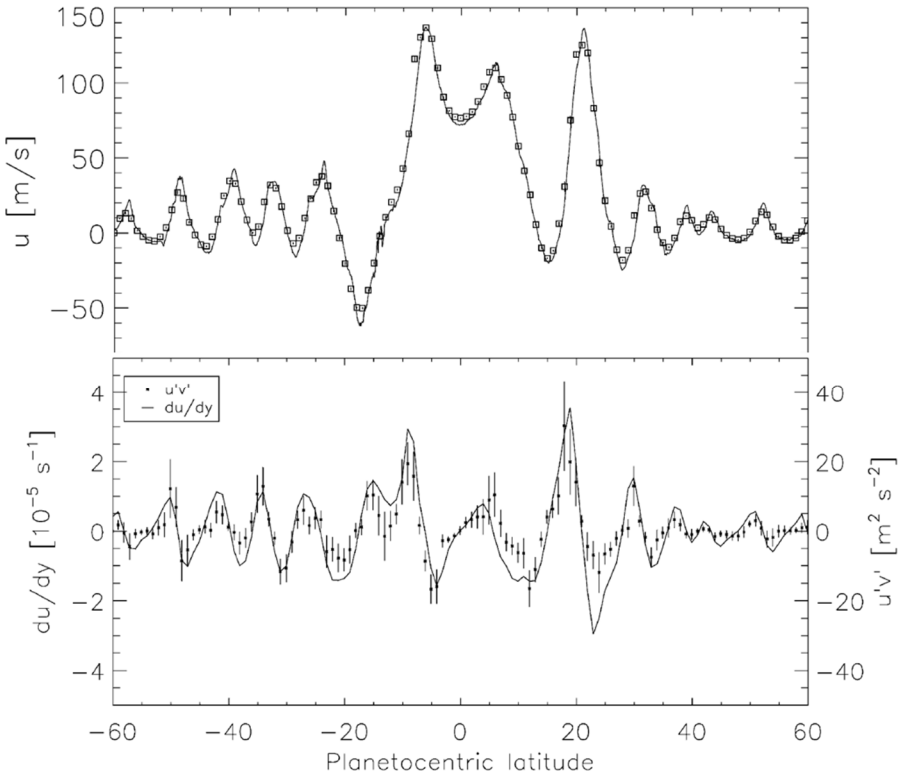

Figure SATURN-19. Eddy momentum transport for Jupiter from Cassini ISS. The eastward and northward eddy winds u′ and v′ are the departures from the zonal means. Their product $\overline{u'v'}$ averaged over longitude and multiplied by density is the northward eddy flux of eastward momentum. The fact that this quantity has the same sign as $\partial\overline{u}/\partial y$, which is the increase of the mean eastward wind with latitude, says that the eddies are putting energy into the jets and not the reverse [Salyk et al. 2006].

deformation through baroclinic instability [Young and Read 2017]. Others have compared visible features in the 70-day movie with fine-scale features in their 3-dimensional numerical models to test the models' treatment of unknown processes and parameters [Heimpel et al. 2005, 2016; Morales-Juberias and Dowling 2013].

- **Jupiter Global Atmospheric Structure and Composition (J_AO2)** – Infer global atmospheric thermal structure and composition with instrumentation not carried by the Galileo Orbiter, complementing the local in situ measurements of the Galileo Probe.

Reactive gases can serve as tracers that reveal regions of upwelling, downwelling, and meridional motion (Figure SATURN-20). During the Jupiter flyby, Cassini CIRS measured the latitude distributions of C_2H_2 and C_2H_6, which are produced in the upper stratosphere by photodissociation of methane. The rate of production is greatest at the equator where the solar ultraviolet (UV) is greatest. C_2H_2 has a chemical lifetime that is short compared to the meridional overturning, so it decreases toward the poles in response to the reduced solar UV. C_2H_6 has a longer chemical lifetime, so following a fluid parcel it increases with time the longer the parcel

spends in the stratosphere. The abundance of C_2H_6 increases toward the poles [Nixon et al. 2007, 2010], suggesting a meridional circulation in the stratosphere with upwelling at the equator and downwelling at the poles. The circulation revealed from the distributions of C_2H_2 and C_2H_6 aids in understanding the origin and chemical lifetimes of HCN and CO_2, which were also measured by CIRS [Lellouch et al. 2006].

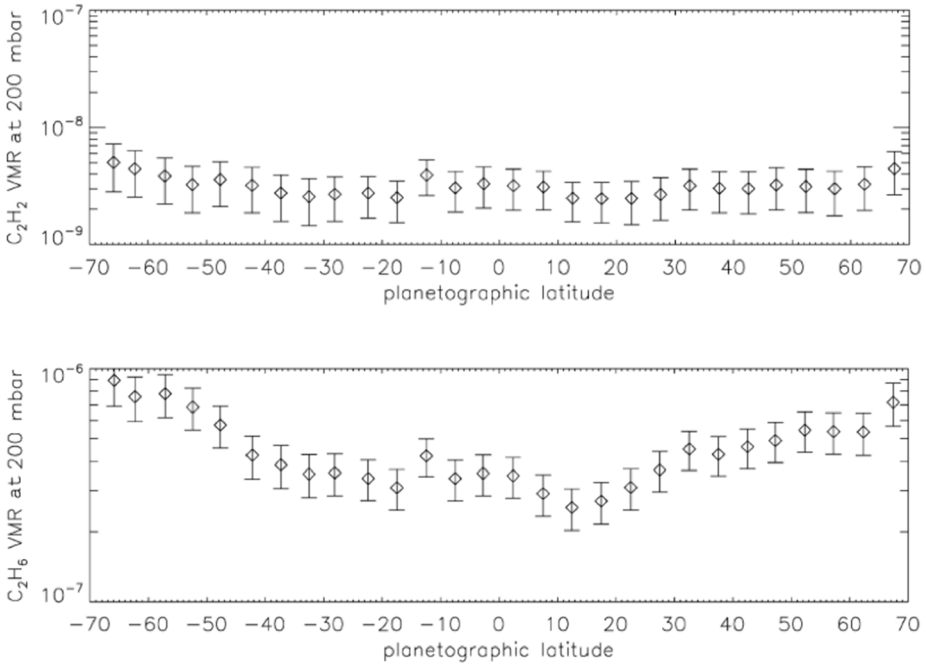

Figure SATURN-20. Chemical tracers in Jupiter's atmosphere at 200 mbar from Cassini CIRS. Both acetylene and ethane are formed at higher altitudes than these observations. C_2H_2 has a shorter lifetime once it is formed than C_2H_6 does, so it decays on the downdrafts faster than C_2H_6. The lower panel indicates downdrafts at the pole and updrafts at the equator. The upper panel shows that the time constant of this circulation is longer than the lifetime of the C_2H_2 molecule, because it has decayed before reaching the 200 mbar level [Nixon et al. 2007].

Since the stratosphere is stably stratified, to maintain steady state the updrafts must be heated and the downdrafts must be cooled. The decrease of sunlight toward the poles is consistent with updrafts at the equator and downdrafts at the poles. CIRS measurements of stratospheric temperatures and abundances of radiatively active gases are used to model the radiative forcing [Zhang et al. 2013a, 2013b], which includes the effects of stratospheric aerosols [Zhang et al. 2013c, 2015].

Cassini CIRS also measured the latitude distributions of phosphine [Irwin et al. 2004; Fletcher et al. 2009a] and ammonia [Achterberg et al. 2006]. The measurements refer to the upper troposphere, at the 100–500 mbar level, and they tell a consistent story. Both gases are removed from the atmosphere at upper levels, phosphine by photodissociation and ammonia by condensation, and both have maximum abundance at the equator and reduced abundance in the cyclonic belts on either side of the equator. This indicates rapid uplift or strong vertical mixing in

the equatorial zone and descent in the neighboring belts. Probing still deeper into the troposphere, Cassini VIMS detected a 3 μm absorption that could be a mixture of NH_4SH and NH_3 [Brown et al. 2003; Sromovsky and Fry 2010] and provided new insights into the composition of fresh ammonia clouds [Sromovsky and Fry 2018].

Gaseous abundances can provide clues to planet formation. CIRS measured the nitrogen isotopic ratio in ammonia [Abbas et al. 2004; Fouchet et al. 2004a]. The ratio is similar to that on the Sun but different from that on Earth, suggesting that the Earth was somehow isolated from the main reservoir of nitrogen during solar system formation. The hydrogen halides, on the other hand, are depleted relative to solar composition and support the halogens' condensation in ammonium salts [Fouchet et al. 2004b].

The Cassini flyby provided insights into aurora-related phenomena on Jupiter as well. UVIS observations of the He 584 Å line were used to infer enhanced eddy mixing in the polar regions, which may account for the enhancement of heavy hydrocarbons there [Parkinson et al. 2006]. Alternately, the enhancement of C_2H_2 and C_2H_6 in the polar regions could be explained by a combination of auroral-driven chemistry and advection by the meridional circulation [Sinclair et al. 2017]. CIRS observations have also been used to study the sources of heating in the polar stratosphere from 1–10 mbar [Sinclair et al. 2018]. The result is that heating by auroral soot particles dominates at 1 mbar altitude, and that heating by charged particles dominates at 10 mbar. Cassini VIMS observations have been used to produce the first maps of H_3^+ emission, temperature, and column density on Jupiter's nightside [Stallard et al. 2015]. The enhanced emission in the polar regions is produced by enhanced H_3^+ density rather than higher temperatures, which further points to the importance of auroral chemistry in that region.

Because of its high spatial and spectral resolution and full angular coverage during the flyby, Cassini obtained useful information about the clouds of Jupiter. Cloud color is a long-standing uncertainty: What chemical gives the Red Spot its redness? How many coloring agents are there? Comparison of laboratory experiments and visible spectra from Cassini VIMS suggests that the red chromophore is the product of photolyzed ammonia reacting with acetylene [Carlson et al. 2016; Baines et al. 2019]. The chromophore occurs in an optically thin layer above the main cloud deck, and may require upward displacement of the air mass to form. A principal component analysis of Cassini ISS data indicates that the red chromophore explains most of the variance across the planet, but a second coloring agent is required to explain the brownish color of the cyclones in Jupiter's North Equatorial Belt [Ordonez-Etxeberria et al. 2016].

The vertical structure of the cloud layers is another long-standing unknown. Cassini CIRS thermal spectra were used to probe into the clouds at a wavelength of 7.18 μm, where the ammonia gas is relatively transparent [Matcheva et al. 2005]. The result is that cloud base is at 0.9–1.1 bar, which is deeper than the nominal ammonia cloud base and might imply another, deeper cloud, possibly NH_4SH. Cassini VIMS covers 4.5–5.1 μm, another wavelength range where the gas is relatively transparent. Holes in the cloud allow thermal radiation to space, so the holes appear as hot spots. The cloud is found to be spectrally flat and at a pressure of 1.2 bar or deeper [Giles et al. 2015]. Pure NH_3 cloud and pure NH_4SH cloud do not match the spectra, and some kind of

coating is implied. Despite the possibility of coatings, CIRS has detected the spectral signature of NH_3 ice particles in the upper tropospheric clouds [Wong et al. 2004].

The planet's global energy budget is a key to its evolution and internal processes, including the separation of helium from hydrogen in the metallic interior. To determine the energy budget accurately, one would have to measure the thermal emission and scattered sunlight at all seasons, latitudes, longitudes, wavelengths, emission angles, incident angles, and phase angles. In practice, one samples these quantities and uses models to fill the gaps. Cassini CIRS, VIMS, and ISS all contribute to this estimate [Simon-Miller et al. 2006; Li et al. 2012; Sato et al. 2013; Mayorga et al. 2016]. North-south asymmetries and changes from Voyager to Cassini are present at the level of a few percent, but whether these are random fluctuations or systematic trends is uncertain.

Venus Atmosphere Observations

The Venus flybys yielded useful data at a variety of wavelengths. The VIMS instrument detected thermal emission from the hot surface at wavelengths of 0.85 and 0.90 μm, and thereby provided a new technique for exploring the surface mineralogy [Baines et al. 2000]. In an attempt to image the surface, the RADAR instrument was operated at 2.2 cm in both scatterometric and radiometric modes during the encounters, but only the thermal emission from the thick absorbing atmosphere was detected [Lorenz et al. 2001]. The UVIS instrument studied the airglow of Venus, focusing on N_2, C, O, and CO as clues to the excitation mechanisms and abundances [Hubert et al. 2010, 2012; Gerard et al. 2011]. Lightning on Venus is a long-standing controversial subject. The RPWS instrument on Cassini searched for lightning signals in the frequency range 0.125 to 16 MHz and found none, even though they easily detected lightning at rates of 70 s^{-1} during the Earth flyby several months later [Gurnett et al. 2001].

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AO	Announcement of Opportunity
CAKE	Cassini Apoapses for Kronian Exploration
CIRS	Composite Infrared Spectrometer
CSM	Cassini Solstice Mission

TITAN

Until the Cassini-Huygens mission, very little was known about Saturn's largest moon Titan, except that it was a Mercury-sized world whose surface was veiled beneath a thick, nitrogen-rich atmosphere. But Cassini mapped Titan's surface, studied its atmospheric reactions, discovered liquid seas there and even sent the Huygens probe to the moon's surface, completely rewriting our understanding of this remarkable world, including the detection of a large internal ocean deep below the surface. By the conclusion of the mission, Cassini-Huygens had revealed a complex Titan surface with a striking resemblance to the total geomorphology of the Earth, including dunes, rivers, gullies, lakes, seas, volcanic constructs, and mountains.

The Titan Discipline Working Group and Science Teams accomplished all surface and atmospheric science objectives in the traceability matrices for the mission. The Titan Observation Science Team (TOST) coordinated every Titan observation and planned all 127 close Titan flybys to ensure that Cassini Titan objectives were met. The Titan Atmospheric Modeling Working Group (TAMWG), comprised of experts in Titan's upper atmosphere and members of the engineering team, was formed to characterize Titan's uppermost atmosphere and its variation with seasons to give advice to the project on how close the spacecraft could approach Titan.

Executive Summary

By the conclusion of the mission Cassini-Huygens had revealed a complex Titan surface with a striking resemblance to the total geomorphology of the Earth. Dunes, rivers, gullies, lakes, seas, volcanic constructs, mountains, are all present. Titan's methane cycle, analogous to the Earth's hydrologic cycle, drives processes including sedimentary transport that lead to the most geologically diverse surface after that of the Earth. Most spectacular was the discovery of several polar seas and hundreds of lakes, covering multiple hundreds of thousands of square kilometers. Some of the coastlines appear very Earth-like, with bays, cliffs, coves and river estuaries, while other boundaries are puzzling and may reflect a tectonic origin of the sea basins. Changes in two of the seas have been seen, suggesting dynamic processes driven by seasonal or other influences. Bathymetry and compositional measurements by Cassini lead to a liquid hydrocarbon inventory of about 70,000 square kilometers, mostly methane.

> The entire duration of the Cassini Mission exceeded 13 years, permitting observations over close to half of a seasonal cycle (almost half of Saturnian year) on Titan and revealed that seasonal variations are not symmetrical.

Cassini and the close-up images provided by Huygens establish fluvial erosion and rainfall as important processes tying together Titan's surface and atmosphere. A variety of cloud and weather patterns, including those generating rain, occur in the lower atmosphere. Comparison of cloud patterns with general circulation models supports the presence of a substantial amount of liquid methane in Titan's crust. From a variety of Cassini data, a surface age between ~0.5–1 billion years is derived. Although Cassini has not detected emission of methane from the crust, various indirect lines of evidence from Cassini point to episodic release of methane from the deep crust, with ethane soaked up by the ice in the form of clathrate hydrate or other trapping mechanisms.

Cassini measured Titan's gravity field and dynamic tidal response, indicating (together with Huygens electric field data) the presence of a deep subsurface water ocean, one denser than liquid water and thus possibly salty. A relatively low density, possibly hydrated, core was detected. The measurement of isotopic argon in the atmosphere supports significant outgassing over Titan's history, while the low abundance of primordial argon along with other isotopic measurements support ammonia as the original parent molecule of Titan's atmospheric nitrogen.

At the end of the Cassini-Huygens Nominal Mission, we had a good first order knowledge of the density and thermal structure of the atmosphere except for the ~ 500–950 km region, variously called the ignorosphere, agnostosphere, etc. Although Huygens Atmospheric Structure Instrument (HASI) inferred the thermal structure at equatorial latitudes through this region, it did not yield a pronounced mesopause as was widely expected from theory. Composite Infrared Spectrometer (CIRS) data provided detailed altitudinal and latitudinal composition and temperature

measurements of the stratosphere. The latter allowed the derivation of stratospheric zonal winds at substantial super-rotation speeds.

The Cassini Equinox and Solstice Missions enabled the study of seasonal variations of composition, temperatures and inferred zonal winds to understand the transition from summer in the southern hemisphere to equinoctial conditions to summer in the northern hemisphere, especially as the northern polar region emerges out of the polar winter night and its strong circumpolar vortex was breaking up. The entire duration of the Cassini Mission exceeded 13 years, permitting observations over close to half of a seasonal cycle (almost half of Saturnian year) on Titan and revealed that seasonal variations are not symmetrical. The eccentricity of Saturn's orbit and the obliquity of its rotational pole is sufficient to produce the observed asymmetry in Titan's seasonal response. But its entire stratosphere is tilted by several degrees from the rotational pole. Seasonal variations in composition, density, and thermal structure of Titan's upper atmosphere were characterized in particular by Ion and Neutral Mass Spectrometer (INMS) with complementary data from Ultraviolet Imaging Spectrograph (UVIS) measurements.

Cassini data determined that the thermosphere is a chemical factory that initiates the formation of complex positive and negative ions in the high thermosphere as a consequence of magnetospheric-ionospheric-atmospheric interaction involving solar extreme ultraviolet (EUV) and ultraviolet (UV) radiation, energetic ions and electrons. This factory produces very heavy positive and negative ions and large molecules, which condense out and are detectable in solar and stellar UV occultations at ~1000 km and initiate the haze formation process. As these particles fall through the 500–950 km region and grow, they become detectable by remote sensing: UVIS at ~1000 km, Imaging Science Subsystem (ISS) at ~500 km and eventually become ubiquitous throughout the stratosphere. These haze particles are strong absorbers of solar UV and visible radiation, play a fundamental role in heating Titan's stratosphere and mesosphere and provide a surface for heterogeneous reactions. The differential heating with latitude drives wind systems in Titan's middle atmosphere, much as ozone does in the Earth's middle atmosphere.

In summary the Titan Discipline Working Group and Science Teams accomplished all surface and atmospheric science objectives in the traceability matrices for the mission.

TOP 10–20 LIST OF SCIENTIFIC DISCOVERIES/ACCOMPLISHMENTS

- Cassini measured the shape of Titan's gravity field, including the tidal response. Cassini-Huygens discovered a global ocean of liquid water below a thick crust, and a relatively low density (hence hydrated?) core were discovered. Gravity and rotational data hint at the ocean being over dense and hence salty.
- Cassini-Huygens measured argon ($^{36,\,40}$Ar) in the atmosphere. Primordial argon was very low, indicating ammonia as the origin of the nitrogen atmosphere. Radiogenic argon indicated communication of the interior with the surface.

- Cassini-Huygens revealed a complex Titan surface with a striking resemblance to the total geomorphology of Earth. Dunes, rivers, gullies, lakes, seas, volcanic constructs, mountains, are all present. Titan's methane cycle, analogous to the Earth's hydrologic cycle, drives processes including sedimentary transport that lead to the most geologically diverse surface after that of Earth.
- Cassini discovered that Titan has several polar seas and hundreds of lakes, covering hundreds of thousands of square kilometers. Cassini determined the composition and bathymetry of the seas and a few lakes. The marine coastlines are very Earth-like, with bays, coves, cliffs and river estuaries, and dynamic changes occur in the seas. The total observable liquid hydrocarbon inventory was constrained (70,000 cubic km).
- Cassini-Huygens determined a range of crustal ages on Titan's surface; the average age is hundreds of millions to a billion years.
- Cassini-Huygens observed dynamic meteorology in cloud behavior and rainstorms, changes in the lakes and seas, and evaporation of liquids from the surface.
- Cassini-Huygens discovered a variety of weather patterns, including rainstorms, in Titan's lower atmosphere and documented seasonal changes therein.
- Cassini further explored the evolution and composition of the winter circumpolar vortex that switches hemispheres seasonally. Titan has strong parallels to Earth with strong winter polar vortices.
- Cassini discovered the entire stratosphere is tilted by several degrees from the rotational pole.
- Cassini discovered ice condensate clouds in the stratosphere.
- Cassini discovered complex, heavy molecules and ions (both positive and surprisingly, negative) in the upper atmosphere, pointing to active chemistry and a link to the initiation of haze formation. The richness and complexity (going up to hundreds, maybe thousands of species) of the heavy molecules.
- Cassini-Huygens discovered Enceladus as one possible source for oxygen compounds in Titan's atmosphere.
- Cassini discovered Titan's thermosphere to be highly variable, contradicting model predictions.
- Cassini firmly established no intrinsic magnetic field.
- Cassini-Huygens came up with the surprising result that lightning is absent despite observed methane moist convection.

Table TITAN-1 shows the assessment of data collected to satisfy an objective. It is not as assessment of the status of data analysis/publications.

Table TITAN-1. Science Assessment. This table is an assessment of data collected to satisfy an objective. It is not as assessment of the status of data analysis/publications.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

Titan Discipline Science Objectives	AO and TM Science Objectives	Titan DWG Assessment	Comments (if yellow, partially fulfilled)
Titan's Great Seas	(TC1a)		
Titan's Global Seasons	(TC1b)		
Titan-Magnetosphere Interaction	(TC2a), (T_AO5)		
Titan's Surface	(TN1a), (T_AO4)		Some work was done, but more work remains for future missions.
Titan's Interior Ocean	(TN1b)		A few crustal structures locally; induced magnetic field difficult due to ionospheric currents.
Titan Atmospheric Composition	(TN1c), (T_AO1, 2)		
Titan Atmospheric Structure	(TN2a), (T_AO5)		
Titan's Icy Shell	(TN2b)		Crustal viscosity not determined from data taken.
Titan Meteorology	(TN2c), (T_AO3)

Open Questions for Titan Science			

KEY SCIENCE OBJECTIVES FOR TITAN

- **Titan Atmospheric Formation and Evolution (T_AO1)** – Determine abundances of atmospheric constituents (including any noble gases), establish isotope ratios for abundant elements, constrain scenarios of formation and evolution of Titan and its atmosphere.
- **Titan Atmospheric Composition and Distribution (T_AO2)** – Observe vertical and horizontal distributions of trace gases, search for more complex organic molecules, investigate energy sources for atmospheric chemistry, model the photochemistry of the stratosphere, study formation and composition of aerosols.
- **Titan Meteorology (T_AO3)** – Measure winds and global temperatures; investigate cloud physics, general circulation, and seasonal effects in Titan's atmosphere; search for lightning discharges.
- **Titan Surface Characteristics and Internal Structure (T_AO4)** – Determine the physical state, topography, and composition of the surface; infer the internal structure of the satellite.
- **Titan Upper Atmosphere (T_AO5)** – Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.

Titan CSM Traceability Matrix Objectives

- **Titan's Great Seas (TC1a)** – Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport.
- **Titan's Global Seasons (TC1b)** – Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.
- **Titan-Magnetosphere Interaction (TC2a)** – Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.
- T**itan's Surface (TN1a)** – Determine the types, composition, distribution, and ages, of surface units and materials, most notably lakes (i.e., filled versus dry and depth; liquid versus solid and composition; polar versus other latitudes and lake basin origin).
- **Titan's Interior Ocean (TN1b)** – Determine internal and crustal structure: Liquid mantle, crustal mass distribution, rotational state of the surface with time, intrinsic and/or internal induced magnetic field.
- **Titan Atmospheric Composition (TN1c)** – Measure aerosol and heavy molecule layers and properties.
- **Titan Atmospheric Structure (TN2a)** – Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission).
- **Titan's Icy Shell (TN2b)** – Determine icy shell topography and viscosity.
- **Titan Meteorology (TN2c)** – Determine the surface temperature distribution, cloud distribution, and tropospheric winds.

Titan DWG System Results

Titan

Titan's great seas (TC1a) T_AO2) [Hayes, Lorenz, Lunine]

Titan's lakes and seas encompass 1% of the total surface area and are restricted to latitudes poleward of ~55° [Hayes 2016]. The majority (97% by area) of surface liquids reside in the north polar region, with 80% of all liquid-filled surface area contained in three large seas; Kraken Mare (5.0×10^5 km^2), Ligeia Mare (1.3×10^5 km^2), and Punga Mare (6.1×10^4 km^2). The only large liquid body in the south polar region is Ontario Lacus (1.6×10^4 km^2), although several large empty basins that encompass an area similar to the northern Maria (7.6×10^5 km^2) have been identified and interpreted as paleoseas [Birch et al. 2018; Hayes et al. 2010, 2011]. While a few small lakes have

been observed to disappear or brighten in both the north and south over the thirteen years of Cassini observations, no large-scale changes have been reported in the shorelines of the northern seas [Hayes et al. 2011]. Although confirmed and stable liquid deposits are currently restricted to polar terrain, the equatorial features Hotei and Tui Regiones have been interpreted as possible low-latitude paleoseas [Moore and Howard 2011]. Both regions are surrounded by fluvial networks that appear to converge on a field of radar-bright, lobate, depressions that are morphologically similar to high-latitude lakes [Moore and Howard 2011]. Dark flow-like features identified adjacent to the radar-bright depressions have been interpreted as cryovolcanic deposits [Barnes et al. 2006; Wall et al. 2009], suggesting that both paleo-lakes and cryovolcanic flows may be present at Tui Regio and Hotei Regio [Lopes et al. 2013]. The existence of modern equatorial lakes has been proposed based on the longevity of low albedo localities observed by Cassini Visual and Infrared Imaging Spectrometer (VIMS) [Griffith et al. 2012; Vixie et al. 2015], although none of these features have been confirmed by higher-resolution Synthetic Aperture Radar (SAR) or altimetry datasets.

For the majority of the Cassini mission, the surfaces of the Titan's lakes and seas were observed to be incredibly flat, …, suggesting little to no wind or currents capable of ruffling liquid surfaces … .

For the majority of the Cassini mission, the surfaces of the Titan's lakes and seas were observed to be incredibly flat, with maximum average surface deviations of order millimeters, suggesting little to no wind or currents capable of ruffling liquid surfaces [Grima et al. 2017; Stephan et al. 2010; Wye et al. 2009; Zebker et al. 2014]. As northern spring approached, evidence for surface waves and other transient features began to emerge [Barnes et al. 2014; Hofgartner et al. 2014]. This increase in activity has been attributed to the increase in solar insolation and surface winds expected with the changing seasons [Hayes et al. 2013; Lorenz and Hayes 2012]. Prior to northern springtime, surface winds were presumably below the threshold for wind-wave generation in hydrocarbon liquids (~0.4 m/s) [Hayes et al. 2013].

During an observation designed to look for surface waves on Ligeia Mare, the Cassini Titan Radar Mapper (RADAR) acquired altimetry echoes that displayed two distinct returns, one from the surface of Ligeia Mare and one from its seabed [Mastrogiuseppe et al. 2014]. The difference in received timing between these returns was a measure of Ligeia Mare's depth (160 m), while their relative intensity provided a measurement of the microwave loss-tangent (i.e., absorbance) of the liquid ($\tan \Delta = \varepsilon''/\varepsilon' = 4.4 \pm 0.8 \times 10^{-5}$, where ε is the complex dielectric constant). Following the identification of Ligeia Mare's seabed, several of the final radar passes of Titan were modified to repeat the experiment over Punga Mare, Kraken Mare, and several small lakes [Mastrogiuseppe et al. 2016, 2017]. As a result, bathymetry measurements over all three of Titan's maria and several small lakes are now available. When combined with SAR observations that also penetrate the shallower seas and assuming a maximum depth of ~300 m for Kraken Mare [Lorenz et al. 2014; 2008b], for which a reflection from the bottom was not observed, the volume of Titan's lakes and seas is estimated at 70,000 km^3 [Hayes 2016]. This represents only ~1/7 the volume of atmospheric methane suggesting that, unlike on Earth, Titan's seas have little influence on the global climate.

This also means that the lakes and seas are not plausible as a long-term resupply reservoir of atmospheric methane.

Laboratory experiments [Mitchell et al. 2015] demonstrated that the microwave loss-tangents measured by Cassini require methane-dominated liquids. If higher-order hydrocarbons (e.g., propane) are considered in addition to ethane, then the loss-tangents measured over Ligeia, Punga, and Kraken Mare require near pure methane-nitrogen mixtures. If a methane-nitrogen-ethane ternary mixture is considered, Ligeia's loss tangent is consistent with 71% methane and 12% ethane by volume [Mastrogiuseppe et al. 2016]. These abundances are generally consistent with predicted equilibrium compositions [Glein and Shock 2013; Tan et al 2015], although higher-order components (e.g., propane) were not taken into account. The loss-tangent of Punga Mare and Kraken are similar (to within error) to Ligeia Mare, while Ontario Lacus was observed to be more absorbent, consistent with a greater ethane content or an increased abundance of more involatile hydrocarbons (e.g., propane). Regardless, the primary constituent of Ontario must still be methane in order to match the derived loss tangent [Mastrogiuseppe et al. 2017]. Earlier in the Cassini mission, VIMS infrared spectra were used to identify the presence of ethane in Ontario [Brown et al. 2008]. The fact that Titan's seas are methane-dominated further exacerbates the long-standing mystery of Titan's missing ethane [Lunine et al. 1983].

Titan's global seasons (TC1b) [Teanby et al. 2017]

Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.

To understand the structure of Titan's atmosphere one must keep in mind certain basic facts from solar system dynamics. First, the axial tilt of Saturn and Titan is 26.73°; and second, Saturn's orbital eccentricity is 0.05415, which yield variations in the distance from the Sun from 9.04 to 10.07 AU and in the total solar flux of ~20 %. Titan's atmospheric seasonal evolution is driven by three mechanisms: the seasonal change in solar declination, the orbital eccentricity of Saturn with Titan receding from the Sun since 2002, and the solar cycle variation of the Sun with activity increasing from its minimum in late 2009 to peak solar activity for cycle 24 in April 2014. Perihelion last occurred in February 25, 2003. Summer solstice in Titan's southern hemisphere was March 17, 2002; summer solstice in the northern hemisphere was on May 24, 2017 after spring equinox on August 11, 2009.

The variation in solar distance and thus solar flux will be most important in the troposphere, stratosphere, and mesosphere, whereas the much larger solar cycle variations in UV and EUV solar radiation will overwhelm the smaller eccentricity effects in situ in the thermosphere. But the contraction and expansion of the underlying stratosphere/mesosphere with increasing and decreasing solar distance must be considered in determining thermospheric seasonal changes. The Voyager spacecraft flybys were at high solar activity, whereas orbit insertion of the Cassini spacecraft in July 2004 was during the descending phase from peak activity, which occurred in April 2000, to deep solar minimum conditions in the August–November 2009 timeframe.

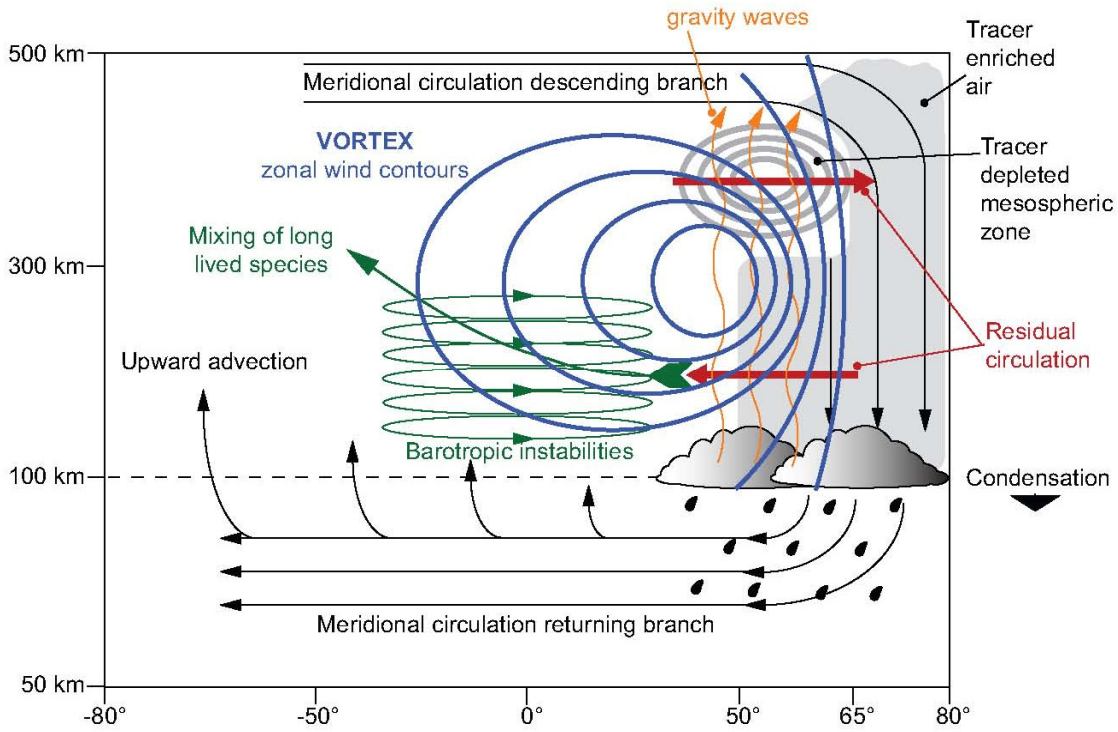

Figure TITAN-1. Schematic of dynamical processes thought to be important in Titan's winter north polar region. A single cell meridional circulation, a polar vortex of strong zonal winds, wave induced mixing by inferred equatorial barotropic and gravity waves. Figure from Teanby et al. [2008].

Accordingly, the nominal Cassini-Huygens Mission was mostly at low solar activity. Peak solar activity for cycle 24 occurred in April 2014.

When the Cassini spacecraft arrived at Titan, there was a well-developed winter polar vortex in the northern hemisphere inferred from the stratospheric temperatures with peak zonal wind velocities on the order of 200 m/s [Achterberg et al. 2008a]. From July 1, 2004 to September 15, 2017, the spacecraft made a total of 127 Titan flybys, spanning nearly half of Titan's 29.5-year orbit around the Sun that allowed observations of the detailed evolution and breakup of Titan's northern winter polar vortex and the formation and early evolution of Titan's southern winter polar vortex (Figure TITAN-1). The former was characterized by the decrease in the upper stratospheric temperatures, weakening of the zonal winds, and the reduction in the enhancement of photochemically produced compounds [Vinatier et al. 2010, 2015; Achterberg et al. 2011].

> "Associated with the polar vortex was a meridional circulation dominated by a single pole-to-pole cell that ascended at southern and equatorial latitudes and subsided over the northern winter pole. Strong vortex winds formed a mixing barrier and effectively isolated the polar air mass, permitting a distinct temperature and composition within the vortex. Pre-equinox observations of the north polar region show the mid-winter vortex is characterized by: trace gas enrichment due to subsidence from upper-

atmosphere photochemical source regions, a cold lower stratosphere due to long-wave radiative cooling and a lack of insolation; and a hot stratopause/mesosphere due to subsidence and adiabatic heating with a peak temperature of ~200 K. Pre-equinox observations detail the nominal configuration of the mid-winter polar vortex, which is broadly consistent with results from numerical models" [Teanby et al. 2017].

"Following Titan's 2009 northern spring equinox, peak solar heating moved to the northern hemisphere, initiating south-polar subsidence and winter south-polar vortex formation with reversal almost immediately of the vertical circulation at the south pole [Vinatier et al. 2015]. Throughout 2010–2011, strengthening subsidence produced a mesospheric hot-spot (~180 K at 300–400 km altitude) and caused extreme enrichment of high-altitude photochemically produced trace gases. The reversal was accompanied by a two-cell transitional global circulation, with upwelling around the equator and subsidence at both poles, which persisted for two years before a fully reversed single circulation cell was established [Vinatier et al. 2015]. The timing of these circulation changes is consistent with numerical models, which subsequently predicted a gradual evolution of the south polar vortex towards a state similar to that observed in the north prior to equinox." [Teanby et al. 2017].

"However, contrary to expectations, in 2012 spectral features of HCN ice were identified at 300 km altitude over the southern winter pole with VIMS [de Kok et al. 2014]".

In addition, CIRS detected C_6H_6 ice in the south polar cloud [Vinatier et al. 2018] and an undetermined 220 cm^{-1} spectral signature suddenly appeared as well in July 2012 but not February 2012 CIRS data set taken there [Jennings et al. 2012].

"This cloud was also observed in high spatial resolution images from ISS. The presence of HCN ice was surprising as it requires temperatures of ~125 K to form at 300 km altitude—over 50 K colder than temperatures observed in mid-2011 at similar altitudes and latitudes. Therefore, development of Titan's winter south polar vortex is more complex than expected. There is not a simple monotonic increase of mesospheric temperatures following equinox to eventually mirror the ~200 K temperatures observed in northern winter at the start of the mission—instead rapid and unexpected cooling occurred accompanied by extreme trace gas enrichment within the polar vortex that dramatically increased mesospheric long-wave radiative cooling efficiency, causing unusually cold temperatures 2–6 years post-equinox. The long timeframe to reach a stable vortex configuration results from the high infrared opacity of Titan's trace gases and the relatively long atmospheric radiative time constant. Whereas winter polar hotspots have been observed on other planets, detection of post-equinox cooling is so far unique to Titan." [Teanby et al. 2017].

Titan-magnetosphere interaction (TC2a) [Strobel et al. 2009; Strobel and Cui 2014; Simon et al. 2010]

Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.

Titan's ambient plasma conditions heavily depend on the properties of Saturn's magnetodisk, which in turn is controlled by the solar wind pressure, Saturn seasons, and inner magnetospheric effects (periodicities and mass loading by rings + Enceladus). Thermal electron [Rymer et al. 2009], ion [Németh et al. 2011], energetic particle [Garnier et al. 2010], and field [Simon et al. 2010] flyby classifications are described extensively in Arridge et al. [2011]. Thermal ion composition in Saturn's magnetodisk is also strongly dependent on magnetic latitude, with heavy (water group) ion density maximizing near Br = 0. [Szego et al. 2011].

The classification of Titan's magnetospheric environment by energetic electrons relies on the four broad types identified by Rymer et al. [2009]: plasma sheet, lobe-like, magnetosheath, and bimodal, which result from variable solar wind pressure, day/night asymmetry, and the vertical flapping of the plasma sheet with respect to the equatorial plane. The plasma sheet region contains relatively high electron densities (~0.05 cm^{-3}) and temperatures (~110 eV), whereas the lobe-like region has high temperatures (~110 eV), but much lower densities (~0.003 cm^{-3}). Their respective energy fluxes into Titan's atmosphere are ~1.6 × 10^{9} eV cm^{-2} s^{-1} (2.6 × 10^{-3} erg cm^{-2} s^{-1}) and ~1.2 × 10^{8} eV cm^{-2} s^{-1} (1.9 × 10^{-4} erg cm^{-2} s^{-1}). Higher thermospheric temperatures have been associated with the plasma sheet environment, which is consistent with the factor of 10 enhancements in electron density. The magnetosheath is encountered, of course only when Titan is outside of Saturn's magnetosphere and characterized by high electron densities (~0.4 cm^{-3}) but cold temperatures (~30 eV) with an energy flux of ~2.5 × 10^{9} eV cm^{-2} s^{-1} (4.0 × 10^{-3} erg cm^{-2} s^{-1}). The bimodal regions have two distinct electron populations: the more energetic population being plasma sheet or lobe-like (electron densities (~0.004 cm^{-3}) and temperatures (~350 eV)) and the less energetic population suggestive of local pick-up (electron densities (~0.1 cm−^{3}) and temperatures (~10 eV)) [Rymer et al. 2009]. For bimodal regions the energy flux is approximately 1 × 10^{9} eV cm^{-2} s^{-1} (1.6 × 10^{-3} erg cm^{-2} s^{-1}).

Titan's location with respect to Saturn's magnetodisk is also dependent on the phase of a rotating perturbation within Saturn's inner magnetosphere [Southwood and Kivelson 2007]. In particular, Titan's proximity to Saturn's magnetodisk current sheet depends [Arridge et al. 2008; Bertucci et al. 2009] on the so-called Saturn Longitude System [Kurth et al. 2008] which organizes fields and particle periodicities inside Saturn's magnetosphere. Vertical and radial excursions of the upstream plasma flow are expected to be influenced by this effect [Sillanpaa et al. 2011; Achilleos et al. 2014].

The solar wind dynamic pressure also influences Titan's interaction by distorting Saturn's magnetodisk into a bowl shape during off-equinox periods [Achilleos et al. 2014]; and in coincidence with the arrival of ICMEs and CIRs [Roussos et al. 2018], by controlling the location of Saturn's magnetopause and bow shock [Kanani et al. 2010].

During solar wind excursions [Bertucci et al. 2008, 2015] the orientation and strength bundles of draped magnetic field lines inside Titan's magnetosphere suggest field lines take between 20 min to 3 h to travel across the interaction region in agreement with predictions [Neubauer et al. 2006]. The geometry of the magnetotail/magnetosphere agrees with upstream conditions for most orbits [Simon et al. 2010].

While a search for an intrinsic Titan magnetic field has yielded negative results, the magnetometer data show that the moon's magnetic environment is strongly affected by its proximity to Saturn's warped and highly dynamic magnetodisk [Simon et al. 2010]. In the nightside sector of Saturn's magnetosphere, the magnetic field near Titan is controlled by intense vertical flapping motions of the magnetodisk current sheet, alternately exposing the moon to radially stretched lobe-type fields and to more dipolar, but highly distorted current sheet fields [Simon et al. 2010]. The upper limit to the intrinsic magnetic moment is 0.78 nT R_T^3 according to Wei et al. [2010].

Titan's thermosphere and exosphere are also very dynamic and temporally variable.

Titan's thermosphere and exosphere are also very dynamic and temporally variable. Qualitatively, Cassini in situ measurements point to an important role for Saturn's magnetospheric interaction as a key driver of this observed variability. Quantitatively based on Cassini data, the measured and derived magnetospheric power inputs to the upper atmosphere are smaller than solar EUV and UV power input on a globally averaged, orbital averaged basis. Only on very rare occasions does magnetospheric power input equal solar input. This leads to the conclusion that solar radiation mostly heats the upper atmosphere, whereas magnetospheric particle precipitation plays a more important role in the ionization of the atmosphere below the main ionosphere ($z < 900$ km). This is consistent with the absence of N_2 ultraviolet signatures of magnetospheric power input to Titan's upper atmosphere in nightside EUV spectra [Ajello et al. 2007; West et al. 2012] and UV dayglow observations [Stevens et al. 2011] with UVIS.

On a related issue, we note that the evidences for a link between magnetospheric inputs and Titan's ionosphere are scarce. The fact that an ionospheric response to magnetospheric inputs is harder to observe than a thermospheric response is associated with the different timescales involved. Characteristic ion-chemical time constants in Titan's ionosphere are ~ (10–1000) sec, shorter than or comparable to the time interval that the Cassini spacecraft typically spent below Titan's exobase. This means any ionospheric response to Saturn's magnetosphere can only be captured as it occurs luckily during a Titan encounter.

Analysis of Cassini data has not yielded any proven correlation between the temperature of Titan's thermosphere and ionospheric signatures attributed to enhanced particle precipitation, which suggests that the correlation is not indicative of a physical connection. In summary based on all of Cassini observational data analyzed to date in conjunction with theoretical studies, an upper limit of 10% on the ratio of magnetospheric power input to solar EUV and far ultraviolet (FUV) power input into Titan's upper atmosphere can be placed on an orbital, globally averaged basis.

Table TITAN-2. Titan energy source magnitudes.

Energy Source	Reference	r at peak (km)	Energy Flux (erg/cm^2/s)	Global Input (GW)
Solar Lyman-alpha	LASP- solar min	3400	0.017	2.4
Solar Lyman-alpha	LASP- solar med	3400	0.022	3.2

The entries in Table TITAN-2 correct the UV entries in Sittler et al. [2009], Table 16.1 shown in Table TITAN-3.

Table TITAN-3. Titan upper atmosphere and its induced magnetosphere. Table from Sittler et al. [2009], Table 16.1.1.

Energy Source	Energy Flux (erg/cm2/s)	Global Input (Watts)[d]	Comments
Plasma protons	1.6e-4	3.4e7	Magnetized
Plasma electrons	1.6e-4	3.4e7	Magnetize
Plasma heavy ions	1.5e-3	3.2e8	Unmagnetized
Energetic ions	5.0e-4 to 1.0e-2	1.05e8 to 2.0e9	$27 < E_p < 255$ keV[a]
Energetic electrons	2.0e-4	4.0e7	$28 < E_e < 533$ keV[a,b]
UV airglow	1.6e-3	3.5e8	Altitude ~1,300 km[c]
UV ionization	1.6e-4	3.4e7	Altitude ~1,300 km[c]
Ohmic heating			Not yet known
GCR	1.6e-4 to 2.7e-3	3.2e7 to 5.4e8	Integrated flux
Dust	1.8e-3	1.8e8	Interplanetary dust

[a] Model by Ledvina et al. [2005] show some magnetic channeling of 50 keV protons. If heavy ions (0^+) Unmagnetized. Expect energetic electrons to be more magnetized than protons.

[b] Energetic electron energy flux derived from Krupp et al. [2005].

[c] For T0 at 90° phase angle UV absorption peaked at 1,325 km, while for TB at 0° phase angle absorption peaked at 1,095 km altitude.

[d] Exobase at r ~4,000 km and 4π area 2×10^{18} cm^2.

Titan's surface (TN1a) (T_AO4)

The Cassini-Huygens mission has revealed the surface of Titan in unprecedented detail, enabling us to discern the different geomorphologic units on the surface, constrain the relative times of emplacement and place constraints on composition. Titan has an icy crust, but water ice signatures are not easily detected due to atmospheric scattering and absorption that hamper the observations, as well as the presence of complex organic molecules on the surface. The extended, dense, and hazy N_2−CH_4 dominated atmosphere shields the surface from direct optical observations, except at certain wavelengths where the methane absorption is weak. These atmospheric windows are exploited by the Cassini VIMS to obtain compositional information and by VIMS and the ISS to map surface features. In addition, Cassini RADAR altimetry and SARTopo [Stiles et al. 2009] have documented elevations ranging over ~2300 m [Corlies et al. 2017; Lorenz et al. 2013] and put constraints on Titan's global topography. Compared to the Moon's or the Earth's surfaces, off-nadir radar response from most of Titan's surface is quite strong at Ku-band, indicating that more complex processes than simple surface scattering, such as a significant volume scattering component, have to be considered [Wye et al. 2007; Janssen et al. 2016]. Indeed, signals from Cassini RADAR Ku-band instrument, given the low Titan surface temperatures and the low loss tangent of material analogs relevant to Titan's surface, should produce radar waves that can penetrate the surface down to a depth ranging from a few decameters, for an organic and compacted near-surface, Paillou et al. [2008], to several meters, for a pure water ice near-surface, Paillou et al. [2008], and have thus multiple opportunities to be scattered. The above referenced observations of Titan's surface are themselves consistent with sub-surface and volume scattering processes, in addition to pure surface scattering. Scatterometer and radiometer measurements alike are even, in some locations, best fit using models where volume scattering is enhanced by coherent backscatter processes [Zebker et al. 2008; Janssen et al. 2011].

Janssen et al. [2016] further advance that a regionally enhanced degree of volume scattering is indicative of a higher abundance of water-ice in the near-surface, water-ice being more transparent to microwaves than organics and thus allowing for more opportunities for scattering. Based on this idea, about 10% of Titan's near-surface is water ice-rich while the composition of the remaining terrains is dominated by more absorbing organic materials, by-products of the intense atmospheric photochemistry (Figure TITAN-2). The regions with a high degree of volume scattering include mountainous terrains, craters as well as fan-like features, possibly corresponding to flowing material resulting from cryovolcanism, the radar signature of which could be explained by a strong volume scattering effect in a thick water-ammonia ice layer using a two-layers scattering model [Paillou et al. 2006] as shown in Figure TITAN-3. Radar-bright sinuous channels in the southwest of Xanadu, showing very large radar cross-sections, are also consistent with the presence of icy low-loss rounded scatterers, acting as efficient natural retro-reflectors [Le Gall et al. 2010].

Weaker radar reflectors such as Titan's dunes are most likely organic in nature, as also supported by VIMS [Soderblom et al. 2009]. However, we note that they exhibit high-amplitude scattering as compared to Earth analogs, which is consistent with a volume scattering component added to the surface component due to the radar wave penetration in aeolian sediments, implying that the dune material is either inhomogeneous or presents a high porosity [Paillou et al. 2014].

Mega-yardang structures were observed on Titan, and they also present a much brighter radar signature than their terrestrial analogs, indicating that additional scattering processes, such as volume scattering, should occur [Paillou et al. 2016].

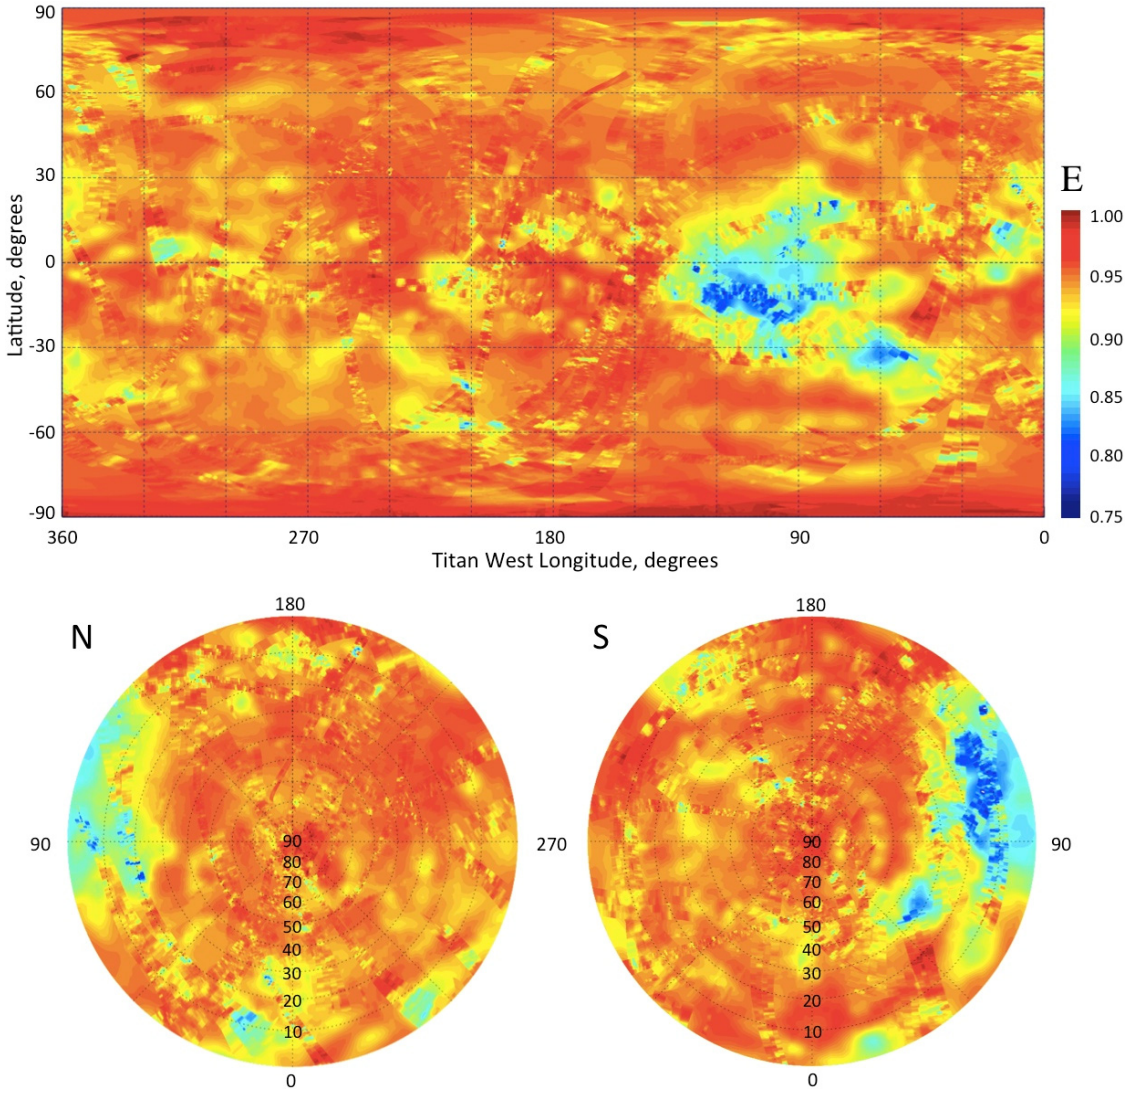

Figure TITAN-2. Global mosaic of emissivity of Titan at the 2 cm wavelength of the Cassini RADAR. This is the final result of the brightness temperature mapping of Titan incorporating all radiometric data obtained from Titan passes Ta through T98, a nearly ten-year span. The brightness temperature was measured as a function of position, polarization and time over a wide range of geometries and ranges and calibrated to about 1% absolute accuracy using Huygens probe and CIRS temperature measurements as described in Janssen et al. [2016]. The polarization data were used to construct a global mosaic of effective dielectric constant, enabling the conversion of all measured brightness temperatures to their equivalent values at normal incidence. The data were then folded into a massive least squares solution for the seasonally varying brightness temperature distribution of Titan over the time scale of the observations. Comparison with surface temperature measurements obtained in the infrared (IR) using Kirchhoff's law then enabled the construction of the emissivity map shown.

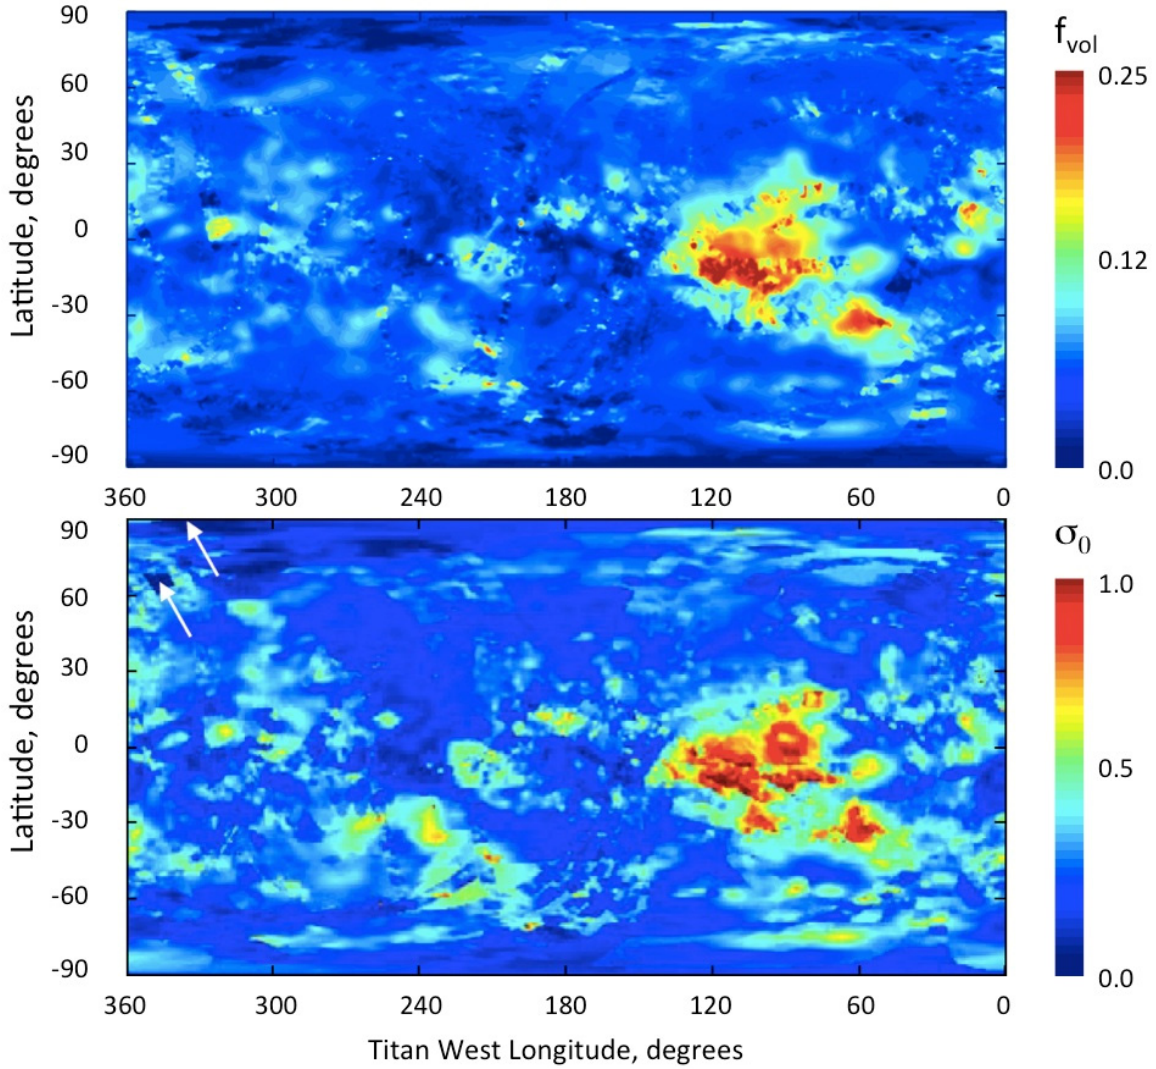

Figure TITAN-3. Predicted and observed maps of scattering from Titan's surface. The upper panel is a map of the volume scattering parameter f_{vol} for a simple surface model composed of a smooth dielectric interface separating free space from an inhomogeneous and isotropically scattering subsurface. f_{vol} is the probability that a photon entering the surface (as determined by the effective dielectric constant) scatters and escapes from the subsurface before it is absorbed. The map of f_{vol} reconciles the maps of effective dielectric constant and emissivity and predicts the overall magnitude of the scattering. The lower panel is a global mosaic of Titan's normalized radar cross-section from all real aperture data through T71 [Wye 2011], showing the actually observed scattering. The white arrows in the upper left-hand corner indicate two small regions that were not mapped.

Lastly and of particular interest is the case of Titan's methane-dominated seas and lakes, where radar waves can penetrate down to several thousands of wavelengths (at least 150 m), and be subsequently backscattered by the lakebeds [Mastrogiuseppe et al. 2014, 2019], consistent with recent laboratory investigation of the electrical properties of liquid hydrocarbons [Mitchell et al. 2015].

Surface observations analyzed in view of deriving the surface albedo and determining the composition are rendered difficult on Titan due to the atmospheric interference with the main opacity due to methane and which allows direct access to the surface only at a few specific frequencies in the near-infrared where the methane absorption is weak—for example, Niemann et al. [2010]. Nonetheless, re-analysis of the entire ISS dataset acquired in the 938 nm methane window has yielded a complete global map of Titan's surface at resolutions better than a few kilometers with albedos calibrated to Huygens Descent Imager/Spectral Radiometer (DISR) ranging from 0.25 in the dunes to 0.9 at Hotei Arcus [Karkoschka et al. 2017]. A combination of RADAR and spectral imaging data—VIMS—is required in order to distinguish and categorize the geomorphological features into units with distinct chemical compositions that remain to be identified. Several investigators have applied radiative transfer codes in addition to data set comparisons—for example, Hirtzig et al. [2013]; Solomonidou et al. [2014]; Lopes et al. [2016]. These studies allow definition of both the surface and the atmospheric contributions in VIMS spectral imaging data in the near-IR after performing the appropriate pixel selection of areas of interest with the help of SAR data.

The radiative transfer code application to the VIMS Titan data yields extracted weighted surface albedos in the seven methane windows tested against a variety of Titan candidate ice and organic constituents to provide constraints on the possible material present at various geomorphological units, as reported in Solomonidou et al. [2018]. An updated material library is being used based on Bernard et al. [2006]; Brassé et al. [2015]; Grenoble Astrophysics and Planetology Solid Spectroscopy and Thermodynamics (GhoSST) database [https://ghosst.osug.fr]. The library includes several materials at different grain sizes, such as ices of acetylene (C_2H_2), ethylene (C_2H_4), ethane (C_2H_6), propane (C_3H_8), cyanoacetylene (HC_3N), water (H_2O), ammonia (NH_3), methane (CH_4) and carbon dioxide (CO_2), in addition to spectra of laboratory tholins [Bernard et al. 2006; Brassé et al. 2015], and spectra of dark materials such as asphalite, kerite, different types of anthraxolite and amorphous carbon, which have been proposed as capable of lowering the total surface albedo of Titan's surface [Lellouch 2006; GhoSST]. Considering the different grain sizes, the library consists of 148 different constituent possibilities that can also be mixed. By using this constituent library spectral simulations are made and via an iterative process the best fit to the observations is obtained, bearing in mind that there is no unique solution for all of the mixtures. With these and other caveats described in Solomonidou et al. [2018], these authors have derived constraints on the possible major constituent for each geological unit and reported a latitudinal dependence of Titan's surface composition, with water ice being the major constituent at latitudes poleward of 30° N and 30° S, while Titan's equatorial region appears to be dominated partly by a tholin-like or by a very dark unknown material. The surface albedo differences and similarities among the various geomorphological units constrain the implications for the geological processes that govern Titan's surface and interior (for example, aeolian, cryovolcanic, tectonic).

Data from SAR and other RADAR modes, aided by data from VIMS and ISS, have provided sufficient information on Titan's surface to distinguish different types of geologic units [Lopes et al. 2010, 2016; Malaska et al. 2016] and establish the major geomorphologic unit classes on Titan and their relative ages using contacts between units. The classes of units are mountainous/ hummocky terrains, plains, dunes, labyrinthic terrains, craters and lakes. The oldest units are the

mountainous/hummocky and the labyrinthic terrains; it is not possible with currently available data to differentiate the relative ages of these two oldest types of terrain. The mountainous/hummocky terrains consist of mountain chains and isolated radar-bright terrains. The labyrinthic terrains consist of highly incised dissected plateaus with medium radar backscatter. The plains are younger than both mountainous/hummocky and labyrinthic unit classes. Dunes and lakes of liquid hydrocarbons are the youngest unit classes on Titan. Additionally, we have identified individual features such as crater rims, channels, and candidate cryovolcanic features. Crater rims and candidate cryovolcanic features are locations more likely to expose materials from the icy crust, while the hummocky/mountainous materials are thought to be exposed remnants of the icy crust.

Characterization and comparison of the properties of the unit classes and the individual features with data from radar radiometry, ISS, and VIMS provides information on their composition and possible provenance. The hummocky/mountainous terrains and impact crater rim features have relatively low emissivity (and greater radar scattering) in radiometric data, consistent with more water ice near the surface. We can also use these correlations to infer global distribution on regions not covered by SAR. This is particularly important as SAR data will not provide complete coverage of Titan by the end of the Cassini mission.

Matching the different surface units with specified mixtures of materials sheds light on the interconnection between the interior, the surface, and the atmosphere.

Matching the different surface units with specified mixtures of materials sheds light on the interconnection between the interior, the surface, and the atmosphere. In Solomonidou et al. [2018] three groups of compositional mixtures are reported, which include the major geomorphological units mentioned in the previous section, among three candidates (water ice, tholin, and a dark component). The units with spectral response similar to water ice are the labyrinth terrains and a number of plains such as the streak-like, the scalloped, and the undifferentiated plains that are concentrated at the higher parts of the midlatitudes. The crater ejecta and the alluvial fans are part of a different compositional group in which a tholin-like material is dominant. Furthermore, the units covered with an unknown dark constituent are the hummocky/mountainous terrains, the variable plains, the dunes, and the undifferentiated plains that are close to the equator and possibly contaminated by dune material [Lopes et al. 2016; Solomonidou et al. 2018].

Plains are the most widespread type of terrain on Titan [Lopes et al. 2016]. Although there are several different types of plains, by far the most extensive are the Undifferentiated Plains, first mapped by Lopes et al. [2010]. These are vast expanses of radar-dark terrains that appear fairly uniform in SAR images, with no major topographic units, and are for this reason often referred to as blandlands. Lopes et al. [2016] mapped the distribution of the Undifferentiated Plains using SAR swaths up to flyby T92 (July 2013) and found that these terrains are located mainly at mid-latitudes. Their gradational boundaries and paucity of recognizable features in SAR data make geologic interpretation challenging, so Lopes et al. [2016] used all the RADAR datasets available, plus VIMS and ISS, to examine and evaluate different formation mechanisms including: (i) cryovolcanic origin, consisting of overlapping flows of low relief; or (ii) sedimentary origins, resulting from

fluvial/lacustrine or aeolian deposition, or accumulation of photolysis products created in the atmosphere. Their analysis showed that the Undifferentiated Plains unit is consistent with a composition predominantly containing organic rather than icy materials and formed by depositional and/or sedimentary processes. They concluded that aeolian processes played a major part in the formation of the Undifferentiated Plains, although other processes (fluvial, deposition of photolysis products) are likely to have contributed, possibly in differing proportions depending on location. However, the distribution of Undifferentiated Plains, both at local and global scales, is consistent with aeolian deposition being the major process contributing to their formation. Spectral differences between the Plains and Dunes seen in VIMS data imply that the materials, at least on the top layers of the surface, are not exactly the same. Spectral differences in terms of surface albedo values between locations of Undifferentiated Plains [Lopes et al. 2016; Solomonidou et al. 2018] show that Plains at lower latitudes (closer to the dune seas) are more spectrally similar to dune materials, implying that they are related and supporting the idea that dunes materials are transported by wind to mid-latitudes. The Undifferentiated Plains appear to be composed of insoluble organic materials which may have been cemented by an organic substance and/or wetted by methane, causing them to become spectrally different from dune materials, at least at a surficial level. If the Undifferentiated Plains materials are the result of aeolian deposition, but contain liquids due to methane rain or fluids transported by channels, this would explain why they show relatively high emissivity (lower global dielectric constant, less efficient volume scattering) as well as why they are free of dunes (reduced sediment mobility). It would also be consistent with the high level of degradation of craters found at mid-latitudes—efficient erosion by fluvial/pluvial/subsurface flow activity, [Neish et al. 2016]. Le Gall et al. [2011] suggested that the latitudinal changes in dune-to-interdune ratio and possible variations in the thickness of the interdunal sand cover are likely related to changes in sediment availability at higher latitudes. These changes may be due to a decrease in sediment supply with distance from sediment source areas, an increased soil moisture content at higher latitudes (reflecting Titan's climate integrated over several seasonal cycles), or an enhanced wind transport capacity.

DUNES

Tens of thousands of sand dunes are found across the surface of Titan at the equatorial regions [Lorenz et al. 2006b]. These appear as long, narrow, and SAR-dark features against a SAR-brighter substrate or interdune (Figure TITAN-4), because dune sands are smooth at the 2.17 cm Cassini SAR wavelength. The dunes are generally 1–2 km wide, spaced by 1–4 km and can be over 100 km long [Lorenz et al. 2006b; Radebaugh et al. 2008]. Limited measurements of heights from radarclinometry suggest they are 80–130 m tall [Neish et al. 2010]. They are grouped together in large dune fields, or sand seas, equatorward of ±30 degrees latitude. Rodriguez et al. [2014] found that dunes cover 13 ±2% of the 58.1% of Titan's surface observed with SAR and HiSAR, and closer to ≈17% (≈14.10^6 km^2, 1.5 × the entire Sahara Desert on Earth), using VIMS.

Titan's dunes interact with topographic obstacles, seen as SAR-bright and generally isolated mountains, in a way that indicates general W-E transport of sand; they pile up on the west side of obstacles, divert in their azimuth around the obstacles, and are sparser on the east side

Figure TITAN-4. Dunes on Titan as seen by the Cassini SAR (wavelength 2.17 cm, with spatial resolution of 350 m) in the Belet Sand Sea, from the T61 (August 2009) swath on the equatorial leading hemisphere, at 11° S, 255° W. Dune surfaces are generally smooth and absorbing to SAR and thus appear as SAR-dark lines against a rougher and/or fractured, SAR-bright substrate. Open arrows indicate the direction of SAR illumination and incidence angle. Figure from Radebaugh et al. [2013].

[Lunine et al. 2008a; Radebaugh et al. 2010]. Their size, general morphology and relationship with underlying terrain and obstacles, and their style of collection are nearly identical to large, linear dunes in Earth's sand seas of the Sahara, Arabia and Namibia [Lorenz et al. 2006b; Radebaugh et al. 2008; Le Gall et al. 2011, 2012]. Such dunes on Earth typically form under bimodal winds [Fryberger and Dean 1979; Tsoar 1983] or a dominant, slightly off-axis wind and a secondary wind causing sand flux down the dune long axis [Courrech du Pont et al. 2014; Lucas et al. 2014].

A fundamental challenge raised by the SAR observations of the dunes is the eastward direction of growth and sand transport [Lorenz et al. 2006b; Lorenz and Radebaugh 2009; Radebaugh et al. 2010]. This contrasts with expectations that low-latitude near-surface winds should generally blow to the west. The solution appears to be that the dunes reflect strong but infrequent eastward winds, either associated with vertical mixing in the atmosphere at equinox leading to strong westerly gusts [Tokano 2010] or methane rainstorms having a similar effect [Charnay et al. 2015]. Additionally, convergence of the meridional transport predicted in models—for example, Lucas et al. [2014] can further explain why Titan's dunes are confined within ±30° latitudes, where sediment fluxes converge—see also Malaska et al. [2016].

Titan's dune sands are not only dark to SAR but they are some of the darkest materials seen by ISS [Porco et al. 2005; Karkoschka et al. 2017] and have a low albedo and red slope as seen by VIMS, thus comprising the VIMS dark brown spectral unit, and highest-resolution VIMS images distinguish individual dunes as dark [Soderblom et al. 2007; Barnes et al. 2008; Clark et al. 2010; Rodriguez et al. 2014]. Volume scattering within the dunes is very low, consistent with smooth,

homogeneous surfaces in general, and lacking large voids or clasts [Janssen et al. 2009, 2016; Le Gall et al. 2011], although modeling by Paillou et al. [2014] suggests possible surface ripples and some volume scattering. The observations indicate the dunes cannot be composed of water ice, but rather must be made of organics, ultimately derived from photolytic processing of methane in the upper atmosphere and precipitation to the surface [Lorenz et al. 2006b, 2008a; Soderblom et al. 2007]. Sand sources could include river channels, as on Earth [Radebaugh 2013]; low-latitude evaporite deposits, which can show similar VIMS properties [Barnes et al. 2011]; or the midlatitude blandlands, though it is more likely that sands are being transported there from the equatorial regions [Lopes et al. 2016; Malaska et al. 2016]. The extent of the dunes indicates that sands have been generated and transported in great volumes across Titan and that processes have acted on the surface long enough to produce extensive and morphologically consistent landforms [Radebaugh 2013], with some evidence of change over time [Ewing et al. 2015].

In addition to dunes, other aeolian features and landforms on Titan's surface include wind streaks and yardangs, or wind-carved ridges. The wind streaks are visible in ISS images as bright features that extend in the downwind direction from obstacles, for example, Porco et al. [2005]; Lorenz et al. [2006b]; Malaska et al. [2016]. SAR-bright, rough, elevated domes are crosscut by a series of parallel, long lineations ~1 km wide, spaced by a few km, and tens of kilometers long [Paillou et al. 2016]. They are similar in appearance and SAR brightness, radiometry and scatterometry to yardangs [Paillou et al. 2016]. These appear to have formed in easily eroded materials, similar to yardangs on Earth and Mars and further indicate the action of wind at moderate to high latitudes now or in the past. Craters: Before Cassini arrived at Saturn, the cratering history on Titan was unknown from direct observations. Estimates of the cratering rate were made by extrapolating the crater distributions observed on other Saturnian satellites, or by predicting impact rates by comet populations. Such estimates suggested that at least several hundred craters larger than 20 km in diameter should be present on Titan [Zahnle et al. 2003]; projectiles that create craters smaller than 20 km in diameter are expected to be disrupted by Titan's thick atmosphere [O'Brien et al. 2005; Korycansky and Zahnle 2005]. However, Cassini observed an extreme paucity of craters compared to these predictions. Only 23 certain or nearly certain craters and ~10 probable craters have been documented on Titan in this size range, with a handful of smaller crater candidates [Wood et al. 2010; Neish and Lorenz 2012; Buratti et al. 2012; Neish et al. 2016]. This population suggests that Titan has a crater retention time of several hundred million years [Wood et al. 2010; Neish and Lorenz 2012], with the oldest regions located near the equator and the youngest regions located near the poles [Neish et al. 2016].

The craters that are observed on Titan all show evidence for extensive modification by exogenic processes (Figure TITAN-5.). River valleys are observed to cut through the ejecta blankets and floors of several impact craters [Wood et al. 2010; Soderblom et al. 2010; Neish et al. 2015]. Many of Titan's impact craters are located in its equatorial sand seas, and also show evidence for extensive infilling by sand [Wood et al. 2010; Neish et al. 2013]. In addition to the morphologic evidence for erosion and burial, Titan's craters are consistently shallower than similarly sized fresh craters on Ganymede (often by many hundreds of meters), suggestive of infill [Neish et al. 2013]. Given the distribution of depths, aeolian infilling appears to be the dominant modification process on Titan [Neish et al. 2013], but fluvial erosion seems to play an important

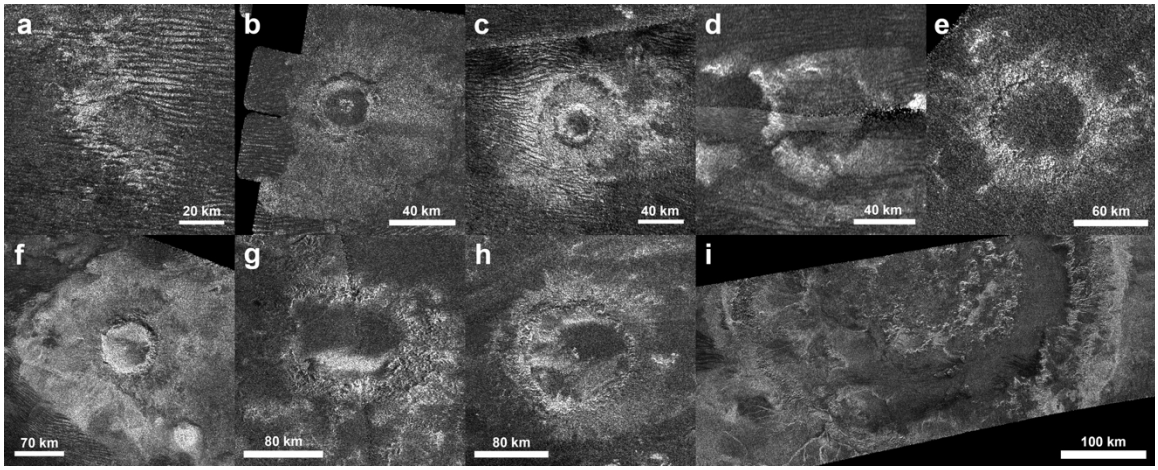

Figure TITAN-5. Nine probable impact craters observed on Titan by Cassini RADAR, from smallest (a) to largest (i). Impact craters on Titan show modification by exogenic processes such as fluvial erosion and infilling by sand. Figure from Neish et al. [2013].

secondary role [Neish et al. 2016]. Modification by viscous relaxation is expected to be minimal given the cold surface temperatures on Titan, although insulation by sand can enable some relaxation in Titan's larger craters [Schurmeier and Dombard 2018].

In addition to being highly modified, Titan's impact craters are not uniformly distributed across the moon. There is an almost complete absence of impact craters near Titan's poles, with the majority of the craters found in the topographically high, equatorial sand seas [Neish and Lorenz 2014]. There have been several hypotheses advanced to explain this observation. Neish and Lorenz [2014] proposed the lack of craters near Titan's poles may be indicative of marine impacts into a former ocean in this region. Moore et al. [2014] suggested that extreme climate change occurred in Titan's recent past, causing global methane rainfall that produced sediment that settled in Titan's topographically low poles, burying any craters there. Finally, Neish et al. [2016] suggested that an increased rate of fluvial erosion near the poles could degrade Titan's craters to the point where they would be unrecognizable from orbit. In any case, it appears that Titan is an extremely dynamic world, and studying its impact craters can reveal much about the processes that have shaped it.

Cryovolcanism: The possibility of finding cryovolcanic features on Titan had been discussed prior to Cassini, for example, Lorenz [1993b, 1996a]. The case for cryovolcanism was strengthened by results from the Gas Chromatograph Mass Spectrometer (GCMS) instrument on board the Huygens probe, which detected the radiogenic isotope of Argon-40 in Titan's atmosphere [Niemann et al. 2005] in concentrations suggesting that the atmosphere was in communication with a reservoir of the parent atom. Prior to the first Titan flyby using RADAR, VIMS imaged a bright feature (later named Tortola Facula) that Sotin et al. [2005] proposed to be cryovolcanic in origin, although SAR images obtained later in the mission showed Tortola Facula to be a local topographic high similar to others elsewhere on Titan [Lopes et al. 2013] and not a candidate for a cryovolcanic feature. Sotin et al. [2005] further suggested that the upwelling of large cryovolcanic plumes might be releasing sufficient methane into the atmosphere to account for the current atmospheric composition.

Cassini RADAR and VIMS revealed several features that have been interpreted as cryovolcanic in origin [Lopes et al. 2007, 2013; Soderblom et al. 2009; Wall et al. 2009; Solomonidou et al. 2016]. However, the interpretation has been the subject of some debate—for example, Moore and Pappalardo [2011]—and has not been entirely resolved by Cassini data [Nixon et al. 2018], primarily due to limitations in spectral resolution and coverage. The interpretations of RADAR—SAR, stereogrammetry [Kirk et. al. 2010], SARTopo [Stiles et al. 2009], and radiometry—and VIMS surface albedos and compositional constraints are based on morphology, albedo differences between the cryovolcanic areas, their surrounding terrains and several other geomorphological features, and temporal variations detected by VIMS [Solomonidou et al. 2014, 2016, 2018]. However, the Cassini mission did not reveal any hot spots, i.e., thermal enhancements that would have provided conclusive proof. The detection of thermal activity at Titan's surface using radiometry data (which is sensitive to variations of ~1K) or VIMS, would require Cassini's instruments to be observing the right locations at the right times and on multiple occasions, an unlikely scenario given the relatively small number of candidate-cryovolcanic features [Lopes et al. 2010].

The strongest evidence for cryovolcanic features on Titan was put forward by Lopes et al. [2013] who combined SAR imaging (including stereogrammetry) and VIMS data for a region that includes two mountains, Doom Mons (40.4° W, 14.7° S) and Erebor Mons (36.2° W, 5.0° S), as well as a depression, Sotra Patera (40.0° W, 14.5° S), and a region consisting of flow-like features, Mohini Fluctus (centered at 38.5° W, 11.8° S). Doom and Erebor Montes are high mountains (Doom being ~70 km in diameter and 1.45 ±0.2 km high), and Sotra Patera is the deepest depression found on Titan (1.7 ±0.2 km deep). It is non-circular, and interpreted as a collapse feature adjacent to Doom Mons. Mohini Fluctus appears to emerge from Doom Mons. Other non-circular, depressions are located between the two Montes, and flow-like features also surround Erebor Mons.

A criticism by Moore and Pappalardo [2011] of initial interpretations by RADAR of cryovolcanic candidates reported by Lopes et al. [2007] is that flow-like features could have been produced by fluvial activity, as channels are seen in areas such as Hotei Regio and Ganesa Macula (which topography later showed was not a shield or dome as initially interpreted). However, the Doom Mons-Sotra Patera-Erebor Mons region is totally devoid of fluvial channels, making a fluvial origin for Mohini Fluctus and other flows unlikely. Moreover, a vast dune field is located between Doom and Erebor Montes, indicating a dry region. The depressions seen in the region, including Sotra Patera, are not circular and are therefore unlikely to have had an impact origin [Lopes et al. 2013]. Additionally, analysis of VIMS data using a radiative transfer code [Solomonidou et al. 2014] showed that the surface albedo of the candidate cryovolcanic features is different from that of plains or dunes, indicating differences in composition [Solomonidou et al. 2014]. Following this, and using a radiative transfer code on a large selection of VIMS data, Solomonidou et al. [2016] revealed temporal changes for the Sotra Patera and Mohini Fluctus area, potentially brightening by up to a factor of two in terms of pure surface albedo and brightness during one year (2005–2006), while surrounding areas and the undifferentiated plains and dunes did not present any significant change for the same period of time. The surface albedo variations, together with the presence of volcanic morphological features, suggest possible relation to the deep interior via cryovolcanic processes. Additional support for the cryovolcanic origin of these features comes from interior structure models

of Titan and corresponding calculations of the spatial pattern of maximum tidal stresses [Sohl et al. 2014], which indicate that the Sotra Patera-Doom Mons-Erebor Mons area is a likely region for cryovolcanic activity.

Titan's interior (TN1b) (T_AO4)

Static and time-varying gravity field measurements [Iess et al. 2010, 2012], rotational dynamics measurements [Stiles et al. 2008, 2010; Meriggiola et al. 2016] and shape models [Zebker et al. 2009; Mitri et al. 2014; Corlies et al. 2017] are used to infer the interior structure of Titan. Magnetic field measurements have shown that an intrinsic magnetic field is not present on Titan [Wei et al. 2010]. The determination of the rotational dynamics from Cassini RADAR SAR images is key to constrain the interior structure of Titan. As described above, Cassini RADAR SAR coverage of Titan is dependent on orbit dynamics and competition for observation time. As a result, SAR swaths appear randomly distributed with coincidental overlaps (with only a few exceptions). Where overlap occurs, and assuming that the same surface features appear in both images, it has been possible to determine how the surface of Titan has moved between observations and thus estimate Titan's pole location and spin rate [Stiles et al. 2008, 2010], analogous to previous work using Magellan SAR imagery to estimate the spin model of Venus [Davies et al. 1992]. First, a set of recognizable landmarks were selected that are observed in two different SAR images obtained at different times. A pixel is chosen in each SAR image that corresponds as closely as possible to the same point on the landmark, using several techniques to minimize landmark mismatches. These pixels are then located in a Titan-centered inertial, non-rotating (J2000) frame. Finally, spin state parameters are estimated by minimizing the misregistration error, i.e., the apparent movement in Titan body-fixed coordinates of the landmarks between observation times. Thus, estimates of Titan's spin state parameters and their error bars are obtained. Using similar methodology, Meriggiola et al. [2016] also provided a rotational model of Titan estimating the spin pole location, the spin rate, the precession and the nutation. Further, these authors have shown that the pole location is compatible with the Cassini state 1.

Stiles et al. [2008] and Meriggiola et al. [2016] have provided an estimate of Titan's obliquity (0.31°). The obliquity together with the quadrupole moment of the gravity field (J_2 and C_{22}) measurements [Iess et al. 2010, 2012] can be used to infer the moment of inertia of Titan and, consequently, the radial mass distribution of Titan [Bills and Nimmo 2011]. Bills and Nimmo [2011] and Meriggiola et al. [2016] have shown that the estimated obliquity is compatible with a deep interior decoupled from the outer ice shell by a global subsurface ocean. The presence of a subsurface ocean inferred from the rotational dynamics of Titan is consistent with the large tidal response of Titan (tidal Love number $k_2 = 0.589 \pm 0.150$) [Iess et al. 2012], see also Mitri et al. [2014]. In agreement with this scenario, the Permittivity, Wave and Altimetry (PWA) instrument on board Huygens' probe has measured a Schumann-like resonance, suggesting also the presence of a subsurface ocean [Bèghin et al. 2012]. In summary, the gravity, topography and rotational dynamics measurements in combination with thermal-evolution models indicate that Titan presents internal differentiation, with an outer ice shell, a subsurface ocean, a high-pressure layer at the base of the ocean, and a deep rocky interior [Hemingway et al. 2013; Mitri et al. 2014; Tobie et al. 2014].

Bills and Nimmo [2011] next used these results, combined with low-degree gravity field derived from Cassini spacecraft Doppler tracking data [Iess et al. 2010], to suggest that Titan's outer shell is mechanically decoupled from the deeper interior, plausibly an outer ice layer which is mechanically decoupled from the deeper interior by an ocean. Taking this conclusion together with other evidence, there is emerging consensus that Titan possesses an internal ocean. Implications for the crustal and internal composition and origin of Titan are discussed by Tobie et al. [2014].

Cassini radar observations in both its altimeter and SARTopo modes reveal its global shape and yield insights to its interior structure. The roughly 60 satellite-derived elevation surface traces (Figure TITAN-6) show that Titan's polar radius is less and equatorial radii greater than predicted by its gravity field.

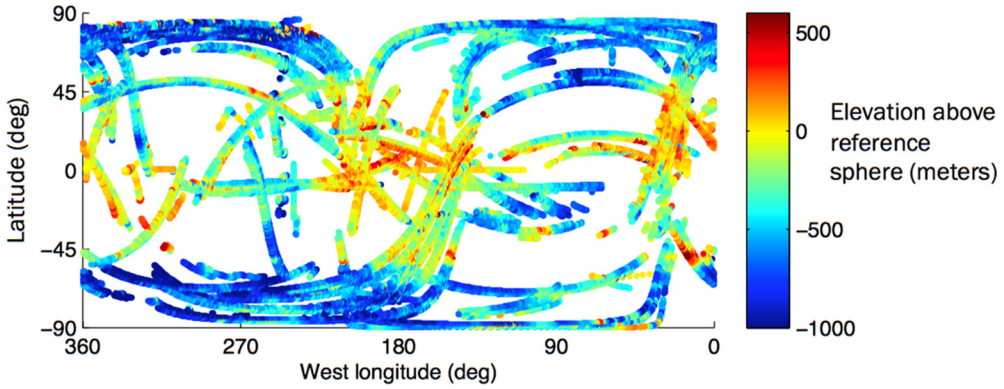

Figure TITAN-6. Cassini measurements of Titan surface height above a reference sphere of 2575 km. Clear triaxial ellipsoid shape implies a body not in hydrostatic equilibrium, suggesting that depth to a subsurface ocean is less at the poles than at the equator.

The ratio (a−c) / (b−c), which is exactly 4 for a spin-locked satellite in hydrostatic equilibrium, for Titan's figure is thus observed to be only 2.65. The corresponding third-degree gravity hydrostatic ratio is 3.83. While the gravity field is consistent with a hydrostatically relaxed body, the figure does not. If both of these data constraints pertain, Titan's interior do not conform to a set of spherically symmetric shells, as these data imply that the average satellite density at the equator is less than that at the poles. If Titan has a vast interior ocean of liquid water, then some ice layers (less dense than liquid water) are thinner at the poles than the equator. A simple model satisfying both sets of data and assuming isostatic compensation (Figure TITAN-7) could be the result of uneven heat dissipation in Titan's interior, such as may result from tidal interaction with Saturn or its other moons.

Another simple model realizing these is greater precipitation of hydrocarbon snow or loosely packed particulates at the equator than at the poles, perhaps with a net equatorward transport from the poles. We note that this is consistent with the observation of 100 m tall dune structures near Titan's equator, so that poorly consolidated material may indeed collect there. Several hundred m of deposition at the equator would match the mean equatorial radii of both models, but precipitation would have to preferentially occur in the directions toward and away from Saturn, which seems unlikely.

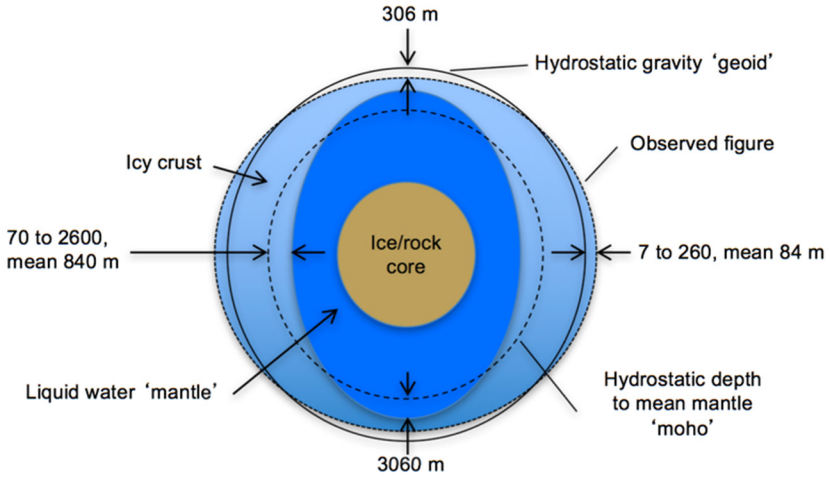

Figure TITAN-7. A model consistent with Cassini gravity and figure measurements, assuming isostatic compensation. The thinner ice shell at the poles could result from uneven heat dissipation within Titan from tidal interactions, and the higher "geoid" at the poles is one explanation for the preponderance of lakes at the most northern and southern latitudes.

Further comparison of the gravity and shape observations constrain the depth of any outer ice shell enclosing a global subsurface ocean. While the exact value varies depending on how the spherical expansion is constrained, our observed gravity to topography ratio is 0.070 for the third order terms and 0.042 for fourth order. These imply ice shell thicknesses of 327 and 187 km, respectively, twice or more of the 100 km expected from thermal models [Sohl at al. 2003; Nimmo and Bills 2010]. Our solution yields a tidal Love number h_{2t} of about 0.5, and a basal heat flow of 2.5 mW/m^2. This would suggest that heat from Titan's core is lower than often assumed, hence the amount of radiogenic material in the core is likely less as well.

These data also constrain the depth of Titan's mantle and density of its core, placing added restrictions on its composition and evolution. Supposing that Titan has an undifferentiated ice/rock core beneath the ocean, and that its moment of inertia is most likely in the range 0.33–0.34 [Iess et al. 2010], a 200 km crust estimate from above, and Titan's well-known mean density of 1.88 g cm^{-3} implies an ocean depth and core density ranging from 308 km and 2.74 g cm^{-3} (MOI = 0.33) to 226 km and 2.55 g cm^{-3} (MOI = 0.34).

Titan atmospheric composition (TN1c) (T_AO2)

Observe vertical and horizontal distributions of trace gases, search for more complex organic molecules. Determine abundances of atmospheric constituents (including any noble gases), derive isotope ratios for abundant elements. Measure aerosol and heavy molecule layers and properties. Investigate energy sources for atmospheric chemistry, model the photochemistry of the stratosphere, study formation and composition of aerosols.

The chemistry of Titan's atmosphere is driven by CH_4 photolysis in the thermosphere and catalytic reactions in the stratosphere, and by N_2 dissociation due to both UV photons and energetic

electrons. Ethane is the most abundant gas product and HCN is the dominant nitrile. The mixing ratios of all photochemical species, except C_2H_4, increase with altitude at equatorial and southern latitudes, indicative of transport from a high-altitude source to a condensation sink in the lower stratosphere. Poleward of 45°, most product compounds are enriched as a consequence of subsidence in the winter polar vortex, particularly for nitriles and more complex hydrocarbons than C_2H_6 and C_2H_2. Most products have lower increases with altitude at high latitudes than at low latitudes. The vertical and horizontal distribution of trace gases with season have been well-reported and documented in publications by Coustenis et al. [2007]; Vinatier et al. [2010, 2015]. The gases include hydrocarbons ($^{12}CH_4$, $^{13}CH_4$, CH_3D, C_2H_2, C_2HD, C_2H_4, C_2H_6, C_3H_4, C_3H_8, C_4H_2, C_6H_6), nitriles (HCN, HC_3N), H_2O, CO, and CO_2, as well as the detection of long sought after propene (C_3H_6) by Nixon et al. [2013] to remove a three-decade gap in the hydrocarbon sequence. Vuitton et al. [2019] give a detailed review of our current understanding of Titan's atmospheric chemistry at the end of the Cassini Mission.

Measurements of C, H, N isotopes provide constraints on photochemical fractionation mechanisms. While the Huygens GCMS measured ^{36}Ar, ^{40}Ar, and possibly ^{22}Ne, only upper limits were placed on Kr and Xe. As a consequence, the origin of CH_4 in the solar versus Saturnian nebula or conversion of CO_2 to CH_4 in Titan's interior remains unconstrained. Also, CIRS tracer gas distributions have been used to diagnose models of stratospheric dynamics [Crespin et al. 2008]. The carbon isotope ratio $^{12}C/^{13}C$ was determined in CH_3D [Bézard et al. 2007]; in HCN [Vinatier et al. 2007]; in HC_3N [Jennings et al. 2008]; in CO_2 [Nixon et al. 2008]; in CH_4, C_2H_2, C_2H_6 [Nixon et al. 2008, 2012]; in C_4H_2 [Jolly et al. 2010]. The hydrogen isotope ratio D/H was derived from CH_4 by Bézard et al. [2007] and C_2H_2 by Coustenis et al. [2008], whereas Nixon et al. [2008] obtained the oxygen isotope ratio $^{16}O/^{18}O$ from CO_2.

The thermosphere is a chemical factory that initiates the formation of complex positive and negative ions in the high thermosphere as a consequence of magnetospheric-ionospheric-atmospheric interaction involving solar EUV and UV radiation, energetic ions and electrons. This factory produces very heavy positive and negative ions and large molecules [Shebanits et al. 2016], for example, benzene, naphthalene, nitriles, which apparently condense out and are detectable in solar and stellar UV occultations at ~1000 km [Liang et al. 2007; Kammer 2015], and initiate the haze formation process [Lavvas et al. 2013]. As these particles fall through the agnostosphere/ ignorosphere/mesosphere and grow, they become detectable by remote sensing: UVIS at ~900 down to ~300 km, ISS at ~500 km and below and eventual become ubiquitous throughout the stratosphere. These haze particles are strong absorbers of solar UV and visible radiation and play a fundamental role in heating Titan's stratosphere [Bézard et al. 2018] and probably the mesosphere [Lavvas et al. 2009]. The differential heating with latitude drives wind systems in Titan's middle atmosphere, much as ozone does in the Earth's middle atmosphere.

The Huygens Probe measurements, and the Cassini orbiter measurements over a significant fraction of the Titan season, in particular, were responsible for major advances. The Descent Imager/Spectral Radiometer (DISR) measured intensity and polarization from the near-UV to 1.6 microns in the near-IR. Haze density profiles along the descent path from the ground to 160 km altitude were derived from these measurements, along with tight constraints on the size of the

monomers that make up aggregate particles, as well as the mean size of the aggregates [Tomasko et al. 2008, 2009; Doose et al. 2016].

All of the Cassini orbiter optical instruments contributed new measurements and insights regarding the Titan haze. Solar and stellar occultations by the UVIS and VIMS instruments provided detailed vertical profiles over near-surface to high altitude (>700 km) [Koskinen et al. 2011]. Limb measurements by the CIRS instrument revealed vertical profiles of haze opacity in the thermal-IR and identified two polar haze layers, probably condensate layers, with spectral signatures near 50 microns. The components of aerosol composition have been inferred from CIRS observed spectral signatures of functional group vibrational modes and compared with laboratory produced Titan tholins [Vinatier et al. 2012] The ISS and VIMS instruments detected a high-altitude winter polar HCN cloud that formed shortly after equinox. The ISS instrument measured Titan's detached haze and followed its altitude changes over a significant part of the seasonal cycle [West et al. 2018].

Titan atmospheric structure (TN2a) (T_AO5)

Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission). Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn (**Titan Upper Atmosphere (T_AO5)**).

Remarkably in the middle stratosphere, the warmest temperatures occur at the equator and the largest meridional temperature gradients are found in the winter hemisphere.

Titan's atmosphere is predominantly N_2 with CH_4 the next most abundant molecule. It has a mole fraction of 0.05 just above the surface decreasing to 0.014 in the stratosphere. Above the homopause (~800–850 km), it increases to 0.12 at the exobase. The third abundant molecule is H_2 with a tropospheric mole fraction of 0.001 increasing to 0.004 at ~1000 km and ~0.02 at the exobase (~1500–1600 km). There is a large suite of hydrocarbons, nitriles, other nitrogen and also oxygen bearing compounds. Titan possesses a mostly stable troposphere with a well-defined tropopause (T ~70 K at ~44 km) and a lower stratosphere with a high static stability, which is extremely cold over the winter polar region and warm over the summer pole (Figure TITAN-8 and Figure TITAN-9). Remarkably in the middle stratosphere, the warmest temperatures occur at the equator and the largest meridional temperature gradients are found in the winter hemisphere. The stratopause from the summer pole to about 45° winter hemisphere remains at a relatively constant pressure of 0.1 mbar/300 km and then it rises rapidly upward to ~0.01 mbar/400 km at the winter north pole, where it is the warmest region in the entire atmosphere. One possible interpretation of the HASI temperature profile is that Titan's atmosphere is essentially isothermal ~170 K from 500–1100 km, with large amplitude thermal waves (10 K) superimposed. The existence and location of a well-defined mesopause is an open question.

The Huygens HASI instrument provided along its trajectory essentially continuous profiles of mass density, pressure, and temperature from an altitude of 1350 km down to the surface. While

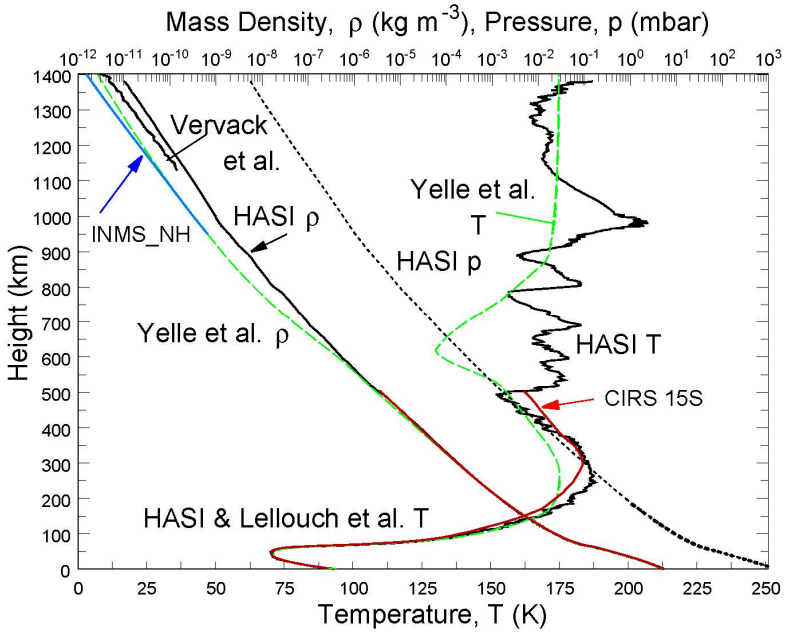

Figure TITAN-8. Titan possesses a mostly stable troposphere with a well-defined tropopause and a lower stratosphere with a high static stability. Black Lines: Comparison of Cassini-Huygens HASI density, pressure, and temperature profiles [Fulchignoni et al. 2005]. Red Lines: CIRS density and temperature profiles at 15 S [Vinatier et al. 2007]. Blue Lines: Average INMS Northern Hemisphere density profile mission with preflight calibration [Müller-Wodarg et al. 2008], needs to be increased by a factor of 2.2 [Teolis et al. 2015]. Green Lines: With the Voyager [Lellouch et al. 1989; Vervack et al. 2004] results, and the Yelle et al. [1997] engineering model, all as functions of altitude above surface.

only at one time and location, it provided an important reference atmosphere to compare with measurements by other instruments of latitudinal and seasonal variations over the 13 years of active observations. But Lellouch et al. [2014] found that the CH_4 mole fraction near 15 mbar (~85 km) varied from ~1.0 % at low latitudes, in disagreement with the Huygens GCMS measurement of 1.48 %, and near ±50–55°, but ~1.5 % at ±30–35° and polar latitudes. The retrieved thermal profile from CIRS is about 3–5 K colder than HASI in the 2–20 mbar region with CH_4 = 1.48 % (cf. Figure TITAN-8). But with CH_4 = 1.0 %, the CIRS derived temperature below 147 km altitude (2.7 mbar), agrees with the HASI direct measurements by its temperature sensor and would resolve the CIRS/HASI differences in the temperatures below 147 km at the Huygens landing site.

The chemistry of Titan's atmosphere is driven by CH_4 photolysis in the thermosphere and catalytic reactions in the stratosphere, and by N_2 dissociation due to both UV photons and energetic electrons. Ethane is the most abundant gas product and HCN is the dominant nitrile. The mixing ratios of all photochemical species, except C_2H_4, increase with altitude at equatorial and southern latitudes, indicative of transport from a high-altitude source to a condensation sink in the lower stratosphere. In northern hemisphere winter northward of 45° N, most photochemically produced compounds are enriched as a consequence of subsidence in the polar vortex, particularly for nitriles

and more complex hydrocarbons than C_2H_6 and C_2H_2, and have lower increases with altitude at high latitudes than at low latitudes.

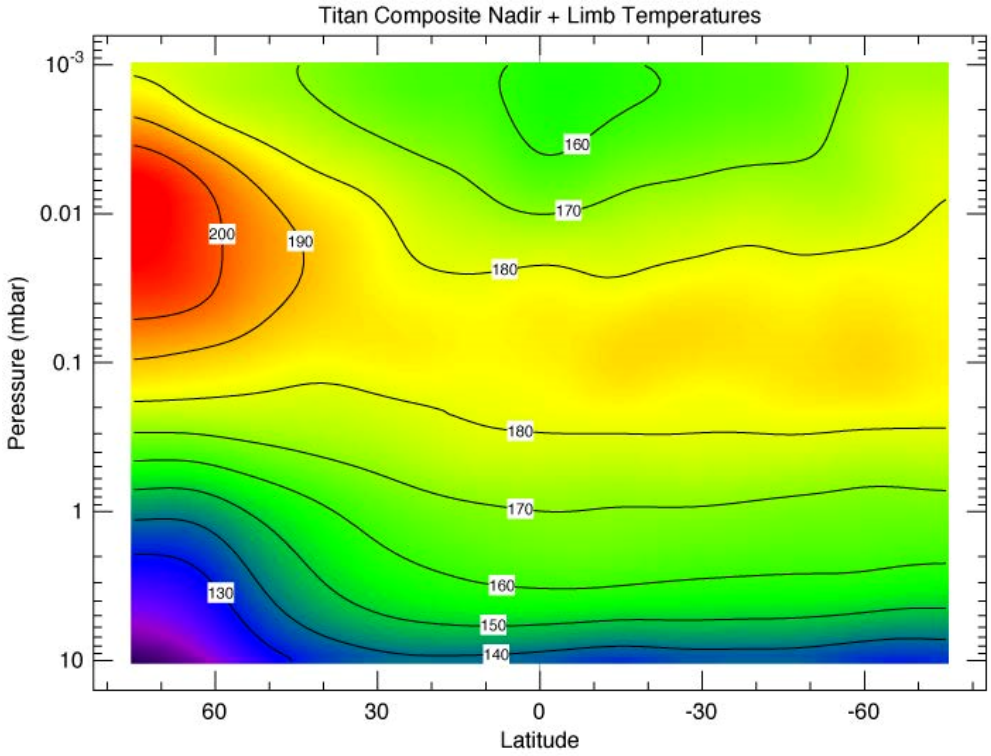

Figure TITAN-9. CIRS zonal mean temperatures (K) from limb and nadir spectra recorded between July 2004 and September 2006. Retrieved temperatures were averaged over 5° latitudinal intervals and smoothed three times with 10° boxcar function, Note that the north pole is on the left. [After Achterberg et al. 2008].

The thermosphere is a chemical factory that initiates the formation of complex positive and negative ions in the high thermosphere because of magnetospheric-ionospheric-atmospheric interaction involving solar EUV and UV radiation, energetic ions and electrons (Figure TITAN-11). This factory produces very heavy positive and negative ions and large molecules—for example, benzene, naphthalene, nitriles—which apparently condense out and are detectable in solar and stellar UV occultations at ~1000 km [Liang et al. 2007] and initiate the haze formation process [Lavvas et al. 2013]. As these particles fall through the mesosphere and grow, they become detectable by remote sensing: UVIS at ~1000 km, ISS at ~500 km and eventually become ubiquitous throughout the stratosphere. These haze particles are strong absorbers of solar UV and visible radiation and play a fundamental role in heating Titan's stratosphere and perhaps the mesosphere [Lavvas et al. 2009]. The differential heating with latitude drives wind systems in Titan's middle atmosphere, much as ozone does in the Earth's middle atmosphere.

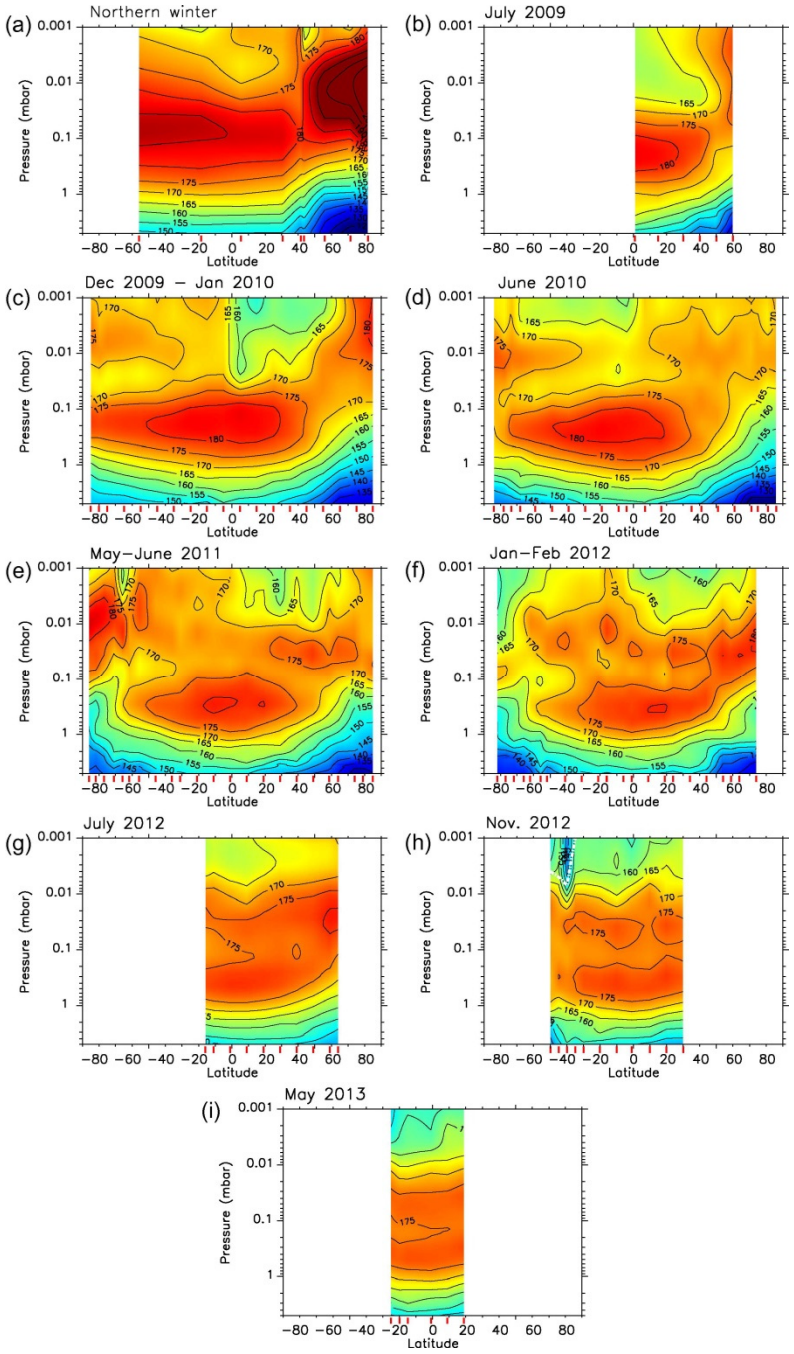

Figure TITAN-10. Pressure/latitudes maps of temperature as a function of season from northern winter through late spring. Note that the north pole is on the right. Red marks on the horizontal scale give the latitudes where limb spectra were analyzed. White areas indicate regions where CIRS did not acquire limb spectra. White dashed lines show the levels above which the constraints on the thermal profiles are poor (typically because of a too low signal-to-noise ratio) [Vinatier et al. 2015].

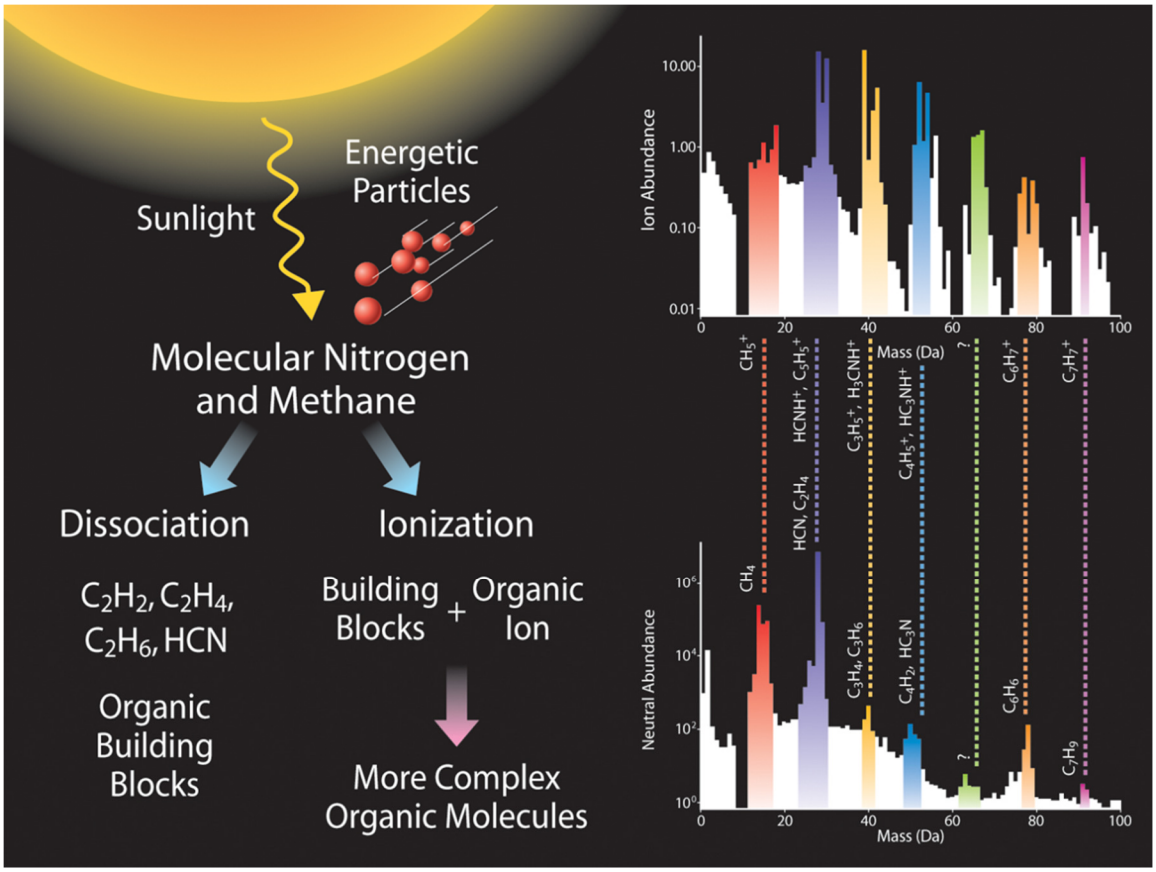

Figure TITAN-11. A cartoon of complex ion/neutral chemistry in Titan's upper atmosphere (950-1000 km) as observed by the Cassini INMS on flyby T16. The upper insert is an ion mass spectrum from 1–100 Daltons and the lower insert a neutral mass spectrum from 1 to 100 Daltons. Note benzene at 78 Daltons. Organic ions can be either negatively (~20 to ~8000 Da) or positively (up to ~350 Da) charged. The end result is the pervasive haze that envelopes Titan and whose particles (called Titan tholins) are eventually deposited on the surface [After Waite et al. 2007].

Escape of atoms and molecules from Titan is a source for mass loading of Saturn's magnetosphere. Strobel and Cui [2014] reviewed the strong evidence for significant escape of hydrogen as atoms (~1 × 10^{27} s^{-1}) and molecules (~1 × 10^{28} s^{-1}) for a total of ~2 × 10^{28} amu s^{-1}, and by far a major source of mass for the magnetosphere. Their escape is controlled by the maximum rate that they diffuse through Titan's atmosphere and confirmation of the principle behind Hunten's limiting flux [Hunten, 1973]. While they escape Titan, they are still gravitationally bound to Saturn and thus subject to ionization. If ionized, they have less impact on the magnetosphere by virtue of Titan's location at the outer boundary of the magnetosphere in comparison to Enceladus with a comparable mass source rate, but in the inner magnetosphere.

In contrast the controversy concerning the escape rate of CH_4 is linked to the analysis of measured CH_4 density profiles and the inference of the magnitude and radial direction of CH_4 diffusion fluxes. Initial INMS results yielded upward flow of ~2 × 10^{27} CH_4 s^{-1}. This suggested escaping CH_4, if there were no compensating downward flow elsewhere in the atmosphere. But not

every INMS flyby data set yielded high CH_4 escape rates. In Cui et al. [2012], Table 5 and Strobel and Cui [2014], Table 10.1, occasionally, the CH_4 flux is downward and/or indistinguishable from diffusion equilibrium, although about half of the orbits yielded preferentially strong upward flow of CH_4. Titan's upper atmosphere has shown considerably variability in the CH_4 density profiles and temperature structure inferred from N_2 density profiles from orbit to orbit—for example, Snowden et al. [2013]. Attempts to identify the drivers for this structure variability and inferred CH_4 escape/loss rates yielded larger escape on the nightside over the dayside, whereas magnetospheric lobe-like conditions (factor of 10 reduction in energetic electron flux) yielded diffusive equilibrium, no net CH_4 fluxes [Cui et al. 2012, Table 6], albeit in the latter case, it is the statistics of few flybys. Given this observed variability, one can question whether 1-D models are appropriate to derive only a single number: the globally averaged, Titan orbit averaged CH_4 escape rate. Whereas one can present arguments that solar heating of Titan's thermosphere is sufficient to support large CH_4 escape rates, to date no models have been capable of accelerating a sufficient number of CH_4 molecules in the collisional atmosphere to speeds that exceed the escape velocity at the exobase [Tucker and Johnson 2009].

Cassini INMS measurements based on roughly 100 Titan flybys during the Cassini mission yielded neutral and ion densities systematically lower, by factors approximately 2 to 3, than alternate methods to derive and infer densities, specifically, torque on the spacecraft measured by the Attitude and Articulation Control System (AACS) and the spacecraft atmospheric drag derived by the Navigation system [Teolis et al. 2015]. By correcting for an under-estimation of gas leakage out of the instrument into space by the original calibration model, and adjusting for the gain change, Teolis et al. [2015] developed a new calibration model that raises INMS densities upward by a constant detector sensitivity correction factor of 1.55 ±21%. With this new model the density ratio of AACS to INMS is now 1.47, but outside of the INMS error bars, and the density ratio of navigation (NAV) to INMS is now 1.16 and within the error bars. Although the three methods of determining atmospheric densities are much closer, one would want to know whether AACS or NAV is the more accurate method to derive densities.

The UVIS stellar and solar occultations are self-calibrating. In the case of the solar occultations one can retrieve density profiles in the altitude range 1120–1400 km for N_2 and 850-1300 km for CH_4, whereas UVIS stellar occultations are limited by interstellar hydrogen absorption to wavelengths above 91.1 nm. The CH_4 dissociation cross-sections vary smoothly with wavelength and allow measurements of CH_4 optical depths and densities, while complex N_2 electronic band systems between 80–100 nm are not accessible to analysis with any confidence. T118 was the only flyby in the mission where UVIS and INMS observe Titan's atmosphere simultaneously at the same latitude. UVIS sampled remotely by observing a solar occultation; INMS sampled the upper atmospheric density in situ with the hypersonic Cassini Spacecraft flying through the atmosphere at Mach 20–25.

The TAMWG report will discuss attempts to resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission).

Titan's icy shell (TN2b) (T_AO2)

Work in this area is discussed in the section entitled *Titan's interior (TN1b) (T_AO4)*.

Titan meteorology (TN2c) (T_AO3)

Determine the surface temperature distribution, cloud distribution, and tropospheric winds. Measure winds and global temperatures; investigate cloud physics, general circulation, and seasonal effects in Titan's atmosphere; search for lightning discharges.

Titan surface temperature maps from CIRS measurements over the period of 2004–2016 [Jennings et al. 2016] can be visualized at https://www.nasa.gov/image-feature/jpl/pia20020/titan-temperature-lag-maps-animation.

Winds were directly measured by the Doppler Wind Experiment (DWE) and inferred from DISR measurements during the descent of the Huygens Probe. From CIRS global mapping of stratospheric temperatures, zonal winds can be inferred via the gradient wind relationship from 10 mbar (~140 km) up to 0.001 mbar (~500 km) as a function of altitude and latitude with season. From the zonal winds one derives information on the location and structure of the polar vortex as a function of season. In conjunction with trace gas enrichment due to subsidence from upper-atmosphere photochemical source regions, the associated meridional circulation structure can be deduced as characteristically a single cell circulation with broad summer hemispheric upwelling and winter polar-confined subsidence or a two-cell transitional global circulation, with upwelling around the equator and subsidence at both poles, characteristic of equinoctial circulation reversal [Vinatier et al. 2015; Teanby et al. 2017]. Also, CIRS tracer gas distributions have been used to diagnose 2-D GCM models of stratospheric dynamics, for example, Crespin et al. [2008].

Cassini discovered not only that the polar vortices appear to be tilted by a few degrees relative to the spin axis of Titan but also that the entire stratosphere is tilted by a several degrees from the rotational pole [Achterberg et al. 2008b].

The radio occultation measurements by Radio Science Subsystem (RSS) have yielded density, pressure, and temperature radial profiles from the surface to ~ 300 km at discrete locations that yield information on the latitudinal structure of the atmosphere and can be coupled with the CIRS remote sensing data [Schinder et al. 2012]. The latitudinal temperature gradients in these radio occultation measurements imply that the velocity minimum in the zonal wind profile detected by the DWE between 70–80 km is a global phenomenon.

Guided by RSS and HASI measurements, Charnay and Lebonnois [2012] used a GCM to simulate the dynamics that governs the thermal structure of Titan's planetary boundary layer, the lowermost atmosphere. From observations of dune spacing (~3 km) and the knowledge that the spacing is limited by the height of the planetary boundary layer [Andreotti et al. 2009], the boundary layer is ~3 km thick. The simulations yielded a convective boundary layer during the day, rising to an altitude of 800 m and a seasonal boundary of 2 km depth produced by the reversal of the Hadley

cell at the equinox, with a dramatic impact on atmospheric circulation. Boundary layer clouds are a better interpretation of the previous discovery claim of fog at Titan's south pole. They concluded that Titan's troposphere possesses two boundary layers that control wind patterns, dune spacing and cloud formation at low altitudes.

Although liquids have flowed on the surface at Titan's equator in the past, currently liquids are only found on the surface at polar latitudes. The vast expanses of dunes that dominate Titan's equatorial regions require a predominantly arid climate.

VIMS near-infrared images of Titan's clouds were acquired between July 2004 and September 2017 [Rodriguez et al. 2009, 2011; Turtle et al. 2018], following the evolution of clouds over 13 years including the equinox and northern summer solstice, greatly helping to further constrain global circulation models (GCMs). After four years of regular outbursts observed by Cassini between 2004 and 2008, southern polar cloud activity started declining. The extensive cloud system over the north pole, stable between 2004 and 2008, progressively fractionated and vanished as Titan entered into northern spring. At southern mid-latitudes, clouds were observed even after equinox, in a latitude band between 30 S and 60 S. Fewer clouds were observed closer to the equator, although they were slightly more frequent as equinox approached. As northern summer approached, cloud activity picked up at mid- and high northern latitudes as well.

ISS observations from April 2004 through September 2017 showed that clouds were generally more prevalent in the summer hemisphere, but revealed some surprises in locations and timing: with clouds remaining common at southern mid-latitudes longer than expected; north-polar clouds initially appearing much sooner than model predictions; and large north-polar summer convective systems not appearing before the mission ended, standing in marked contrast with south-polar activity observed over several years leading up to the southern summer solstice. Twice during the Cassini mission, ISS observations revealed changes in surface brightness consistent with methane rainfall darkening the surface [Turtle et al. 2009, 2011], first at Arrakis Planitia near the south pole in 2004–2005, Titan's southern summer, and secondly along the southern boundary of the Belet dune field in 2010, following the equinox. Comparison of ISS and VIMS cloud observations to GCMs suggests that a polar-wetlands scenario, with subsurface reservoirs at both poles and relatively dry lower latitudes, better matches cloud locations and timing as well as the sporadic nature of the activity documented [Lora and Mitchell 2015; Mitchell and Lora 2016; Faulk et al. 2017; Turtle et al. 2018]. For a comprehensive discussion on weather, clouds, and storms on Titan from Cassini observations, see also Griffith et al. [2014].

Searches have been conducted for lightning by HASI, RPWS, and ISS with negative results. The full seasonality of the methane hydrological cycle has not been observed, in particular the pole to pole transport of methane, which may operate on the timescale of Milankovitch cycles [Aharonson et al. 2009].

Other Titan science not in CSM TM: Titan as a system – its origin and mysteries

Titan Atmospheric Formation and Evolution (T_AO1) – Constrain scenarios of formation and evolution of Titan and its atmosphere.

Titan is the only moon in the solar system with an atmosphere so massive that it dominates the total volatile inventory in the surface-atmosphere system as well as providing strong radiative forcing and an active meteorology [Lorenz et al. 2005]. It also obscures the surface from view in both the optical and infrared, which is why the Cassini RADAR has been such a crucial tool. However, by the irreversible deposition of heavy hydrocarbons, nitriles, and other photochemical products from methane and nitrogen, the atmosphere also obscures the underlying surface geology to some extent. Were the current inventory of methane to condense onto the surface, it would form a layer 5 meters thick [Mitchell and Lora 2016], but a variety of evidence suggests that many times that number is present in various solid and liquid deposits of organics on and within the crust [Hayes et al. 2018].

Therefore, Titan's geologic history is poorly constrained and in particular there is a significant uncertainty as to what fraction of body's 4.5 billion year of existence is recorded in the surface. Observations relevant to its history include:

1. The low observed numbers of impact craters [Porco et al. 2005] yield an age of hundreds of millions of years, not billions [Lorenz et al. 2007; Wood et al. 2010; Neish and Lorenz 2012].

2. The rate of photodissociation of methane in Titan's atmosphere implies that the current gaseous inventory will be depleted in some tens of millions of years [Yung et al. 1984].

3. Titan's interior has at least partially differentiated, resulting in a rock-metal core, a high-pressure ice mantle of uncertain thickness, a liquid water ocean [less et al. 2010] perhaps with salts and ammonia [Mitri et al. 2014], and an ice crust 50 to 100 km thick. The core is either significantly hydrated [Castillo-Rogez and Lunine 2010], or there is a mixed rock-ice layer somewhere in the interior, see for example, Tobie et al. [2014].

4. A range of chemical and physical data from the atmosphere to the interior suggest that a significant event, or change in the way Titan evolves, occurred sometime between a few hundred million and a billion years ago [Hörst 2017].

The relatively youthful age of the surface, which may be the result of geologic activity or substantial burial in organic matter, or both, means that there is little if any geologic evidence of the first 3/4 of Titan's history. Two unanswered questions are what was the process(es) that eroded or covered older impact craters and other landforms? and, Did the obscuration of features older than a few hundred million years occur continuously over time, or in some singular event?

There is no evidence of the answer to the second question, but a theoretical model of the evolution of Titan's interior by Tobie et al. [2006] provides an intriguing scenario that implies Titan had a significant change in the working of its interior, crust, and atmosphere about 500 million years ago [Wood 2018]. In the Tobie et al. [2006] model, Titan has a thin and rigid clathrate crust (with methane as the dominant guest species) up until 500 million to one billion years ago. During that earlier epoch, several major heating events resulted in the release of large (compared to the present atmospheric inventory) amounts of methane from the clathrate hydrate into the surface-atmosphere system. Within the last 500–1000 million years the interior has cooled sufficiently to allow an ice I crust to form underneath the buoyant clathrate hydrate crust, with diapirism in the thickening ice I crust providing one or several episodes of further release of methane into the surface-atmosphere system.

… a theoretical model of the evolution of Titan's interior by Tobie et al. [2006] provides an intriguing scenario that implies Titan had a significant change in the working of its interior, crust, and atmosphere about 500 million years ago … .

Wood [2018] called the onset of the ice I subcrust the "Great Crustal Thickening Event" and noted that the mode of geologic processes would change dramatically as Titan transitioned from a body with a thin rigid conductive crust over the ocean to one with a thicker and rheologically heterogenous crust.

This is but one model for Titan's interior [Tobie et al. 2014]. What remains unresolved, however, is whether the methane hydrological cycle that we see today shaping so many aspects of Titan's surface is ancient or recent, episodic [Lunine et al. 1998] or continuous. While the idea is commonly held that the source of the methane to resupply the atmosphere is in crustal clathrate hydrate, such a crust going back to pre-Voyager days [Lewis 1971], how the resupply works is unclear. Simple forcing out of the methane from the clathrate by the photochemically produced ethane eventually fails because of the stoichiometry (two methane molecules making one ethane), although this replacement could eventually weigh down the crust and cause an overturn because clathrate with predominantly ethane is heavier than ice I [Choukroun and Sotin 2012]. This could cause interesting geologic consequences in the present era when the clathrate is nominally underlain by warm ice I.

Birch et al. [2017] have pointed to geologic evidence (notably the presence of evaporite deposits seen in Cassini/VIMS data), for example, Mackenzie et al. 2014, suggesting that the present epoch of lakes and seas of methane, ethane, and nitrogen might have been preceded by one with a widespread ocean of methane and other hydrocarbons. However, it is not possible to constrain the longevity of such an ocean, and the implications in terms of tidal dissipation of the orbital eccentricity during ocean shrinkage [Sagan and Dermott 1982; Sears 1995] have yet to be evaluated for the known Titan topography. Finally, it is possible that Titan has run out of atmospheric and surface methane multiple times in its history, leading to dramatic atmospheric

changes [Lorenz et al. 1997] and possibly epochs in the which the surface is worked by liquid nitrogen seas and rivers [Charnay et al. 2014].

If Titan's geologic and atmospheric nature have changed in a secular way over its history, it would join the other terrestrial planets—Venus, Earth, and Mars, in this regard. In each case, interior and surface-atmosphere changes over time have led to present-day characteristics that are likely to have been dramatically different from those in the past.

Open questions for Titan science

Some questions are taken directly from Hörst [2017], see also Nixon et al. [2018].

1. What are the abundances of the heavy noble gases in Titan's atmosphere and surface?
2. What is the ice phase that dominates the crust?
3. How intimately coupled are the various atmospheric layers?
4. How do you go from the very heavy ions and molecular species to haze particles?
5. What is the role of heterogeneous reactions in determining the partitioning of gas phase molecules and the composition of haze particles?
6. The controversy concerning the escape rate of CH_4 is linked to the analysis of INMS and UVIS measured CH_4 density profiles and the inference of the magnitude and radial direction of CH_4 diffusion fluxes.
7. What are the very heavy ions in the ionosphere, how do they form, and what are the implications for complexity of prebiotic chemistry?
8. How do the organic compounds produced in the atmosphere evolve on the surface?
9. What are the dynamics of Titan's surface-atmosphere interactions? Fluvial erosion?
10. How variable is the climate over 104 years and longer?
11. How old is Titan's current atmosphere and what happened on Titan 300–500 million years ago?
12. Is Titan's atmospheric methane episodic, and what are the implications on habitability?
13. What are the origin of Titan's methane and the fate of the photochemically produced ethane?

14. What is controlling Titan's H_2 profile and potential spatial variations?
15. What is the organic and inorganic composition of the surface?
16. What is the circulation in the lakes and seas and how is it affected by the atmosphere?
17. What is the composition of the dune particles and how are they produced?
18. How did the lakes and sea basins form?
19. Does cryovolcanism occur on Titan?
20. What is the salinity and composition of the deep ocean and is it in contact with rock beneath?
21. Is there life in the deep ocean, and some exotic life in hydrocarbon solvents?
22. What are the characteristics of the methane meteorology (of often clouds form, how typical is the half Titan year that we observed, etc.)?
23. What is the nature of the asymmetry in seasonal effects?
24. What is the nature and extent of the exchange between the surface/atmosphere and deep subsurface and ocean?
25. What is the depth and thickness of the subsurface ocean?
26. To what extent is the surface fluvially dissected?
27. What is the role of heterogeneous reactions in determining the partitioning of gas phase molecules and the composition of haze particles?
28. What are the sources of the stratospheric tilt?
29. What is the origin of Xanadu as a distinct geologic province?
30. What are the origin, evolution, and ultimate fate of Titan's atmosphere?
31. What is the impact of the influx of water and water vapor from Enceladus to Titan's upper atmosphere?

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AACS	Attitude and Articulation Control System
AO	Announcement of Opportunity
AU	astronomical unit
CIRS	Composite Infrared Spectrometer
CSM	Cassini Solstice Mission
DISR	Descent Imager/Spectral Radiometer
DWE	Doppler Wind Experiment
DWG	Discipline Working Group
EUV	extreme ultraviolet
FUV	far ultraviolet
GCMS	Gas Chromatograph Mass Spectrometer
HASI	Huygens Atmospheric Structure Instrument
INMS	Ion and Neutral Mass Spectrometer
IR	infrared
ISS	Imaging Science Subsystem
PWA	Permittivity, Wave and Altimetry
RADAR	Titan Radar Mapper
RSS	Radio Science Subsystem
SAR	Synthetic Aperture Radar
TAMWG	Titan Atmospheric Modeling Working Group
TM	Traceability Matrix
TOST	Titan Observation Science Team
UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph
VIMS	Visual and Infrared Imaging Spectrometer

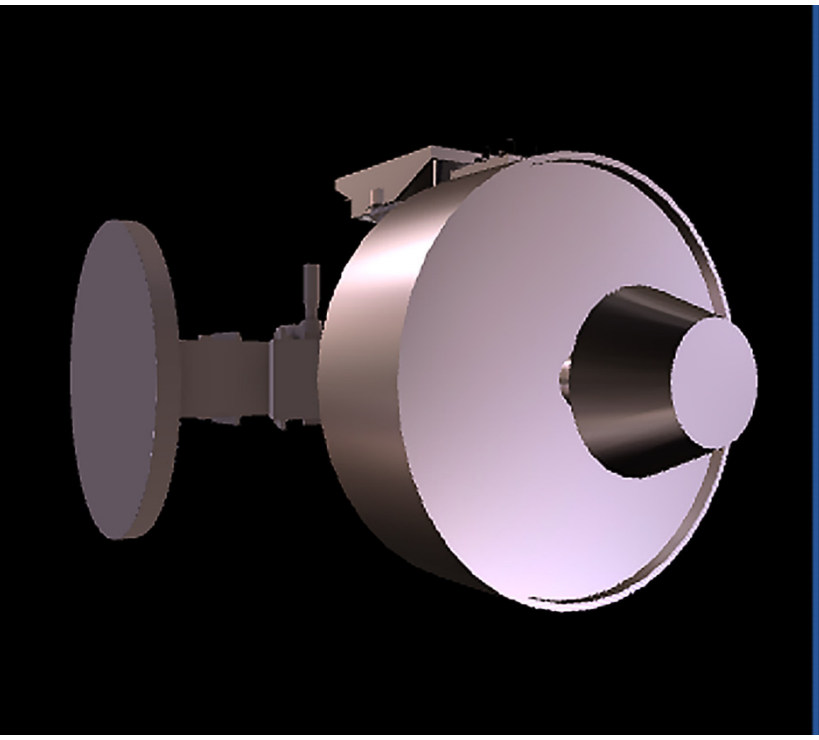
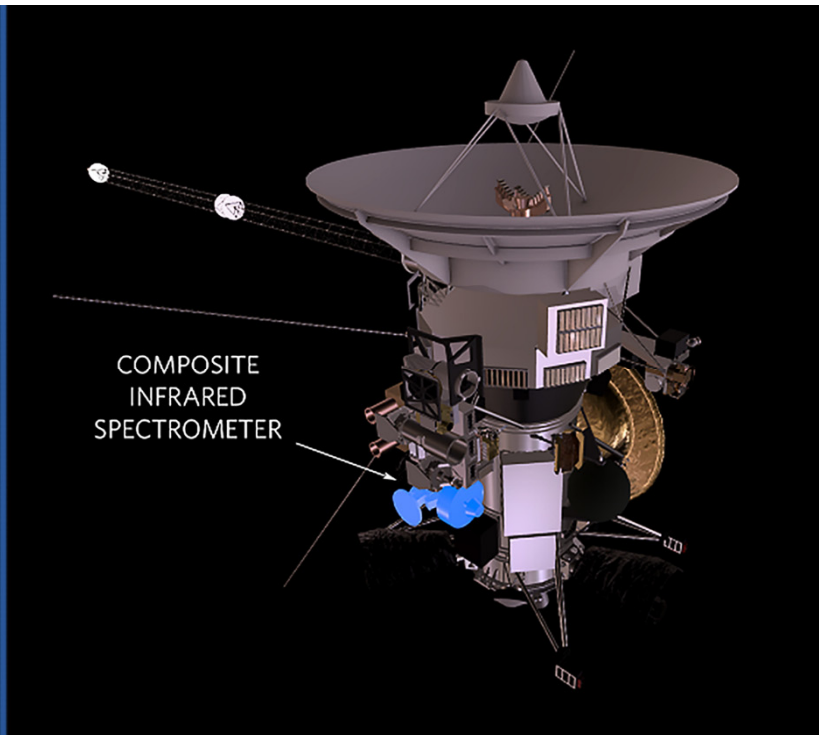
INSTRUMENT SCIENCE RESULTS





Composite Infrared Spectrometer

The Composite Infrared Spectrometer (CIRS) was an infrared Fourier Transform Spectrometer that measured infrared radiation from 7-1,000 μm that was emitted by Saturn, its rings and its moons. The **science objectives** of CIRS were to measure infrared emissions from atmospheres, rings and surfaces in the Saturn system to determine their composition, temperatures and thermal properties; to map the atmospheres of Saturn and Titan in three dimensions to determine temperature and pressure profiles with altitude, gas composition, and the distribution of aerosols and clouds. Molecular composition is determined in the infrared by the emitted or absorbed energy at specific wavelengths. The infrared spectrum identifies the gases or solids present and their relative amounts.

CIRS consisted of two interferometers that operated in the far-infrared and mid-infrared. They shared a common telescope and scan mechanism. CIRS included three sets of infrared detectors (Focal planes 1, 3, and 4) and a passive radiative cooler plate.

EXECUTIVE SUMMARY

Key Science Results

Saturn

- Characterization of the great northern storm in the troposphere and stratosphere, which erupted unexpectedly in northern spring. For the first time, a detailed picture was obtained of the major disturbance in the stratosphere (warm, anticyclonic vortices, enhancement of trace hydrocarbons) that persisted for nearly three years.
- Determination for the first time of the vertical structure of Saturn's equatorial oscillation; measurement of the descending pattern of temperatures and zonal winds with time and its disruption by the great northern storm.
- Improvement in the abundance determination of methane, and as a result, of carbon.
- Characterization of the temperature and zonal wind structure of polar vortices at high spatial resolution.
- Determination of the vertical and latitude distribution and seasonal variation of stratospheric hydrocarbons.

Rings

- Slowly rotating ring particles discovered in Saturn’s main rings. These slowly rotating particles provided the first direct evidence for anisotropic thermal emission of rings versus a broad range of phase and emission angles at geometries not visible from Earth.
- First complete far-infrared (IR) roll-off measured in main ring temperature. Cassini CIRS obtained the first continuous submillimeter spectrum of Saturn’s main rings over a broad range of wavenumbers, from 25 microns to 0.5 millimeters. Until these observations, the location and shape of the spectral roll-off was not well determined. The roll-off in emissivity occurs around 200 microns and contains key information on material properties of the particles.
- A-ring particles with dense cores inferred from incomplete cooling down at solar equinox. At the solar equinox in August 2009, the CIRS onboard Cassini showed the lowest Saturn's ring temperatures ever observed. The observed equinox temperatures of Saturn's A-ring are much higher than model predictions as long as only the flux from Saturn is taken into account. This means that A-ring particles did not completely cool down at the equinox. The detailed seasonal model showed that A-ring particles have dense cores beneath the fluffy regolith mantles.

- Vertical thermal gradient detected in B-ring. A vertical thermal gradient was detected in the B-ring, which yields constraints on the diffusivity of this porous medium, and by extension on its thickness (which is unique for the thick B-ring).
- First cooling profile of main rings from near solstice through equinox CIRS observed the main rings of Saturn cool down from the orbit insertion of the spacecraft in 2004 until Saturn's equinox in 2009, and through northern summer solstice in 2017. The solar elevation varied from 26 degrees to 0 degrees with respect to the rings. The data showed that the A-ring, B-ring, and C-ring temperatures varied as much as 29–38, 22–34 and 18–23 K, respectively. Interestingly the unlit sides of the rings showed important temperature variations as well.
- First far-IR radial profile in optical depth CIRS obtained the first radial profile in optical depth in far-IR, filling in gap between near-IR and radio observations. CIRS observed a ring occultation of the far-IR source, Eta Carinae, to derive the ring optical depth.

Titan

- Discovery of a tilted stratospheric rotation [Achterberg et al. 2008].
- Observation of seasonal change in the 220 cm^{-1} absorber [Jennings et al. 2012a, 2012b, 2015].
- Observation of a late onset to the reversal of the seasonal gas distribution [Teanby et al. 2012b].
- Measurement of the vertical profile of water [Cottini et al. 2012a].
- Detection of the important $^{13}CH_3D$ [Bézard et al. 2007] and C_2HD isotopes [Coustenis et al. 2008].
- Detection of propene in the stratosphere [Nixon et al. 2013a].
- Characterization of hydrogen cyanide (HCN) ice above the south pole [de Kok et al. 2014].
- Hypothesis of grain surface chemistry to explain far-infrared absorption [Anderson et al.2016].
- Measurement of aerosol spectral opacity [Vinatier et al. 2012].
- Discovery of benzene ice [Vinatier et al. 2018].

Icy satellites

- Endogenic thermal emission from the Enceladus tiger stripes at temperatures up to 190 K, with large spatial variations on scales from 10 s of kilometers to 10 s of meters.

- Endogenic heat flow from Enceladus' south pole is larger than can be explained by simple steady-state tidal heating.
- Large spatial variations in thermal inertia on Mimas, Tethys, and Dione due to electron bombardment.
- High daytime temperature of Iapetus dark terrain, implying that thermal segregation is a major contributor to the extreme albedo dichotomy on Iapetus.
- Determining low thermal inertia throughout the Saturnian system.
- Ruling out significant activity on Dione and Tethys.
- Detecting surface temperatures of Ring Satellites.

Jupiter

- First characterization of the detailed vertical structure of Jupiter's equatorial oscillation and the discovery of an intense jet in the stratosphere centered at 4 mbar.
- Detection of the puzzling distribution of HCN and CO_2 in Jupiter's stratosphere, originally thought to be products of the SL9 impact in 1994.
- Mapping of the northern infrared auroral hot spot, and the determination of the lower limit to its penetration (4 mbar) and the composition of acetylene and ethane within the spot.
- First detection of diacetylene and the methyl radical in the northern and southern auroral hotspots.
- Discovery of anticorrelated abundance trends with latitude for acetylene and ethane.

CIRS Summary

The CIRS is an infrared Fourier Transform Spectrometer (FTS) on the Cassini orbiter that measures thermal radiation over more than two decades in wavenumber (ν) from 10 to 1400 cm^{-1} (1 mm to 7 μm). CIRS is described in detail in Kunde et al. [1996]; Flasar et al. [2004]; and Jennings et al. [2017]. Further information on CIRS and its operation throughout the mission is given in the Cassini Final Mission Report Volume 3 Instrument Performance Assessment, and the Cassini Final Mission Report Volume 5 Mission Operations System Performance Assessment.

The CIRS instrument consists of two interferometers, sharing a common telescope and scan mechanism. They operate in the far-infrared (10–600 cm^{-1}) and mid-infrared (600–1400 cm^{-1}) with a commandable, apodized spectral resolution as high as 0.5 cm^{-1}. The far-IR interferometer is a polarization interferometer, with a single focal plane consisting of two thermopile detectors with a 3.9 microradians (mrad) circular field of view (FOV), labeled FP1. The mid-IR interferometer is a

conventional Michelson interferometer with two linear focal plane arrays (FP3, FP4), each containing 10 HgCdTe detectors, with 0.273 mrad FOV per pixel. The center of the FP3 and FP4 arrays is aligned with the boresights of the other optical remote sensing instruments—Imaging Science Subsystem (ISS), wide-angle camera (WAC) and narrow-angle camera (NAC), Visual and Infrared Mapping Spectrometer (VIMS), and Ultraviolet Imaging Spectrograph (UVIS). The FP1 boresight is offset by 4 mrad [Flasar et al. 2004a; Jennings et al. 2017].

CIRS instrument operation allows data to be acquired at spectral resolutions between 0.5 cm^{-1} and 15 cm^{-1} by varying the scan length of the moving mirror. The low-resolution data have the highest signal to noise ratio (SNR) and the shortest scan length. The calibration for FP1 utilizes deep space spectra while FP3 and FP4 have, in addition, a shuttered target source at 170 K.

KEY OBJECTIVES FOR CIRS

Key Science Objectives for Saturn

1. **Formation, evolution, and internal structure:** Helium, carbon, nitrogen, and sulfur abundances in Saturn's atmosphere.

2. **Atmospheric gas composition:** Disequilibrium tropospheric compounds (PH_3, CO…), ortho-para H_2 conversion, disequilibrium stratospheric compounds (hydrocarbons), external sources—oxygen compounds.

3. **Clouds and aerosols.**

4. **Atmospheric structure and circulation:** Temperatures, zonal winds, meridional circulations, waves, eddies, compact vortices.

5. **Temporal behavior:** Seasonal, internal dynamical (northern Saturn storm, equatorial oscillation, neither fully anticipated).

Key Science Objectives for the Rings

CIRS has provided major advances over previous spacecraft infrared observations of Saturn's rings in three respects: 1) extension of the spectral range to submillimeter wavelengths; 2) higher spatial resolution on the rings as result of closer proximity during the Cassini tour, as well as of a linear detector array with much finer spatial resolution in the mid-infrared; and 3) temporal extent of the mission, which provided greatly improved sampling in illumination and viewing geometries. With its enhanced capabilities, CIRS addressed many of the rings science objectives of the Cassini mission, particularly those pertaining to radial thermal structure, ring optical depth in the mid-IR, ring particle thermal properties and rotation states, ring-scale

CIRS has provided major advances over previous spacecraft infrared observations of Saturn's rings.

properties including vertical structure, and thermal roll-off in the submillimeter. The key CIRS ring science objectives are listed below and each one is discussed in the section entitled Science Results.

1. **Ring Thermal Structure:** Determine Saturn's ring thermal structure and how the ring temperatures vary with ring optical depth, solar elevation, phase angle, azimuth angle and distance to the planet. What is the source of the temperature variations? Determine the azimuthal asymmetries in the rings, apart from the diurnal cooling/heating cycle. What is their origin?

2. **Ring optical depth at mid-IR wavelengths:** Determine the variation of ring optical depths at mid-IR wavelengths and compare to ultraviolet (UV) and near-IR optical depths.

3. **Particle-scale Properties:** Determine key particle properties such as Bond albedo, thermal inertia and particle spin. On what factors do they depend? Determine the distribution of particle spins of the ring particles. What does this distribution tell us about local dynamics? Compare the diurnal and seasonal thermal inertia and any differences between them.

4. **Ring-scale Properties:** Determine the volume filling factors for the rings. Search for an opposition surge in the thermal infrared. Is it driven by mutual shadowing alone? Determine vertical temperature gradient between lit and unlit sides of the rings. What does this tell us about the ring vertical structure and dynamics? Determine the ring thermal inertia and compare it to the particle thermal inertia. Does it change with seasons?

5. **Regolith Properties deduced from CIRS Emissivity Roll-off:** Determine the wavelength of the roll-off in ring emissivity. What do we learn from this roll-off about particle structure and composition?

Key Science Objectives for Titan

1. **Formation and evolution:** Volatiles—methane.

2. **Atmospheric composition:** Organics (hydrocarbons and nitriles), oxygen compounds, new species.

3. **Aerosols and condensates.**

4. **Atmospheric structure and circulation:** Temperatures, zonal winds, meridional transports, eddies and waves.

5. **Seasonal behavior:** Evolution of polar vortices—gas composition, condensates, temperatures and winds.

Key Science Objectives for the Icy Satellites

1. **Enceladus' Activity:** Determine Enceladus' heat flow, to help constrain its activity mechanism. Determine whether Enceladus' activity varies with seasonal change.

2. **Activity on other Satellites:** Search for activity on Dione and Tethys, and search for a ring and debris disk around Rhea.

3. **Comparative study of Saturn's icy satellites:** Compare the surface properties of Saturn's mid-sized icy satellites. Determine the uniqueness of Mimas' thermally anomalous region. Observe Saturn's small satellites as opportunities arise (including but not limited to Epimethus, Janus, Methone and Promethus).

4. **Better understand unusual surfaces:** Constrain Hyperion's unusual surface's thermophysical properties, constrain Iapetus' albedo dichotomy.

CIRS Science Assessment

Saturn

Table CIRS-1 contains an assessment of CIRS Saturn science based on the objectives in the original Announcement of Opportunity (AO) and the Cassini Traceability Matrix (TM) developed for the Equinox and Solstice missions. Each CIRS Saturn science objective is paired with an AO and TM science objective. The key AO and TM objectives addressed by CIRS are:

- **Saturn Temperature, Clouds, Composition (S_AO1):** Determine temperature field, cloud properties, and composition of the atmosphere of Saturn.
- **Saturn Winds and Weather (S_AO2):** Measure the global wind field, including wave and eddy components; observe synoptic cloud features and processes.
- **Saturn Interior Structure and Rotation (S_AO3):** Infer the internal structure and rotation of the deep atmosphere.
- **Saturn Formation and Evolution (S_AO5):** Provide observational constraints (gas composition, isotope ratios, heat flux...) on scenarios for the formation and the evolution of Saturn.
- **Seasonal Variations (SC1a):** Observe seasonal variations in temperature, clouds, and composition in three spatial dimensions.
- **Saturn's Winds (SC1b):** Observe seasonal changes in the winds at all accessible altitudes coupled with simultaneous observations of clouds, temperatures, composition, and lightning.

- **Saturn's Rotation Rate (SN1a):** Determine Saturn's rotation rate and internal structure despite the planet's unexpected high degree of axisymmetry.
- **2010–2011 Great Storm (SN1b):** Observe the aftermath of the 2010–2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon.
- **Saturn Trace Gases (SN1c):** Measure the spatial and temporal variability of trace gases and isotopes.

Table CIRS-1. CIRS Saturn Science Assessment: AO and TM Objectives are paired with CIRS Science objectives.

Fully/Mostly Accomplished: Partially Accomplished: Not Accomplished:

CIRS Saturn Science Objectives	AO and TM Science Objectives	CIRS Saturn Science Assessment	Comments if yellow (partially fulfilled)
Formation, evolution, internal structure			
Helium	S_AO1, S_AO5		Analysis in progress.
Carbon	S_AO1, S_AO5		
Nitrogen	S_AO1, S_AO5		
Carbon monoxide	S_AO1, S_AO5		
Internal rotation	S_AO3, SN1a		
Atmospheric gas composition			
Disequilibrium tropospheric compounds: PH_3, CO, halides	S_AO1,SN1c		
Ortho-para H_2	S_AO1,SC1b,SN1c		
Stratospheric hydrocarbons	S_AO1,SN1c		
External sources—oxygen compounds	S_AO1		Analysis in progress.
Atmospheric structure and circulation			
Temperatures & zonal winds	S_AO1, S_AO2, SC1b		
Meridional circulations	S_AO1,SC1b,SN1c		
Waves & eddies	S_AO2,SN1c		Larger scale waves done: N. hexagon, equatorial waves.
Compact vortices	S_AO2		Polar vortices.
Temporal behavior			
Seasonal	SC1a		
Northern storm	SN1b		Persisted to 2013 in stratosphere.
Equatorial oscillation	SC1a,SN1b		

Rings

Table CIRS-2 contains an assessment of CIRS ring science based on the objectives in the original AO and the Cassini TM developed for the Equinox and Solstice missions. Each CIRS ring science objective is paired with an AO and TM science objective. The key AO and TM objectives addressed by CIRS are:

- **Ring Structure and Dynamics (R_AO1):** Study configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.

Table CIRS-2. CIRS Ring Science Assessment: AO and TM Objectives are paired with CIRS Science objectives.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

CIRS Ring Science Objectives	AO and TM Science Objectives	CIRS Ring Science Assessment	Comments if yellow (partially fulfilled)
Ring Thermal Structure			
Radius and Ring Optical Depth	R_AO1, RC1a		
Solar elevation	R_AO1, RC1a		
Phase angle	R_AO1, RC1a		
Ring Equinox temperatures	R_AO1, RC1a		
Azimuthal dependence	R_AO1, RC1a		
Ring Optical Depth at mid-IR Wavelengths	R_AO1, RC1a		
Particle-scale Properties			
Bolometric Bond Albedo	R_AO1, RC1a		
Particle Spin	R_AO1, RC1a		
Diurnal Thermal Inertia	R_AO1, RC1a		
Seasonal Thermal Inertia and Particle Size	R_AO1, RC1a		
Average Thermal Emissivity	R_AO1, RC1a		
Ring-scale Properties			
Volume Filling Factors of A-ring and B-ring	R_AO1, RC1a		
Opposition Surge	R_AO1, RC1a		
Energy budget and heat transfer in B-ring	R_AO1, RC1a		
Thermal Properties, Thickness and Surface Mass Density of B-ring	R_AO1, RC1a		
Self-gravity wakes in the A-ring	R_AO1, RC1a		
Regolith Properties Deduced from CIRS Emissivity Roll-off			
Thermal Emissivity Roll-off at Submillimeter wavelengths	R_AO1, RC1a		
F-ring Clumps	RC2a		

- **Changing Rings (RC1a):** Determine the production mechanisms of spokes, and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near Solstice.
- **Ring Temporal Variability (RC1b):** Understand the time-variability of ring phenomena on decadal timescales (Encke gap, D-ring, ring edges, etc.) by substantially increasing the time baseline of observations.

Titan

Table CIRS-3 contains an assessment of CIRS Titan science based on the objectives in the original AO and the Cassini TM developed for the Equinox and Solstice missions. Each CIRS Titan science objective is paired with an AO and TM science objective. The key AO and TM objectives addressed by CIRS are:

Titan AO objectives

- **Titan Atmospheric Formation and Evolution (T_AO1):** Determine abundances of atmospheric constituents (including any noble gases), establish isotope ratios for abundant elements, constrain scenarios of formation and evolution of Titan and its atmosphere.
- **Titan Atmospheric Composition and Distribution (T_AO2):** Observe vertical and horizontal distributions of trace gases, search for more complex organic molecules, investigate energy sources for atmospheric chemistry, model the photochemistry of the stratosphere, study formation and composition of aerosols.
- **Titan Meteorology (T_AO3):** Measure winds and global temperatures; investigate cloud physics, general circulation, and seasonal effects in Titan's atmosphere; search for lightning discharges.
- **Titan Surface Characteristics and Internal Structure (T_AO4):** Determine the physical state, topography, and composition of the surface; infer the internal structure of the satellite.

Titan Cassini Solstice Mission (CSM) traceability matrix objectives

- **Titan’s Great Seas (TC1a):** Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport.
- **Titan’s Global Seasons (TC1b):** Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.

- **Titan's Surface (TN1a):** Determine the types, composition, distribution, and ages, of surface units and materials, most notably lakes (i.e., filled versus dry and depth; liquid versus solid and composition; polar versus other latitudes and lake basin origin).
- **Titan Atmospheric Composition (TN1c):** Measure aerosol and heavy molecule layers and properties.
- **Titan Atmospheric Structure (TN2a):** Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission).
- **Titan Meteorology (TN2c):** Determine the surface temperature distribution, cloud distribution, and tropospheric winds.

Table CIRS-3. CIRS Titan Science Assessment: AO and TM Objectives are paired with CIRS Science objectives.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

CIRS Titan Science Objectives	AO and TM Science Objectives	CIRS Titan Science Assessment	Comments if yellow (partially fulfilled)
Surface Temperature	T_AO4, TN2c		
Latitudinal variation	T_AO4, TN2c		
Temporal changes	T_AO4, TN2c		
Variation with topography and terrain	T_AO4, TN1a		Insufficient data and S/N, footprint too large.
Atmospheric Thermal and Dynamical State	T_AO3, TC1b		
Global temperature mapping	T_AO3, TC1b		
Winds and jets	T_AO3, TC1b		
Rotation axis	T_AO3, TC1b		
Global Energy Balance	T_AO3, TC1b		
Seasonal changes	T_AO3, TC1b		
Gas Composition and Chemistry	T_AO2, TN1c		
Global gas distribution near equinox	T_AO2, TN1c		
Seasonal changes	T_AO2, TN1c		
Search for new gas species	T_AO2, TC1a		
Isotopic ratios	T_AO1, N/A		Still under study to reduce errors, improve agreement between measurements.
Hazes and Condensates	T_AO2/3, TN1c		Hazes and condensates mapped, but ongoing work to elucidate composition.
Haze characteristics	T_AO2, TN1c		
Condensates: location and identification	T_AO3, TN1c		

The majority of the science goals for Titan laid down at the start of the mission (Key Objectives for CIRS) have been achieved successfully, and much progress has also been made on the revised goals from the Cassini Solstice Mission. Table CIRS-3 shows a final assessment for the surface temperatures, only the issue of correlation with topography remains uncertain, and is unlikely to be gleaned from the CIRS dataset given the large FP1 detector footprint. All atmospheric temperature science goals have been achieved, although a discrepancy between CIRS and Huygens stratopause levels may require further investigation, as described later. Gas abundance measurements have also been largely met, although isotopic ratios, which require the highest accuracy, have proved susceptible to systematic errors. More analysis is needed of the dataset in this area to resolve remaining differences between published values. Finally, much new information has been returned about hazes and condensates, although work is still ongoing to determine composition, for example with regard to the notorious 220 cm^{-1} emission feature.

Icy Satellites

The key TM questions of Icy Satellite science that CIRS has helped address are:

Level 1

- **Changes on Enceladus (IC1a):** Determine whether Enceladus exhibits any seasonal changes. Other temporal changes (e.g., mean anomaly) are also considered.
- **Enceladus' interior (IN1a):** Determine the surface temperature in active regions and constrain Enceladus' heat flow, to better constrain models of its activity.
- **Compare Saturn's mid-sized satellites (IN1b):** Compare the surface characteristics of Saturn's mid-sized satellites, including the thermally anomalous Pac-Man regions.
- **Activity on Dione (IN1c):** Determine whether Dione is currently active, or has been so on recent geological timescales.

Level 2

- **Rhea's Ring (IN2a):** Determine if there is a ring (or debris disk) around Rhea, and if so, characterize the spatial and particle size distribution.
- **Tethys and the E-ring (IN2b):** Determine whether Tethys is geologically active, and thus could be contributing to the E-ring.
- **Characterize the surfaces of Saturn's small satellites (IN2d):** Derive the surface thermophysical properties of Saturn's small satellites, including (but not limited to) Epimethys, Janus, Methone, and Promethus.

Table CIRS-4. CIRS Ice Satellite Science Assessment: AO and TM Objectives are paired with CIRS Science objectives.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

CIRS Icy Satellite Science Objectives	AO and TM Science Objectives	CIRS Ring Science Assessment	Comments only if yellow or red
Enceladus			
Enceladus' Surface Temperatures	IC1a, IN1a		
Constrain Enceladus' heat flow	IC1a, IN1a		
Activity On Other Satellites			
Dione	IN1c		
Tethys	IN2b		No evidence for activity was found when looking at temperature maps of Tethys using CIRS data for in Howett et al. [2012].
Ring around Rhea	IN2a		No thermal inertia signature connected with ring infall were observed on Rhea in Howett et al. [2014], but any signature (including the 'blue dots') are likely to be too small to be resolved in this work.
Comparative Study of Saturn's Icy Satellites			
Search for thermally anomalous regions on Tethys	IN1b		
Search for thermally anomalous regions on Dione	IN1b		
Search for thermally anomalous regions on Rhea	IN1b		
Characterizing the properties of small satellites	IN2d		Work is in progress.
Unusual Surfaces			
Constrain Hyperion's thermophysical surface properties	IN2d		CIRS work included in paper by Howard et al. [2012].
Constrain Iapetus' albedo	IN1b		

CIRS Saturn System Science Results

Saturn

Formation, evolution, and internal structure

Helium, carbon, nitrogen, halides

In principle, the helium abundance can be retrieved from thermal infrared spectra, but placing tight bounds on helium has proved elusive. Three approaches have received the most attention so far.

1. Using far-infrared spectra alone. Here the helium abundance is derived from its effect on the collisionally induced absorption S(0) and S(1) lines of H_2 at 320 cm^{-1} and 600 cm^{-1}, respectively, and the translational continuum at 50–200 cm^{-1}. The difficulty arises in that the para-fraction of H_2 (f_p) deviates from its equilibrium value, and it must be retrieved along temperature and helium mole fraction [Achterberg et al. 2014b]. These variables are not independent, and as a result the problem becomes poorly constrained. One can only place a rough upper limit to [He]/[H_2] of 0.15. The smallest deviations from equilibrium f_p occur when the ratio is ~0.05.

2. Using far-infrared spectra with temperatures retrieved from radio-occultation soundings. With helium uniformly distributed the retrieved refractivity profiles translate into profiles of temperature divided by the molecular mass and of pressure times the refractivity per molecule divided by the molecular mass. In this case one greatly increases the precision of the helium abundance determination. One proceeds as before, except now the temperature-pressure profile is constrained, and determines f_p and the helium abundance. One iterates until the synthetic spectrum, computed for a particular T(P), f_p, and [He]/[H_2], matches the observed spectrum. With this technique Achterberg et al. [2016] obtained ratios [He]/[H_2] ~0.065–0.085. However, there is some evidence that systematic errors are present, particularly at mid and high latitudes, where the shape of the best-fit synthetic spectrum can exhibit large deviations from the observed one. The source of this discrepancy is under study.

3. Koskinen and Guerlet [2018] have combined Cassini stellar occultation soundings with the UVIS with CIRS mid-infrared limb spectra. The UVIS soundings provide vertical profiles the H_2 density versus radius down to the base of the thermosphere near 0.03 μbar. The CIRS observations retrieve temperature versus pressure up to the 1–3 μbar level. Hence, there is a gap of 30 or more in barometric pressure over the region that presumably contains the homopause. The pressure scale height decreases with molecular mass, and the trick here is to find a solution that matches the CIRS T-P condition at the bottom of the gap with the correct density-altitude condition from the UVIS sounding in the thermosphere. Koskinen and Guerlet [2018] argue that an isothermal profile across the gap provides the most viable solution, which yields an estimate of [He]/[H_2] = 0.124.

Saturn is enriched in carbon, relative to the Sun. Flasar et al. [2005b] reported the mole fraction of CH_4 as 4.5 ±0.9 × 10^{-3}. This was later refined by Fletcher et al. [2009b], who averaged over a larger number of CIRS observations, as 4.7 ±0.2 × 10^{-3}, about 10 times the solar value of C/H—see also the review by Fouchet et al. [2009].

Teanby et al. [2006] analyzed CIRS far-infrared spectra (10–600 cm^{-1}) to improve upper limits on hydrogen halides. Their derived 3 σ upper limits indicated that HF, HCl, and HBr were sub-solar at 500 mbar, similar to what was found for Jupiter (see the section entitled Halides). Because the

line strengths of HI are so weak and its solar abundance so small, they were not able to constrain its abundance to sub-solar values.

ISOTOPES

Fletcher et al. [2009] derived isotopic ratios in methane by modeling the emissions of $^{12}CH_4$, $^{13}CH_4$ and $^{12}CH_3D$. The derived D/H ratio in methane of (1.6 ±0.2) × 10^{-5} appears to be smaller than on Jupiter, in contrast with expectations that D-enriched ices would form a progressively larger proportional of the giant planets, moving outward from Jupiter to Neptune. The reason for this is still unclear. In contrast, the carbon isotopic ratio $^{12}C/^{13}C$ = 91.8 (+8.4/−7.8, is consistent with both the terrestrial ratio and Jovian ratio, suggesting that carbon was accreted from a shared reservoir for all of the planets.

D/H from HD/H_2. Pierel et al. [2017] made a careful modeling of the far-IR HD rotational lines on CIRS FP1. The modeling effort uncovered substantial uncertainties in current knowledge of the HD line parameters, especially the line widths at low temperatures, which contributed to substantial error bars dominated by systematic uncertainties rather than spectral noise. The bulk D/H was found to be (2.95 ±0.55) × 10^{-5} on Jupiter and somewhat lower (2.10 ±0.13) × 10^{-5} on Saturn, indicating potential interior differences. The results were compared to previous estimates from ISO and Herschel data, as well as to inferences about bulk D/H extrapolated from methane measurements. Overall, Saturn shows a trend toward slightly lower D/H than Jupiter, in contrast to expectations of a higher value, due to a larger ice/gas ratio at formation. However, the errors and spread in values is large and the difference remains statistically marginal. Further work is needed, first on better laboratory estimates of the HD and H_2 quadrapole line strengths and widths at low temperatures, followed by re-retrievals of the spectral data.

INTERNAL ROTATION

Saturn's internal rotation rate remains a subject of interest and controversy.

Saturn's internal rotation rate remains a subject of interest and controversy. Read et al. [2009] proposed a novel way to estimate the internal rotation period based on the potential vorticity, observed at the cloud tops. The authors assumed that the zonal flow was marginally stable with respect to the nonlinear stability as prescribed in Arnol'd's 2nd stability theorem. The theorem is couched in terms of the zonal phase velocity of the longest, fastest, and mostly deeply rooted Rossby waves, which presumably are closest to the internal rotation. Using the tracked cloud-top winds from Cassini imaging and temperatures retrieved from CIRS spectra, the authors computed the potential vorticity and used the stability criterion to infer an internal rotation period of 10 h 34 min 13 ±20 s for the interior.

Atmospheric gas composition

DISEQUILIBRIUM TROPOSPHERIC COMPOUNDS

Phosphine (PH_3) is a disequilibrium compound in the upper troposphere. It is generally believed to be a product of rapid vertical mixing from deep atmospheric levels. PH_3 is transported upwards in a time much shorter than the chemical depletion time in the upper troposphere, so the observed abundances represent the quenched equilibrium conditions deeper down. Hence, meridional variations in the observed abundance are diagnostic of the vertical motion. CIRS observations indicate an enhancement of PH_3 in the equatorial region [Fletcher et al. 2007a, 2009a, 2018], which is consistent with rapid vertical upwelling and the cold temperatures observed there. At 23° N (planetographic), PH_3 is depleted, suggesting subsidence, perhaps indicative of a Hadley-type cell. Lower values of PH_3 have also been inferred in the upper troposphere in the cores of the polar vortices, where there is subsidence [Fletcher et al. 2008, 2010] found a hemispheric asymmetry in the phosphine distribution over 2004–2009, with the southern hemisphere (in summer) on average having higher abundances.

Hurley et al. [2012b] investigated whether thermal disassociation associated with lightning and shock waves generated by thunder in Saturn's water clouds could generate an enhancement of tropospheric acetylene (C_2H_2) that would be transported upward to the tropopause region, and thereby serve as a chemical fingerprint of thunderstorm activity. Analyzing CIRS mid-infrared spectra, they found no systematic enhancement around regions in which there are known occurrences of normally sized (2000 km) thunderstorms, beyond what would be expected from photolysis under ambient conditions.

ORTHO-PARA H_2

CIRS far-infrared spectra can probe the para-fraction of H_2 (f_p) in the upper troposphere (100–400 mbar). Because the equilibration time between the ortho and para states are thought to be long compared to seasonal time scales, the distribution of f_p should provide an indication of vertical motion from deeper levels of the atmosphere. In the equilibrated state, f_p increases with decreasing temperature. CIRS observations show that f_p remains depressed near the equator, relative to the average over latitude in the upper troposphere, indicating upwelling, throughout the Cassini tour [Fletcher et al. 2007a, 2010, 2016, 2018]. The meridional structure at mid and high latitudes is more difficult to interpret. An exception is the depression of f_p at 20°–50° N, resulting from upward transport after the outbreak of the Saturn storm (see the section entitled Temporal behavior).

DISEQUILIBRIUM STRATOSPHERIC COMPOUNDS (HYDROCARBONS)

The review chapter by Fletcher et al. [2018] provides a good summary of CIRS observations of stratospheric hydrocarbons. Observations in nadir-viewing [Howett et al. 2007; Hesman et al. 2009; Sinclair et al. 2013; Fletcher et al. 2015] and limb-viewing [Guerlet et al. 2009; Sylvestre et al. 2015]

geometries have provided information on meridional and vertical structure of C_2H_2 and C_2H_6. Quantitative differences exist among the spatial distributions and temporal behaviors identified by different authors, but some general common trends can be identified: (i) C_2H_2 decreases from equator to pole while C_2H_6 is largely uniform with latitude; (ii) There are regional enhancements of both species at the highest latitudes within polar vortices, possibly associated with auroral chemistry and entrainment; (iii) There are general spring hemisphere enhancements and autumn hemisphere depletions in the millibar region, suggestive of stratospheric transport from the southern to the northern hemisphere that may be related to the local meridional cells associated with the equatorial oscillation (see section the entitled Equatorial Oscillation).

CIRS limb observations [Guerlet et al. 2009, 2010, 2015; Sylvestre et al. 2015] have also provided information on the spatial distributions of C_3H_8, CH_3C_2H, C_4H_2, and C_6H_6. Like those of C_2H_2 and C_2H_6, these bear little resemblance to photochemical model predictions in the absence of dynamical transport.

External sources—oxygen compounds

Prior analysis of the rotational lines of H_2O and CO has been based on disk average measurements. While CIRS observations spatially resolve Saturn, the rotational lines are weak at its spectral resolution, the relatively cold temperatures require large spectral averages for analysis. Little on this has been published as yet. Using spectral averages of nadir and limb observations, Abbas et al. [2013] analyzed the Q-branch of the ν_2 band of CO_2 in the 667 cm^{-1} region, and they did not find any discernable meridional trends, obtaining a mixing ratio ~5 × 10^{10} near ~1 mbar.

Clouds and aerosols

CIRS thermal-infrared spectra have placed fewer constraints on clouds and aerosols on Saturn that on Jupiter (see the section entitled Jupiter - Clouds and Aerosols). In part this can be attributed to the lower temperatures and signal-to-noise ratios of spectral features. Constraints from observations near-infrared, visible, and ultraviolet wavelengths have been more definitive. And unlike Titan, limb sounding in the far-infrared was not feasible at Saturn, because of the greater distance between the spacecraft and atmosphere.

There have, however been more indirect indications of the haze distribution from retrieved CIRS temperatures. One of the interesting features of Saturn's vertical temperature profile is the knee, which is an undulation that occurs over the range ~150–300 mbar and effectively broadens the tropopause region. This was originally seen in temperatures retrieved from Voyager IRIS spectra, obtained in early northern spring, mainly in the southern hemisphere. Retrieving temperatures from Cassini CIRS spectra obtained in early northern winter, Fletcher et al. [2007b] detected the temperature knee and mapped its variation with latitude. They found it to be larger in the summer hemisphere than in the winter, smaller and higher at the equator, deeper and larger in the equatorial belts, and small at the poles. They proposed solar heating of tropospheric haze as a possible mechanism for the temperature knee, with larger aerosols in the summer hemisphere.

Atmospheric structure and circulation

GLOBAL STRUCTURE

Flasar et al. [2005a] reported the first observations of Saturn by CIRS. From nadir-viewing observations, they found little variation with altitude of the zonal winds in the upper troposphere and stratosphere, except near the equator, where they found a general decay with altitude between 500 mbar and 2 mbar. Later limb and more detailed nadir observations would reveal the oscillatory undulation of the zonal winds in the stratosphere associated with the equatorial oscillation (see the section entitled Equatorial Oscillation). The earlier CIRS observation also found that the south pole was warmer than the equator in the stratosphere near 1 mbar by 15 K—about 3 times that expected just from the radiative response to solar heating in southern summer—suggesting that descending motion and adiabatic compression and heating played an important role over the south pole. Fletcher et al. [2007b] found that the south pole in the same season was 25–30 K warmer than the north pole at 1 mbar. They also quantified the knee in the vertical temperature profiles, a flattening of the temperature lapse rates between 150 and 300 mbar in the tropopause region, which was first seen in temperatures retrieved from Voyager IRIS spectra obtained in 1980–1981. This was most noticeable in the southern hemisphere, becoming more compact in the equatorial region. They suggested that this could result from solar heating of heterogeneously distributed aerosol hazes.

Li et al. [2010] undertook a careful study of Saturn's thermal emission during 2004–2009. They found an effective temperature of 96.7 K, but found that the emission from the southern hemisphere (in summer) was 17% higher than in the north. They also found evidence of seasonal and variations in the total power ~2% and some interannual variability.

POLAR STRUCTURE

During northern winter, both poles exhibited compact spots in the upper troposphere, associated with cyclonic vortices, with subsidence and adiabatic heating [Fletcher et al. 2008]. At the southern (summer) pole, the warm structure persisted into the stratosphere near 1 mbar, where the warm region was slightly broader in extent. In the north, the warm pole was less compact and intense in the stratosphere. Evidence for polar subsidence was further supported by the depletion in PH_{3}¬, a disequilibrium compound thought to be transported upward from the deeper atmosphere. CIRS observations also detected the cold anticyclonic zone (warm cyclonic belt) poleward (equatorward) of the jet at 77° N, associated with the polar hexagon. (The hexagonal shape actually represents the orthographic projection of a wavenumber 6 sinusoidal variation of the amplitude in latitude with longitude.) As Saturn's seasons moved from northern winter to northern summer, the hexagon retained its structure in the thermal infrared and the north polar stratosphere developed a well-defined warm region that is broader than in the troposphere [Fletcher et al. 2015; Sayanagi et al. 2018]. On the other hand, the warm stratosphere over the south pole has weakened considerably. More recently, the recent Grand Finale orbits have provided observations of the poles with the highest spatial resolution of the mission. Tropopause temperatures over the north pole, now in

summer, increase sharply between 89° and 90° N [Achterberg et al. 2018]. The average subsidence velocity in this region, assuming a balance between adiabatic heating and radiative damping, are modest, ~0.05 mm/s. However, the circulation appears to be deeply rooted, still depressing the isentropes over the pole at the deepest levels probed by CIRS, ~600 mbar.

Temporal behavior

SATURN STORM

One of the key advantages of having a long-term orbiting spacecraft about a planet is the ability to map the fourth dimension—time—in addition to the three spatial dimensions. Geophysical systems are inherently nonlinear, and their temporal behavior is often not easily predictable. This is particularly true of meteorology. Our terrestrial experience has taught us that continued observation is critical to understanding an atmosphere's dynamical behavior.

One of the key advantages of having a long-term orbiting spacecraft about a planet is the ability to map the fourth dimension—time . . .

An intriguing phenomenon is the outbreak of the great Saturn storms. These originate as the appearance of a white compact spot that quickly spreads and encircles the planet with clouds within a latitude band. The storms recur in the northern hemisphere roughly every 30 years (approximately Saturn's orbital period) generally in northern summer, when Saturn is near periapsis—see, for example, the review by Sánchez-Lavega et al. [2016]. However, storms prior to the last one, which erupted in December 2010, were observed by Earth observatories, and this may have introduced some bias in the detections because of obscuration by the rings. The last storm, which was observed by Cassini, was unexpected in that it erupted early, just after the northern spring equinox. For the first time, an observatory was in hand to observe the storm evolution, not only up close, but with a full array of instruments spanning much of the electromagnetic spectrum as well as obtaining in situ data.

CIRS observations were critical in characterizing the effect of the storm on atmospheric structure. Current thinking attributes the storm outbreak as driven by a moist convective instability associated with Saturn's water clouds. Retrievals from CIRS spectra, obtained over the course of 18 months after the outbreak, indicated that tropospheric temperatures in the latitude band encircled by the clouds were elevated and the para ratio of H_2 was lower, relative to the ambient atmosphere at adjacent latitudes [Achterberg et al. 2014a]. This is broadly consistent with the notion of a rapid convectively unstable updraft that transports a higher fraction of ortho H_2, in equilibrium with the higher temperatures at depth. If, as on Earth, the convective updrafts are confined to narrow towers, surrounded by compensating downdrafts, which occupy most of the horizontal surface area in the perturbed latitude band, the adiabatic compression and warming would produce the higher temperatures observed, rather than lateral mixing of latent released in the updrafts. The mean zonal winds and temperatures are coupled via the thermal wind equation.

The warmer tropospheric temperatures at the storm latitude band means that winds become more westward with altitude equatorward of the band and eastward with altitude poleward, hence increasing the mean zonal anticyclonic vorticity with altitude. This is roughly consistent with the behavior inferred from cloud tracking studies using various filters [Sayanagi et al. 2013].

Li et al. [2015] examined the effect of the storm on Saturn's radiant power. The storm increased the total power near 45° by 9%, causing the globally emitted power to increase by 2%.

For the first time, the effects of the storm on the stratosphere was observed. CIRS observations indicated that initially two warm spots were observed near 2 mbar at the same latitude as the storm [Fletcher et al. 2012]. It was quickly realized that these could not have resulted directly from updrafts, because, with the sharp increase in static stability above the tropopause, any updraft would quickly become negatively buoyant. Instead, the effect of any updrafts hitting the tropopause region would be analogous to tossing a stone into a pond, generating waves that would propagate upward. The waves would likely be nonlinear, with the warm spots resulting from local subsidence and adiabatic heating. There were no accompanying colder regions at other longitudes, perhaps because of the presumed nonlinearity. It should be appreciated that Cassini observations, because they had been pre-programmed several months in advance, were not optimally configured to track the storm. Therefore, ground-based observations were brought to bear to fill in the gaps. VLA observations tracked the evolution of the two warm spots initially detected [Fletcher et al. 2012]. Because zonal pressure gradients were relatively weak in the troposphere, application of hydrostatic balance implied that the warm regions were high pressure centers, hence anticyclonic vortices with clockwise flow, with wind velocities ~200 m/s. Both anticyclonic vortices moved slowly westward at different speeds with respect to the background zonal flow. Eventually, in May 2011, they merged, with the vortex increasing in strength. At that time, the vortex temperature at 2 mbar was 80 K warmer than the ambient atmosphere at this isobaric level, unheard of in the normally quiescent Saturn stratosphere. CIRS observations indicated that not only were temperatures elevated, but there was a 100-fold enhancement of ethylene (C_2H_4) [Hesman et al. 2012]. The cause of this enhancement is not understood, but it may result from the release of condensed C_2H_4 bound onto aerosols that was released by the higher temperatures in the merged vortex.

The tropospheric disturbances associated with the storm dissipated over eight months. In contrast the stratospheric disturbance lasted nearly three years after the storm began [Fletcher et al. 2017]. The persistence of the stratospheric disturbance shows evidence of interfering with the descending phase of the equatorial oscillation (see next sectional paragraph below).

EQUATORIAL OSCILLATION

One of the remarkable phenomena on Jupiter and Saturn is the occurrence of equatorial oscillations in the planets' stratospheres. Equatorial oscillations on Earth—the quasi-biennial oscillation (QBO), with an irregular period ranging from 22–34 months, and the semi-annual oscillation (SAO) with a well-defined periodicity—have been extensively studied. The zonally symmetric structure in the equatorial middle atmosphere (stratosphere and mesosphere) is

characterized by an alternating series of warmer and colder layers with height. Because of Earth's rapid rotation, temperatures and zonal winds are in thermal wind balance, and the warm and cold regions are associated with decreasing and increasing zonal wind shear, respectively. The alternating shears are large enough that the zonal winds alternate between eastward and westward with altitude. Associated with the temperature and wind structure are a series of stacked meridional circulation cells. At equatorial levels where there is subsidence (ascent), adiabatic warming (cooling) produces warmer (colder) temperatures. These meridional cells close at higher latitudes in each hemisphere, and thus affect the structure of temperatures and winds at higher altitude. Indeed, there is evidence that the strength of the winter polar vortices on Earth, is correlated with the phase of the QBO. The terrestrial equatorial oscillations are thought to be mechanically driven, from the absorption of upwardly propagating atmospheric waves with both eastward and westward zonal phase velocities.

Ground-based observations [Orton et al. 2008] have indicated an oscillatory behavior in Saturn's equatorial stratosphere for decades, but they did not spatially resolve the vertical structure. Cassini CIRS observations resolved this structure for the first time. Fouchet et al. [2008] found the analogous warm and cold anomalies at the equator from limb-viewing spectra. The warm and cold anomalies were spaced apart by approximately two pressure scale heights. The zonal winds implied by the thermal wind equation did not reverse, as on Earth, but remained eastward. However, the peak-to-peak variation between the largest and smallest eastward winds was roughly 200 m/s, compared to the characteristic value between 400 and 500 m/s for the cloud-top winds. Some evidence for the extratropical extent of the implied meridional circulations associated with the equatorial oscillation was seen in the enhancement of C_2H_6 near 20° N. Since ethane increases with altitude, this suggested that subsidence was transporting it downward. The CIRS limb observations were limited and did not provide direct evidence that the observed undulatory structure in the temperatures and winds was indicative of the zonal mean structure, like on Earth. The evidence for that came from Cassini radio occultations [Schinder et al. 2011a]. Occultations at several different longitudes over the course of a few months indicated larger-scale undulations in the retrieved temperature profiles that agreed with those found with CIRS and which did not differ markedly with longitude. In addition, there was much smaller-scale structure that did vary from profile to profile, that could be indicative of atmospheric wave structure, perhaps of internal gravity waves.

Cassini not only provided close-up viewing of Saturn, but also an opportunity to observe the temporal behavior of the oscillation. Guerlet et al. [2011] compared CIRS limb observations 4–5 years apart of the equatorial regions. They observed that the pattern reported by Fouchet et al. [2008] had descended. The descent rate of warm and cold layers was consistent with the ~15-year period—approximately half of Saturn's year—that had been inferred from the ground-based observations by Orton et al. [2011]. Cassini radio occultations [Schinder et al. 2011a] also indicated a roughly comparable descent rate. During the descent the pattern is not rigid, and the vertical structure undergoes some modulation. The Earth's QBO and SAO also exhibit descending patterns that modulate. This behavior is linked to the deposition of zonal momentum of the absorbed vertically propagating waves that drive the oscillation—see, for example, Baldwin

et al. [2001]. More recent limb observations of Saturn, from 2015 [Guerlet et al. 2018] have shown the descent continues.

Li et al. [2011a] have combined cloud-tracking of Cassini imaging data and application of the thermal wind equation to CIRS temperature retrievals from nadir-viewing observations to assess the temporal variation of the zonal winds near the equator. Although they cannot access the higher altitudes associated with limb-sounding observations, they can probe the tropopause region better. They find variations in the zonal winds consistent with the previously cited work, but with the amplitude reduced near the tropopause.

The question arises whether the Saturn equatorial oscillation is really semi-annual, like the SAO on Earth. Comparison of temperatures retrieved from Voyager measurements in 1980–1981 with Cassini observations one Saturnian year later in 2009–2010 by Sinclair et al. [2014] and Li et al. [2013] at 2.1 mbar and 50–100 mbar, respectively, indicated that the later temperatures were noticeably warmer than expected if the oscillation were strictly periodic [see also the review by Fletcher et al. 2018]. More recently, Fletcher et al. [2017] found that the descent of the equatorial oscillation was significantly affected by the great northern storm, described earlier, at the beginning of 2011, when the equatorial region at pressures less than 5 mbar cooled by 10–12 K. This disruption persisted until at least 2014, after which the normal phasing of descending warm and cold equatorial anomalies appears to have resumed. Recent observations of Earth's QBO have revealed a disruption in the phase of the descending pattern in 2016. The origin of this disruption is not known, although zonal momentum transport from the northern hemisphere by mid-latitude planetary waves has been suggested. There have been a few analyses of Saturn's temperatures to characterize wave structure, from the Voyager Infrared Interferometer Spectrometer—IRIS—measurements [Achterberg and Flasar 1996] and from Cassini CIRS [Li et al. 2008; Guerlet et al. 2018], and these have suggested the presence of planetary waves with low to intermediate zonal wavenumbers. More effort is warranted.

Rings

This section contains an introduction which outlines the nature of ring thermal emission, a brief overview of Saturn's rings and their key characteristics, and a brief discussion of CIRS ring data analysis. Following the introduction is a discussion of CIRS ring models, the key CIRS ring results, the modeling of those results organized by the CIRS science objectives and the science assessments, and conclusions and future work. Thermal measurements of Saturn's rings by ground-based or spacecraft-based observations are summarized in book chapters by Cuzzi et al. [1984]; Cuzzi et al. [2009]; and Spilker et al. [2018]. The CIRS ring material in the following sections is taken primarily from Flasar et al. [2004] and Spilker et al. [2018], and a multitude of CIRS ring papers.

Introduction

The thermal response of a ring is determined by the way particles absorb, transfer heat in their interior and re-radiate it through the ring. The radiation source functions depend upon the ring structure. Energy sources include direct, reflected and scattered solar light, mutual heating by neighboring ring particles, and thermal and visible radiation from Saturn. Because of mutual shading and heating between particles, the thermal emission is determined not only by the physical properties of the particles, but also by the structural and dynamical properties of the ring disk itself. Friction in mutual dissipative collisions between particles, due to their possibly irregular surfaces, transforms orbital kinetic energy into spin. The particle surface temperature and its thermal emission are expected to vary on the surface along the rotation axis and azimuthally. Ring particles, as they collide into each other, are tumbling around the ring mid-plane with a vertical excursion governed by the local ring dynamics. The thermal history of a particle along its orbit is then an indicator of vertical dynamics. The particle is conditioned by the time it spends in sunlight and in the planetary shadow. At the exit of the shadow, its thermal inertia scales its ability to warm up as a function of time. Any difference in the heating curves between the lit and unlit sides should reveal the time each particle spends on each side.

Friction in mutual dissipative collisions between particles, due to their possibly irregular surfaces, transforms orbital kinetic energy into spin.

The thermal emission of planetary rings is thus expected to be a complex function of ring particle properties, ring disk structure, and observed geometry. Individual particle properties include size, regolith characteristics, Bond albedo, thermal emissivity and inertia, spin rate, and spin axis orientation. Ring structural and dynamical properties include optical depth, particle size distribution, vertical thickness and excursion, filling factor, and thermal inertia, too [Spilker et al. 2003a; Ferrari and Leyrat 2006; Morishima et al. 2009; Ferrari and Reffet 2013]. The emission observed from Saturn's rings also depends on the illumination and viewing conditions and to the position of the targeted ring segment relative to those two. Phase angle, solar elevation angle, observer elevation angle, local hour angle, and radial location in the rings are thus parameters of variable impact on that thermal emission.

SATURN RINGS OVERVIEW

The major ring features, from closest to farthest from Saturn, are the D-ring, C-ring, B-ring, Cassini Division, A-ring, narrow F-ring, faint G-ring and extended, and faint E-ring. The main rings (D through A) range from ~67,900 km to 136,800 km from the center of Saturn, and lie in a thin disk that is typically less than 10 meters thick [Tiscareno et al. 2007]. The C-ring and Cassini Division optical depths are lowest; 0.05–0.35 and 0–0.1, respectively. The B-ring optical depth is highest, 0.4 to >5, while the A-ring optical depth is intermediate, 0.4 to 1. Some gravitational wakes—temporary clumping of particles—have been detected in these to rings. Such a diversity in

the opacity of the rings versus distance is expected to play a role in the temperatures measured by CIRS and allowed us to address additional key questions such as: how does clumping affect the thermal radiation from the rings, and what does this tell us about the nature of these aggregates? Are the rings organized in a multi-particle-layer or mono-particle-layer, and how does the clumping affect this structure? How does the thermal inertia of the rings vary with the disk structure (thickness, filling factor, particle vertical excursion, etc.) or with particle properties such as albedo, surface roughness, porosity, or spin?

CIRS was indeed able to observe all but the faint and optically thin D-ring, G-ring, and E-ring, with optical depths ranging from ~10^{-5} to 10^{-6}. CIRS results from Saturn's F-ring, with the best data taken during the ring-grazing orbits near the end of the mission, are still under study.

CIRS RING DATA ANALYSIS

The ring spectra (Figure CIRS-1) delivered by the FP1 focal plane have been predominantly used for obtaining information about the ring temperatures because they contain the peak of the Planck function for typical ring temperatures (50–100 K). This allows a determination of the characteristic temperature within the FOV. Nearly every uncontaminated FP1 spectrum taken during the mission is well fit by a Planck function such that [Spilker et al. 2006; Pilorz et al. 2015]

$$I(\nu) = \beta B(\nu, T)$$

where $I(\nu)$ is the spectral intensity in W cm^{-2}sr^{-1}cm, $B(\nu, T)$ is the Planck function dependent on the wavenumber ν, T the effective temperature in the FOV. The β-factor is scalar, and stands for the product of the geometric filling factor β_{geo}, the infrared emissivity ε_{IR}, and the factor β_{therm} that arises due to a distribution of temperatures within the FOV [Altobelli et al. 2007]:

$$\beta = \beta_{geo}\varepsilon_{IR}\beta_{therm}$$

The expected deviations from the single-temperature fit resulting from the presence of multiple temperatures within the FOV are relatively small [Spilker et al. 2005].

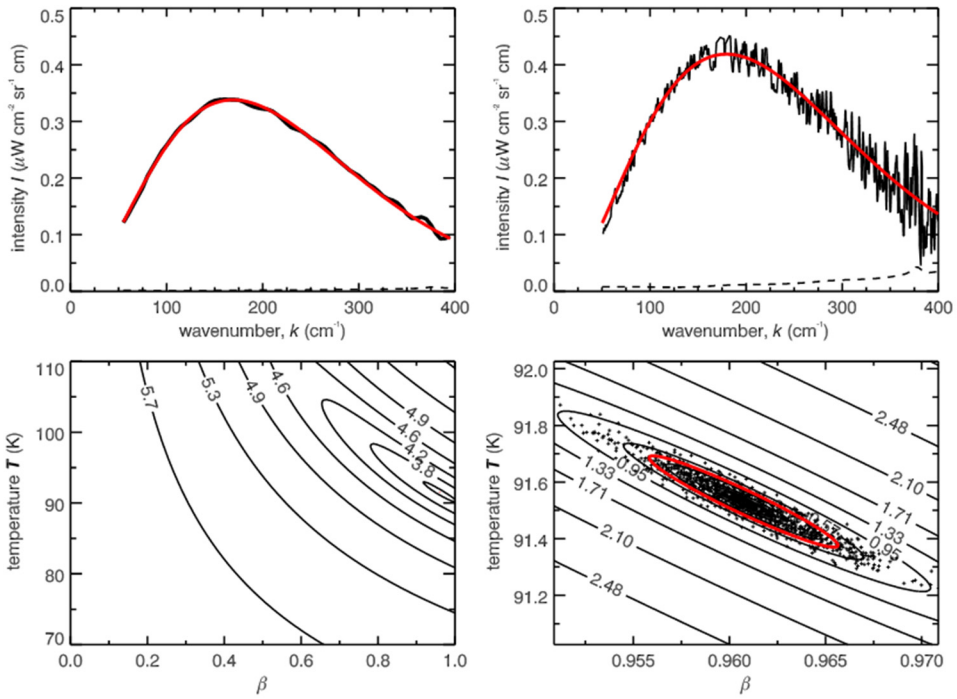

Figure CIRS-1. *Top panels*: show examples of low and high spectral resolution spectra used in the fitting process. We show two spectra selected from the B-ring at 105,000 km from Saturn. *Top left panel*: is from the lit, high-phase low-resolution (15.5 cm^{-1}) scan. *Top right panel*: is from the lit, low-phase high-resolution (1 cm^{-1}) scan. Noise spikes have been removed from these spectra. Each spectrum is plotted with the best fit to the single-temperature Planck function. The NESR at these wave numbers are shown as dashed lines. *Bottom panels*: show an example of the chi-square fitting procedure for the high-resolution spectrum. *Bottom left panel*: contours of the chi-square are shown over a large range of possible values. These contours are typical, and there are no local minima other than around the best fit (shown as a red dot). *Bottom right panel*: is an expanded plot of the contours in the vicinity of the best fit. Here, the theoretical 1 σ contour that we use in our error analysis is highlighted in red; the crosses represent the temperature and beta values derived from 1000 perturbations to the best fit spectrum, using uncorrelated, randomly generated noise with a standard deviation equal to the NESR at any wavenumber. In this realization 672 of the 1000 points lie within the theoretical contour, in close agreement with the expected 68%. Figure from Spilker et al. [2006], Figure 2.

Ring thermal structure

The main result obtained on the way the thermal emission, first as a function of the distance from the planet and of optical depth, then as a function of the solar elevation about the ring plane or as a function of the spacecraft position relatively to the Sun and finally with local hour angle, are presented below.

TEMPERATURE VARIATION WITH DISTANCE AND RING OPTICAL DEPTH

The effective temperature of Saturn's rings, as defined above, varies with radial distance from the planet. Radial temperature variations (Figure CIRS-2) are observed across both the lit and unlit

rings at both low and high phase angles [Spilker et al. 2006]. On the lit side of the rings, at low phase angle, the dominant trend across the ring system is a rough anti-correlation between optical depth and temperature. The optically thin C-ring and Cassini Division are considerably warmer than the optically thick A-ring and B-ring. However, within the A-ring and B-ring, the correlation between optical depth and temperature is distinctly positive and stronger at low phase angles (phase angle dependence will be discussed in more detail below). At high enough optical depth, the sunlight does not penetrate so deeply into the ring. The C-ring and Cassini Division also have lower albedos than the A-ring and B-ring. The lower albedos, lower optical depth and reduced mutual shadowing in these rings all contribute to their higher temperatures.

The temperatures of the A-ring and B-ring are correlated with their optical depths when viewed from the lit side of the rings and are anti-correlated when viewed from the unlit side. On the unlit side of the B-ring the lowest temperatures correlate with the largest optical depths and are also the same at both low and high phase angles, indicating that very little sunlight penetrates to the unlit side of the densest ring region. This also suggests that vertical mixing of ring particles is not very efficient in the optically thickest part of the rings. In the densest part of the unlit B-ring the phase variation nearly vanishes, indicating that direct sunlight does not play a significant role in heating these particles.

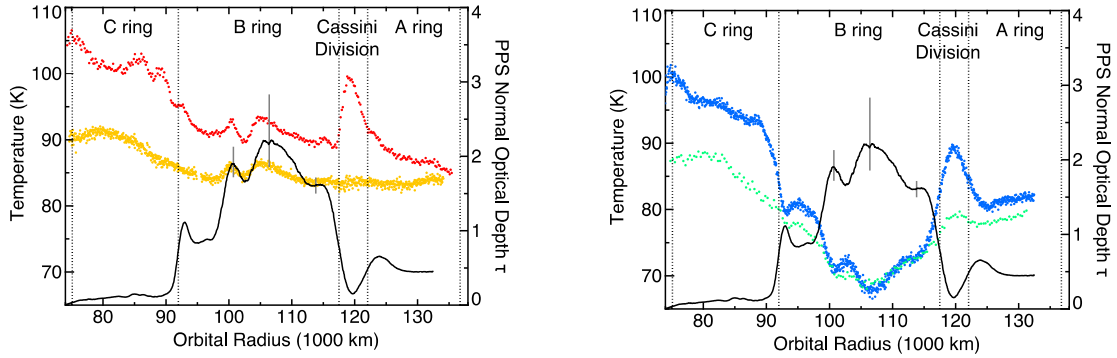

Figure CIRS-2. Radial temperature variations. *Left*: Radial temperature variation across the lit rings at both low and high phase angle. The ring temperatures at low phase (red symbols) and high phase (gold symbols) are shown as a function of ring radius, with boundaries between rings indicated by dashed lines. Both scans were taken at afternoon local times. The Voyager PPS optical depth profile is superposed, smoothed to the CIRS FP1 resolution. Vertical gray bars indicate the calibration uncertainty (1σ) in the PPS-derived B ring optical depths. Elsewhere the uncertainties are narrower than the width of the plotted line. *Right*: Same as the left, but for the ring temperatures at low phase (blue symbols) and high phase (green symbols). Figures from Spilker et al. [2006].

TEMPERATURE VARIATION WITH SOLAR ELEVATION AND THE EQUINOX CASE

One of the strongest effects observed in the ring thermal data is the decrease of temperature with decreasing solar elevation [Flandes et al. 2010]. The solar insolation is therefore, to first order, the main driver of the ring temperature. This effect is observed in all ring regions. Regions with low optical depth, the C-ring and Cassini Division, appear to have more limited amplitudes in

temperature variations. In contrast, larger differences are found between solar solstice and equinox in the B-ring and A-ring. The measurements of ring temperature with solar elevation (Figure CIRS-3) now cover a full seasonal cycle. The analytical model from Froidevaux [1981] assuming a monolayer with only slow rotators was fit to each ring data set using the visible bond albedo as the only model parameter—see Flandes et al. [2010] for model details—and can reproduce the observed temperature changes.

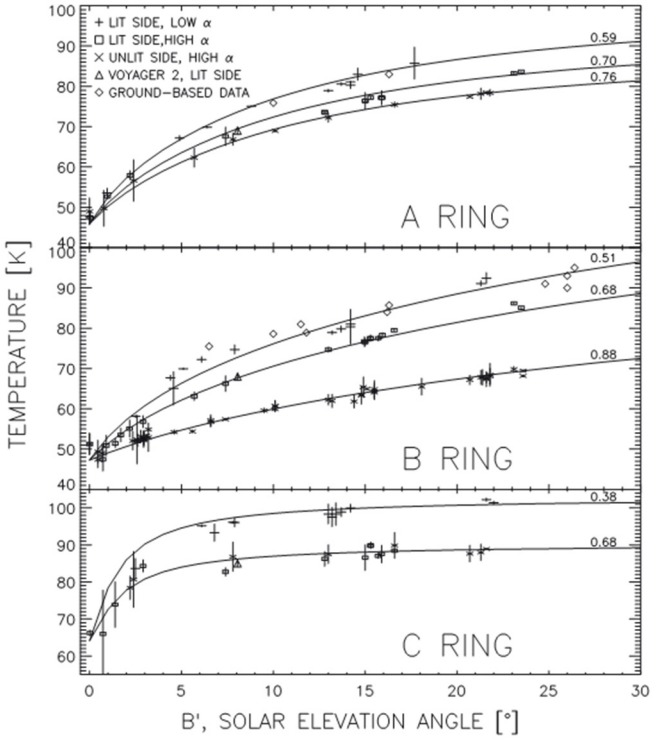

Figure CIRS-3. Saturn's ring temperatures as a function of solar elevation angle for the A-ring, B-ring, and C-ring. Observational data from Cassini CIRS (plus mark, cross and square), ground-based (diamond) and Voyager 2 (triangle) are shown. Data are presented at low (α ~ 30 deg) and high (α > 120 deg) phase angles for lit and unlit sides of the rings. The error bars represent the observed standard deviation. The analytical model from Froidevaux [1981] was used to fit the CIRS data assuming a mono-particle-layer of a ring and only slowly rotating particles. Figure from Flandes et al. [2010].

The solar equinox occurred on August 11, 2009. During the equinox period (August 11–13), CIRS obtained 15 radial scans [Spilker et al. 2013]. These observations took place when the solar elevation was between 0° and 0.036° above the ring-plane, mostly after the equinox. The very low solar elevation angle guarantees that the direct solar illumination is negligible. The absolute spacecraft elevation angle was about 20° for all the scans. Assuming that the heat source at the equinox is simply the infrared flux from Saturn, the simplest zeroth-order model gives the expected particle temperatures (Figure CIRS-4) [Spilker et al. [2013]. Saturn infrared emission is definitely structuring the radial variations of ring temperatures at equinox. The anti-correlation between the

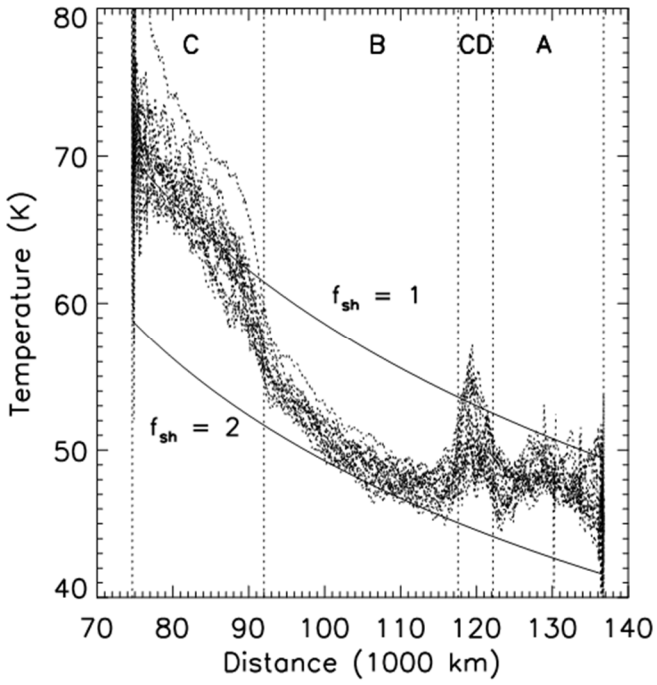

Figure CIRS-4. Ring temperature versus saturnocentric distance at the solar equinox (dotted curves). The temperature and the optical depth are anticorrelated and the temperature decreases with distance, as expected for the case of central heating. The temperature profiles from a simple model are also shown for optically thin (f_{sh} = 1) and thick (f_{sh} = 2) rings. See Spilker et al. [2013] for details.

ring temperature and the optical depth strongly supports the idea that nearby particles partially block Saturn's radiation depending on their optical depth.

The local observed temperature variations from scan to scan are caused by a change in observer geometry if the particles are not isotropic emitters. We found that the leading hemisphere of the particle is warmer than the trailing hemisphere at least for the C-ring and probably for the A-ring and B-ring too, although the temperature differences are as small as the error bars. This asymmetry indicates that some fraction of particles has spin rates lower than the synchronous rotation rate, provided that their thermal inertia is not zero. Spins slower than synchronous are indeed expected for the largest particles in N-body simulations [Salo 1987; Ohtsuki and Toyama 2005; Morishima and Salo 2006].

A multi-particle-layer model of Morishima et al. [2009] can reproduce the observed equinox temperatures for the C-ring and B-ring. C-ring temperatures were being well reproduced by the mono-particle-layer model of Ferrari and Leyrat [2006] while the multi-particle-layer model significantly underestimated the A-ring temperatures. This, in fact, indicates that the A-ring was not completely cooled down at the equinox and that it is possible to give constraints on the size and seasonal thermal inertia of A-ring particles. For further detail see the section entitled Seasonal Thermal Inertia and Particle Size, and the paper by Morishima et al. [2016].

TEMPERATURE VARIATION WITH PHASE ANGLE

The analysis of the temperature variations with phase angle across the main rings (Figure CIRS-5) reveals a variable dependence on optical depth and solar elevation [Altobelli et al. 2007, 2009; Morishima et al. 2017]. A surge in temperature is observed at low phase angles, if the solar elevation is low enough and the (normal) optical depth of the ring region observed (high enough) typically above ~0.3.

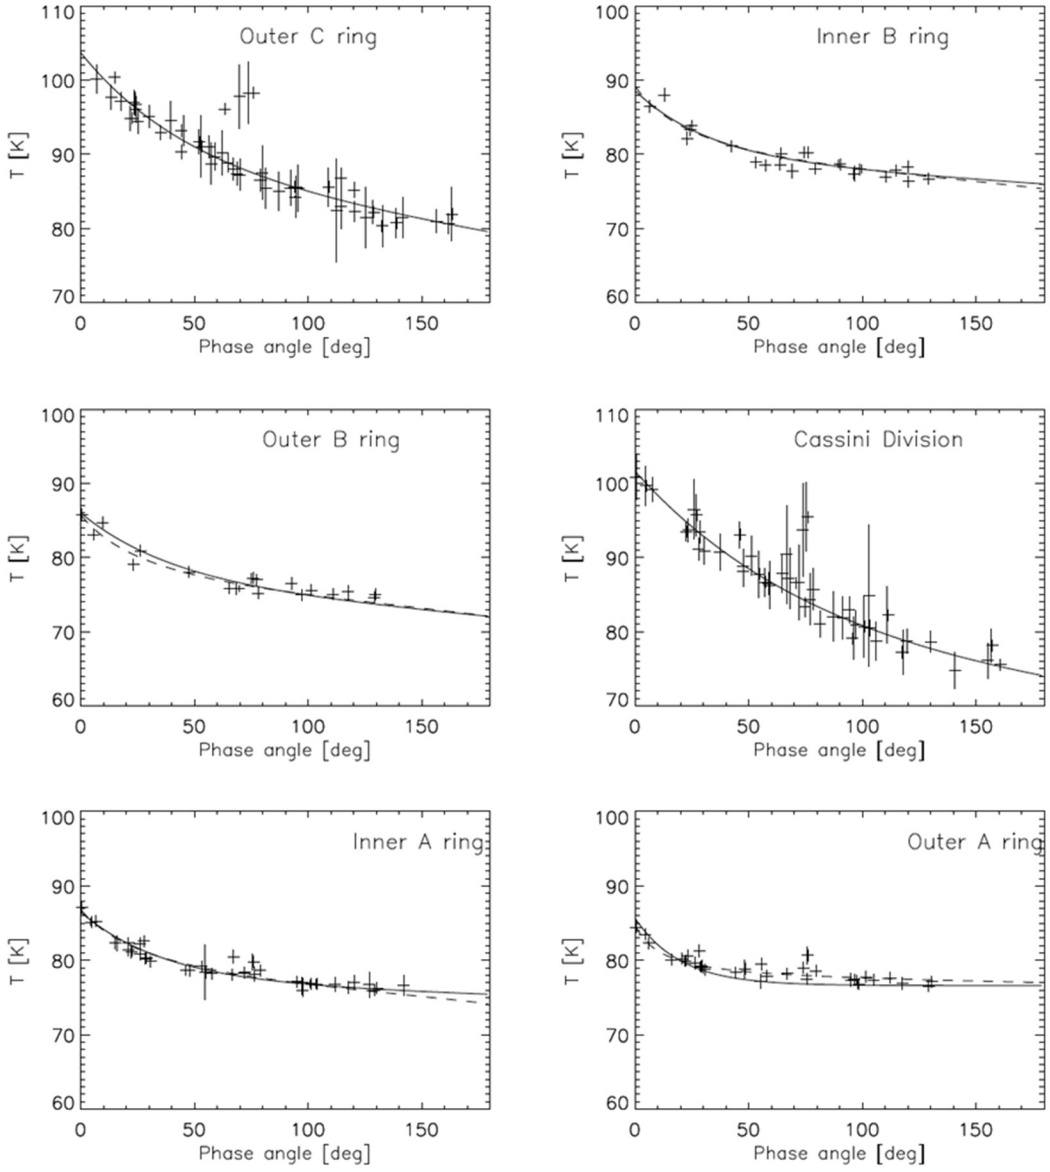

Figure CIRS-5. Temperature versus phase angle obtained at different ring locations. In all ring regions, an exponential-linear fit is applied (plain curve). In the A-ring and B-ring only, a fit based on the shadowing function of Hapke [1993] is also plotted (dashed curve).

The shape of thermal phase curves does not vary with solar elevation in the optically thin portions of the C-ring and Cassini Division. However, the shape does vary in the optically thicker regions of the B-ring, with an opposition surge at low solar elevation [Altobelli et al. 2007]. A similar behavior is observed in the C-ring plateaus [Altobelli et al. 2009] which are optically thicker than the surrounding background. The temperature surge is more pronounced for the plateaus than the C-ring background at low phase angle while similar phase curves are seen for both the plateaus and background at large phase angle.

The morphology of the phase curve, in particular the thermal surge in optically thicker regions for combinations of low phase angles and low solar elevation, can be explained by mutual shadowing between particles. Lower solar elevations obviously favor mutual shadowing by increasing the length of shadows projected on the ring-plane. (For futher detail see the section entitled Modeling of Opposition Surge for Packed Particulate Medium.)

AZIMUTHAL DEPENDENCE

CIRS executed azimuthal scans (Figure CIRS-6) of the lit and unlit rings at constant radial distance from the planet to measure ring temperature variations with local hour angle [Leyrat et al. 2008a]. Some scans investigated eclipse cooling, from which the thermal inertia of the rings and possibly of wake structures within dense rings were inferred.

Temperature scans of A-ring, B-ring, and C-ring versus local hour angle all exhibit a large drop in temperature from the entry into the shadow to a few hours after the shadow exit. This eclipse event is the major source of azimuthal temperature variations. The thermal gradient between entry

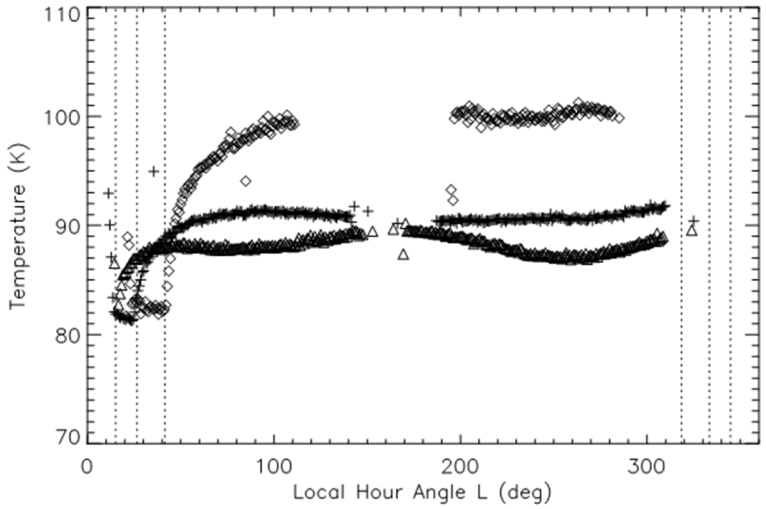

Figure CIRS-6. Typical azimuthal scans of ring temperatures versus local hour angle: C-ring (diamond), B-ring (cross), and A-ring (triangle). The vertical dotted lines mark the shadow boundaries for each ring. At this epoch, the Sun is relatively high above the ring plane (*B'*=-21.4 deg) and the shadow sector is significantly smaller for the A-ring. The phase angle ranges between 14 deg and 25 deg.

and exit from the shadow increases with solar elevation and decreases with phase angle [Leyrat et al. 2008a]. The shadow crossing is not detectable on the unlit side of the thick B-ring [Leyrat et al. 2008a; Reffet et al. 2015], which is consistent with the expectation that no direct sunlight reaches this side.

The temperature of the A-ring exhibits a quadrupole azimuthal modulation of 2–3 K on top of the eclipse drop, which is about 5–6 K [Leyrat et al. 2008a]. This modulation appears to vary with viewing and lighting geometry [Morishima et al. 2014]. Ferrari et al. [2009] showed that the model fit for the A-ring azimuthal variations of the scaling factor β at different solar elevations were improved using the regularly spaced, infinitely long, opaque elliptical cylinders, first introduced by Hedman et al. [2007] (Figure CIRS-7).

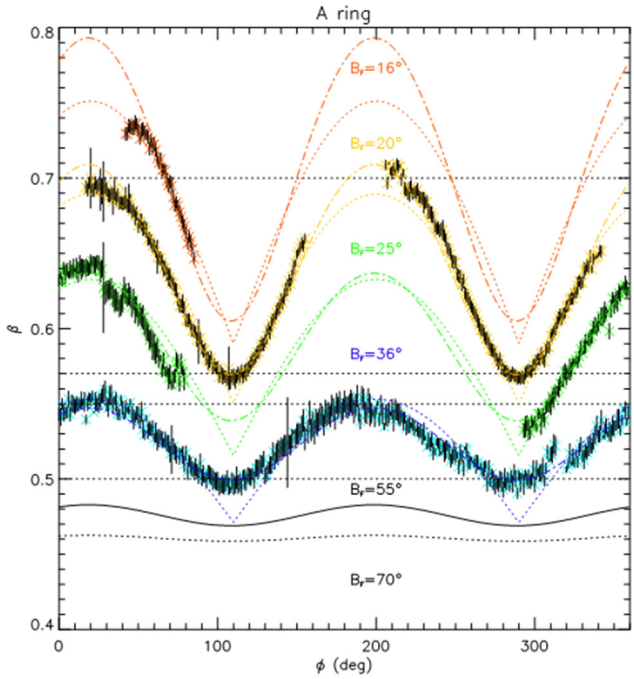

Figure CIRS-7. Averaged azimuthal profiles of the A-ring filling factor as a function of S/C azimuthal angle in the rotating frame ϕ at various spacecraft elevation *B* (shown as B_F in the figure). Best fit for elliptical cylinders wake model (dash-dot) or rectangular bars wake model (dot) are superimposed with the same color. Expected profiles at elevation *B* = 55 deg and *B* = 70 deg are also plotted. Figure from Ferrari et al. [2009].

Ring optical depth at mid-IR wavelengths

Differences between radial profile of optical depths at different wavelengths provide information on changes in the size distribution versus distance. Such profile was definitely missing at infrared wavelengths. Several CIRS ring occultations of the bright stars Eta Carinae and CW Leo were observed using the CIRS FP3 10-pixel array, with the objective of obtaining such mid-infrared (MIR) optical depths of Saturn's main rings (Figure CIRS-8). Since the rings also emit thermal photons at these wavelengths, the FP3 array was aligned along the occultation track. The stars and their

extended dust clouds were observed across two pixels, and the remaining pixels were used for background subtraction of the rings. CIRS optical depths were compared to UVIS optical depths from a high-resolution UVIS occultation of the star β Persei. It was expected that the cross-sections in the UV and MIR would behave similarly, but a linear fit of the observed MIR power to the UVIS-derived line of sight filling factor for a UV occultation indicates that the observed MIR filling factor is approximately 4% smaller than that predicted from the ultraviolet occultation of Saturn's rings [Pilorz et al. 2018a]. The optical depths agree well in the C-ring and A-ring, but in the B-ring the CIRS derived optical depth is smaller. This could result from the simplistic calibration, or be due to details related to the saturation of the CIRS signal in that region due to strong B-ring emission in the MIR. Additional CIRS Eta Carinae occultations obtained late in the mission are still to be processed.

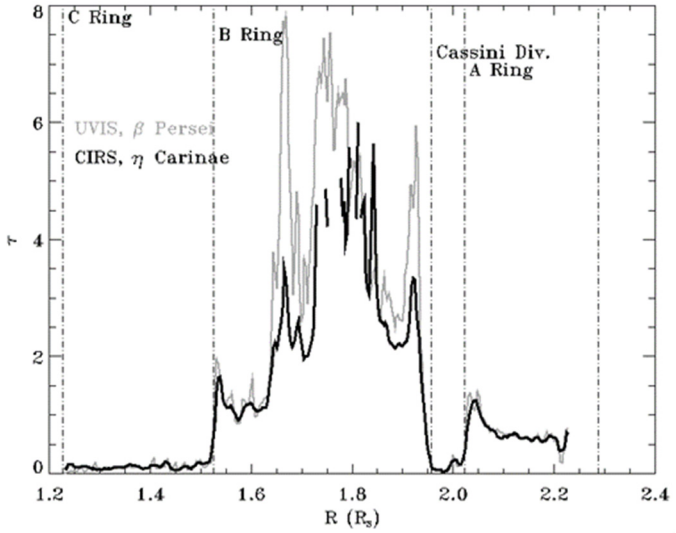

Figure CIRS-8. MIR optical thickness. This is an estimate obtained from the Eta Carini occultation, which may change pending ongoing work to correct for the response of the FP3 detectors, the location of the star within the FOV, the thermal signal from the rings, and the maximum signal received. Figure from Pilorz et al. [2018a].

Ring thermal models

Saturn's rings offer a wide diversity of optical depths and dynamical contexts. Particle properties are expected to be more easily probed in optically thin rings or in rings with very low volume filling factor *D*. As the volume filling factor increases or as tidal effects diminish, particles may interact dynamically to form wakes, gravitational instabilities of any form, like typically suggested for Saturn's A-ring and B-ring. The thermal behavior of the ring depends on the structure of group ensembles or on the dynamics of colliding particles, which is still not well known. If *D* is low, particle-based models are generally used. In case of high volume filling factor, the ring can be treated either as infinitesimally long elliptical or rectangular cylinders or as a slab or static packed bed with limited excursion of ring particles. These latter slab-based models do not usually consider individual particles but can eventually treat heat transfer both at the particle scale and

the scale of the ring itself. They may be suitable for the thick A-ring and B-ring and for the wake structures seen in these rings.

Various models have recently been developed to tentatively reproduce the observed thermal behaviors of Saturn's rings. They rely on different a priori hypotheses and produce various observables to be fitted to data. At this stage, none of these models is able to reproduce all observed thermal behaviors at once. We describe here models for the ring geometric filling factor and temperatures that have been developed in the past decade. These thermal models are classified into particle-based models and slab-based models.

Heat transfer

The particle-based models solve the heat diffusion equation at the scale of the particle and its facets, whereas the slab models solve it at the scale of the ring. Both ring and particle can be considered as porous media. In order to follow the change of the temperature T with time in such media, the thermal diffusion equation needs to be solved with appropriate boundary conditions, i.e., energy balance, assuming effective thermal properties of a mixture of voids and matter.

The temporal variation of the incoming flux at the chosen scale occurs due to the particle spin, to azimuthal motion around the planet, or to vertical motion of particles in optically thick rings. While some models explicitly take into account these variations by solving the thermal diffusion equation, the heat conduction term is often ignored in simple models. On a long timescale, seasonal variation occurs due to the obliquity of Saturn. It is reasonable to ignore the heat conduction term for the seasonal effect as the thermal relaxation time is much shorter than the Saturn's orbital period. An exception is at equinox, at which the rings may not completely cool down to the equilibrium temperatures that are determined in the absence of direct solar illumination.

The total radiation flux consists of the sum of the direct solar radiation, the thermal radiation from Saturn, the sunlight reflected by Saturn, the thermal radiation from nearby particles, and the radiation of visible light multiply scattered by neighboring particles. Methods to calculate these fluxes vary among models but the direct solar radiation term dominates other terms except near solar equinox.

Particle-based models

The two extreme examples of the particle-based models are the mono-particle-layer model [Froidevaux et al. 1981; Ferrari and Leyrat 2006] and the multi-particle-layer model [Kawata 1983; Morishima et al. 2009]. The particle-based thermal models that have been recently developed [Ferrari and Leyrat 2006; Morishima et al. 2009] calculate temperature distribution over the surfaces of individual particles. The ring temperature is derived by integrating the emitted spectrum averaged over the particle surfaces. Therefore, these models are applicable to any observational geometries while the early models are practically applicable only to ground-based observations. Particles may oscillate around the ring mid-plane and exhibit spin. Their properties are characterized by various

parameters such as bolometric Bond albedo, distribution of spins, thermal inertia, infrared emissivity, or surface roughness.

Monolayer Model: Ferrari and Leyrat [2006] proposed a standard spin model that calculates the temperature of a monolayer ring of spinning particles with finite thermal inertia. It calculates exactly the surface temperature pattern as a function of spin rate, obliquity and thermal inertia. The surface temperature map of a particle is calculated over time along its specified orbit, taking into account the periodic crossing of the planetary shadow and the changing directions of the heating sources in the particle rotating frame.

For each particle facet the heat diffusion equation is solved in 1D-spherical coordinates over several times the larger one of the skin depth associated with the particle spin or that with the rotation around Saturn. The energy balance is applied at the scale of a facet of a particle. It takes into account mutual shadowing between particles, visible light scattered and infrared heating by nearby particles or by the planet. The effective temperature of the unresolved particle is calculated from its integrated thermal spectrum as seen from the spacecraft position. Model parameters are the probability density functions for spin rates and orientations, the particle Bond albedo, emissivity, and thermal inertia.

Ferrari and Leyrat [2006] showed that the spin rate, orientation and thermal inertia significantly modulate the ring temperature along local hour angle L and that the longitude of the peak temperature mainly depends on the spacecraft local hour angle, as it alternatively observes the morning, noon, afternoon, or night-time face of particles. The distribution in spin rates or obliquities, prograde or retrograde, the thermal inertia affects this modulation to a lesser extent.

Multilayer Model: In the multi-particle-layer model of Morishima et al. [2009], the vertical thickness of a ring is assumed to be much larger than the particle size or equivalently the ring's volume filling factor $D = 0$. The model numerically solves the classical radiative transfer equation [Chandrasekhar 1960; Modest 2003] using the multi-stream method. The model adopts the plane-parallel approximation so rings are horizontally homogeneous.

The model takes into account heat transport due to particle motion in the vertical and azimuth directions by following temporal thermal evolution of thousands of ring particles. The model employs two different types of vertical motion of particles: sinusoidal motion without collision and cycloidal motion that mimics bouncing at the mid-plane. The model assumes, instead of an actual continuous size distribution, a bimodal size distribution consisting of fast and slow rotators. Fast rotators are small rapidly spinning particles having spherically symmetric thermal structure whereas slow rotators are large non-spinning Lambertian particles. The areal fraction of fast rotators and the ratio of the scale height of fast rotators to that of slow rotators are the input parameters. The ring effective temperature is derived by summing up the thermal emission of all ring particles toward the observer, taking into account the attenuation factor due to other particles on the line of sight.

MODELING OF OPPOSITION SURGE FOR PACKED PARTICULATE MEDIUM

Models for packed particulate medium [Lumme and Bowell 1981a; Hapke 1993], which were originally derived to explain reflectance measurements of atmosphereless bodies, was used by Altobelli et al. [2007, 2009]. These models envision Saturn's rings as a packed particulate medium. In this approach, the drop-off in temperature with increasing phase angle is related to a net reduction of the particles' illuminated cross-section as a result of mutual shadowing. In addition, particles must be big enough and far enough apart with respect to the wavelength so that diffraction effects are negligible, which is certainly the case for Saturn's rings at visible and thermal infrared wavelengths. For a given optical depth, the relevant physical parameter for particles to cast shadow is their volume filling factor *D*.

SLAB-BASED RING STRUCTURE MODELS

Current slab-based ring thermal models follow diverse objectives. They aim at predicting ring lit side temperatures with no attempt to implement the physical processes at the origin of the thermal emission [Altobelli et al. 2014], at reproducing the thermal opposition surge with a varying degree of surface roughness [Morishima et al. 2017], or at estimating the thickness of rings from thermal gradients between lit and unlit sides [Ferrari et al. 2005; Ferrari and Reffet 2013; Pilorz et al. 2015]. The slab-based models that reproduce the diurnal or seasonal temperature variations of lit and unlit sides help us understand how heat transfers from one side to the other and why the thermal inertias observed are so low.

Empirical modeling of lit side ring temperatures: Altobelli et al. [2014] attempted to fit the entire CIRS data set using a slab-based model with correction factors due to variations of observation geometries defined empirically. They focused on only the lit side, non-shadowed by the planet. This analytical model has proven to be a good predictor of temperature variations for most of the viewing geometries. The model has been tested over the whole ring radial extent, using radial slices 1500–4000 km wide. The radial resolution is constrained by requiring at least one hundred individual measurements with an error below 2 K within each ring slice. The resulting full parameter values are provided in Altobelli et al. [2014].

Particle scale properties

The models cited below have been compared to CIRS ring temperatures to provide constraints on ring and particle properties. They share some basic common parameters like albedo, spin or thermal inertia, which can be defined at both the scales of the particle and the ring. Some models include unique parameters.

BOLOMETRIC BOND ALBEDO

The bolometric albedo A_V (Figure CIRS-9) is the albedo averaged over ultraviolet to near-infrared wavelengths, weighted by the solar intensity. It controls the overall temperature level at any

observational geometry: the temperature increases with decreasing A_V. From Morishima et al. [2010] the albedo A_V derived from CIRS data is lowest, ~0.1, at the innermost C-ring and increases with increasing saturnocentric distance up to 0.6 at the mid B-ring. Through the mid B-ring to the outer B-ring, A_V is nearly constant. The Cassini division shows $A_V \sim 0.4$. The A-ring has a nearly constant A_V of ~0.5. The values of A_V derived from this thermal model can be compared with those from photometric observations and models. Although overall agreements are good, the thermal data generally give lower values of A_V than those from the photometric data, particularly for the C-ring. One possible explanation for the deviation is that the infrared emissivity ε_{IR} is less than unity while the thermal model assumes $\varepsilon_{IR} = 1$. Other studies (see the section entitled Scalar Thermal Emissivity for particle and ring emissivity) derive values for ε_{IR} of ~0.9 across all rings.

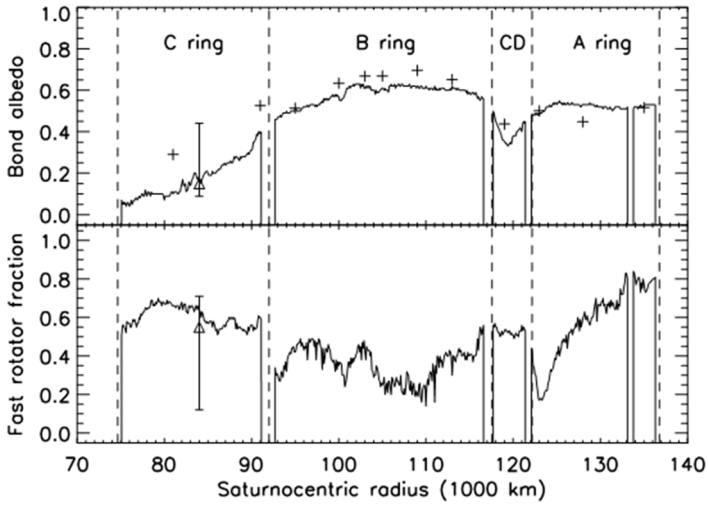

Figure CIRS-9. Bolometric Bond albedo A_V and areal fraction of fast rotators f_{fast} estimated from CIRS radial scans and the multi-particle-layer model. [Morishima et al. 2009, 2010]. The triangles are A_V and f_{fast} estimated from Voyager IRIS data and the mono-particle-layer model [Leyrat et al. 2008a]. *Top panel*: plus marks are the values of A_V calculated using visible and near-infrared albedos [Poulet et al. 2003; Porco et al. 2005].

SPIN RATE

The phase dependence and first-order azimuthal variations of ring temperatures can be interpreted as being caused by spherical spinning particles, as demonstrated by particle-based models. Slowly spinning particles emit predominantly toward the heat source, while fast spinning particles emit more isotropically.

The multi-particle-layer model of Morishima et al. [2009] employs a bimodal spin distribution consisting of slow rotators and isotropic emitters fast rotators with fraction f_{fast} which is roughly half for the all rings although some regional variations, such as smaller particles and more fast rotators in the outer A-ring, are seen. Roughly speaking, fast rotators are defined so that their spin periods are shorter than the thermal relaxation time [Morishima et al. 2011]. The spin periods of the largest particles are about the orbital period while the orbital periods of smaller particles are proportional

to particle sizes [Salo 1987; Ohtsuki 2006a, 2006b; Morishima and Salo 2006]. Therefore, f_{fast} increases with increasing particle-size distribution width and with increasing thermal inertia. Morishima et al. [2011] found good agreements between the size distribution width suggested from f_{fast} and thermal inertia and those estimated from stellar occultations [French and Nicholson 2000]. The analysis with Ferrari and Leyrat [2006] model of the temperatures of the C-ring at equinox epoch implied that both population are indeed present [Spilker et al. 2013].

DIURNAL THERMAL INERTIA

The thermal inertia Γ is a measure of the thermal responsiveness of a material to variations in the incoming flux. When Γ is small enough the particle temperature quickly reaches the equilibrium value determined by the instantaneous flux. Morishima et al. [2011] applied their multi-particle-layer model to CIRS azimuthal scans (Figure CIRS-10) that include data in Saturn's shadow and estimated the diurnal thermal inertia (diurnal here represents a variation due to rotation around Saturn).

The values of Γ are estimated from individual CIRS azimuthal scans at different solar phase angles. The values are about 10–20 $Jm^{-2}\ K^{-1}\ s^{-1/2}$ for all the rings. The Cassini division shows the lowest values. These are comparable to or slightly higher than those estimated with the mono-layer spin model both for pre-Cassini studies [Leyrat et al. 2008b] or Cassini observations of the C-ring at 10 $Jm^{-2}\ K^{-1}\ s^{-1/2}$ [Ferrari 2006; Spilker et al. 2013].

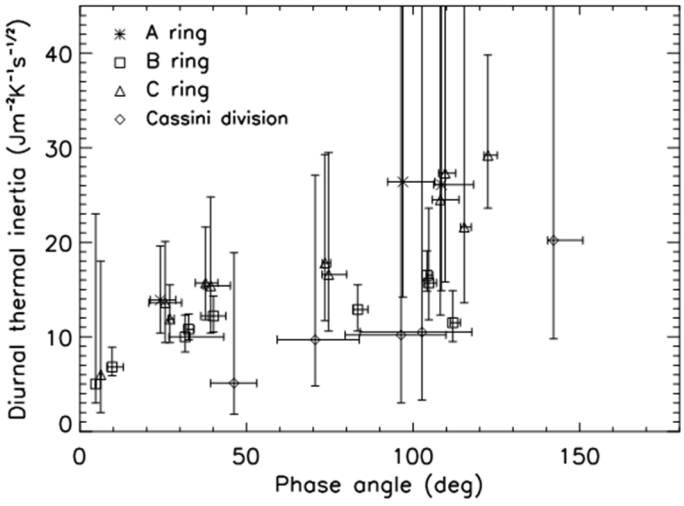

Figure CIRS-10. Diurnal thermal inertia estimated from CIRS azimuthal scans. The multi-particle-layer model [Morishima et al. 2009, 2011] is used. Thermal inertias of the B-ring and C-ring at the lowest phase angles (~5 deg) are those estimated by Ferrari et al. [2005] who applied their mono-particle-layer model to the ground-based data.

However, it was found that Γ increases with solar phase angle for all the rings. Morishima et al. [2011] interpreted this trend as caused by the size-dependent thermal inertia; large slow rotators have lower thermal inertia values than those for small fast rotators because the thermal emission

of slow rotators is relatively stronger than that of fast rotators at low phase and vice versa. Their additional parameter fits, which assume that slow and fast rotators have different thermal inertia values, showed the thermal inertia of fast rotators are 30–80 $Jm^{-2}\ K^{-1}\ s^{-1/2}$ and that of slow rotators are 5–9 $Jm^{-2}\ K^{-1}\ s^{-1/2}$. A probable reason for the large thermal inertia of fast rotators is that they cannot hold very fluffy regolith layers because of their fast spins while the slow rotators can accumulate a thicker, porous regolith layer leading to smaller thermal inertias.

SEASONAL THERMAL INERTIA AND PARTICLE SIZE

Morishima et al. [2016] applied both the multi-particle-layer model [Morishima et al. 2009] and the wake model [Morishima et al. 2014] to the equinox data of the A-ring. They found that the observed equinox temperatures are much higher than model predictions as long as only the flux from Saturn is taken into account. In addition, the post-equinox temperatures are lower than the pre-equinox temperatures at the same absolute solar elevation angle. These facts indicate that the A-ring was not completely cooled down at the equinox and that it is possible to give constraints on the size and seasonal thermal inertia of ring particles.

A simple seasonal model based on the monolayer model (Figure CIRS-11) was used to estimate the seasonal thermal inertia and the particle size for the A-ring [Morishima et al. 2016]. If the internal density and the thermal inertia of a ring particle are assumed to be uniform with depth, the seasonal thermal inertia is found to be 30–50 $Jm^{-2}\ K^{-1}\ s^{-1/2}$ in the middle A-ring, whereas it is ~10 $Jm^{-2}\ K^{-1}\ s^{-1/2}$ or as low as the diurnal thermal inertia in the inner and outermost regions of the A-ring. The particle size is estimated to be 1–2 m. Another internal structure model, in which a particle has a high-density core surrounded by a fluffy regolith mantle with Γ of 10 $Jm^{-2}\ K^{-1}\ s^{-1/2}$ shows that

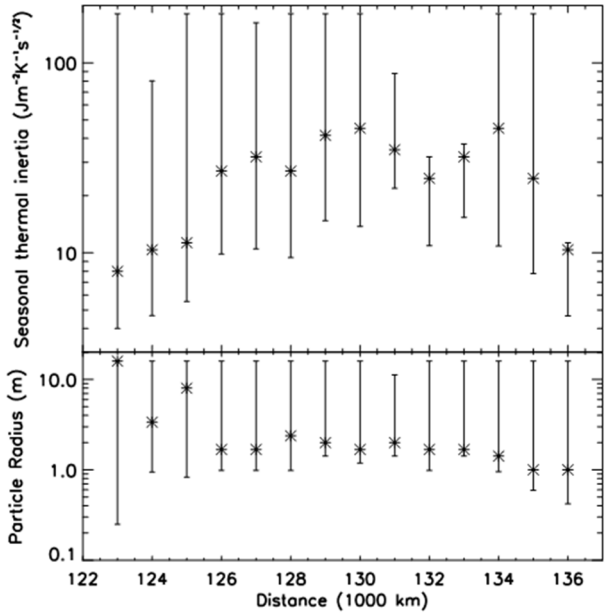

Figure CIRS-11. Seasonal thermal inertia and size of particles for the A-ring [Morishima et al. 2016].

the core radius relative to the particle radius is about 0.9 for the middle A-ring and is much less for the inner and outer regions of the A-ring [Morishima et al. 2016]. This means that the radial variation of the internal density of ring particles exists across the A-ring. Some mechanisms may be confining dense particles in the middle A-ring against viscous diffusion. Alternatively, the middle A-ring might have recently formed ($<10^8$ yr) by destruction of an icy satellite, so that dense particles have not yet diffused over the A-ring and regolith mantles of particles have not grown thick.

Scalar Thermal Emissivity

Since the thermal infrared emission of the particle is proportional to the scalar emissivity ε_{IR}, the temperature increases with decreasing ε_{IR}. A degeneracy between A_V and ε_{IR} is expected, as the particle temperature is proportional to $((1 - A_V)/\varepsilon IR)^{1/4}$ with a single heat source emitting visible light (e.g., the Sun).

It is possible to constrain ε_{IR}, if the ring temperature and the geometric filling factor are known [Altobelli et al. 2008]. For optically thin rings, the geometric filling factor is well represented by the formulation of the multi-particle-layer model. Using the formulation, Altobelli et al. [2008] derived $\varepsilon_{IR} = 0.9$ for the C-ring. For the thickest part of the B-ring, the geometric filling factor is almost unity, and $\varepsilon_{IR} = 0.9$ is derived, too [Spilker et al. 2005; Altobelli et al. 2008]. Morishima et al. [2016] applied the wake model of Morishima et al. [2014] to the A-ring equinox data and estimated the lower limit of ε_{IR} to be ~0.9. The most recent work by Pilorz et al. [2018b] supports the previous results (Figure CIRS-12).

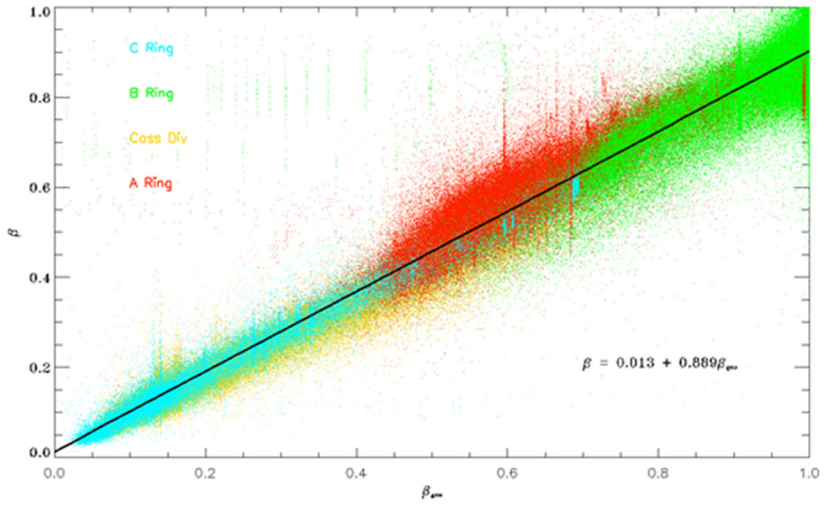

Figure CIRS-12. Scaling factor β versus convolved geometric filling factor β_{geo}. Figure from Pilorz et al. [2018b].

Ring-scale properties

When compared with the orbital and seasonal temperature variations of the lit and unlit sides, slab-based thermal models have provided new insights into the structure of dense rings, their volume filling factor, thickness, mass and thermal properties. The observed correlation of the vertical thermal gradient between both sides with optical depth proved useful in this regard.

VOLUME FILLING FACTORS OF A-RING AND B-RING

Both the thermal opposition effect model [Altobelli et al. 2009] and the multi-scale slab model favor a relatively high volume filling factor for the dense central B-ring. For a mono-disperse population of spherical particles, the half-width-half-maximum (HWHM) of the thermal opposition peak $h \approx -(3/8)\ \ln(1-D)$ yields $0.3 < D < 0.4$ in the B-ring. In the outer A-ring, $D < 0.2$. The C-ring background and Cassini division thermal phase curves could hardly be reproduced by this model, suggesting that, as expected, the thermal emission is not modulated by mutual shadowing in these thin rings. The C-ring plateaus, on the other hand, show strong opposition surge and Altobelli et al. [2007] yielded $D = 0.001–0.01$.

Reffet et al. [2015] also demonstrated that, in the frame of a multi-scale slab approach, the correlation between the lit-unlit face temperature difference and the optical depth seen in the B-ring [Spilker et al. 2006] could not be explained by an increasing compaction D but rather by an increasing slab thickness. The fit of this model to orbital and seasonal temperatures all along the Prime Mission in the central B-ring (across the B2 and B3 thickest regions of the B-ring yielded a volume filling factor $D = 0.34 \pm 0.01$, remarkably consistent with the value derived from the opposition surge [Altobelli et al. 2009] and with expectations from numerical simulations of ring dynamics [Salo and Karjalainen 2003; Salo and French 2010].

ENERGY BUDGET AND HEAT TRANSFER IN B-RING

The optically thick B-ring is a good region for a slab-based modeling approach because the ring particles are expected to be close together, as confirmed by its measured filling factor. The slab approach allows the heat transfer to be quantified through such a dense ring structure and provides an effective thermal inertia or thermal conductivity through a vertical slab from the lit to the unlit side of the B-ring. The heat transfer can be by conduction through the solid phase of particles, by radiation through voids or by the vertical particle motion.

Ignoring vertical particle motion in the thick B-ring, Ferrari and Reffet [2013] proposed a model for the B-ring slab, including both heat transport by radiation and conduction and being able to disentangle ring and particle thermal inertias thanks to a multi-scale approach (Figure CIRS-13). This model was successfully fitted to more than 600 temperature measurements of both lit and unlit sides of the B-ring and spread all along the Cassini Prime mission (2004–2009) [Reffet et al. 2015]. Only mid-phase angle data were used to avoid the low-phase angle thermal hotspot, which the model cannot account for, assuming particles are isothermal. Self-gravity wakes have been

observed in the B-ring and the reduced width of the inter-wake gap allows them to be considered as a continuous slab. This is not the case for these structures observed in the A-ring.

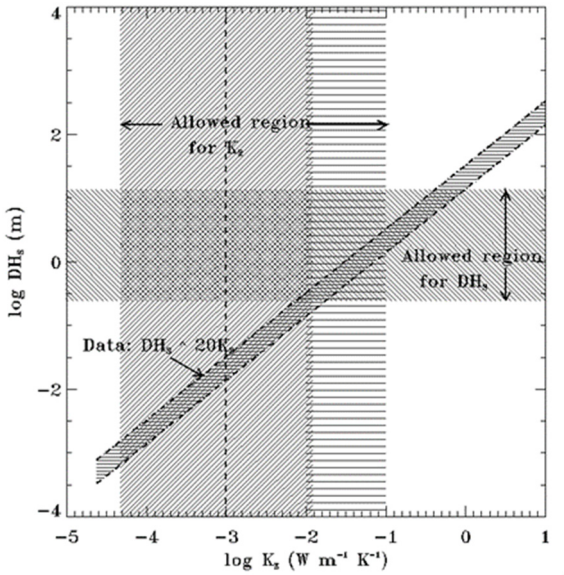

Figure CIRS-13. Diagram of the allowed values of effective ring thickness, DH_S, and effective heat conductivity, K_E, for the B-ring. These values are consistent with the ratio K_E/DH_S constrained in Pilorz et al. [2015]. The diagonal hashed region indicates combinations of values of DH_S and K_E such that ratio K_E/DH_S agrees with observations of the seasonal variation of heat throughput. The horizontal and vertical hashed regions indicate ranges of values for DH_S and K_E, respectively that are currently accepted as reasonable for ring thickness and the conductivity of icy moon regoliths or ring models.

THERMAL PROPERTIES, THICKNESS, AND SURFACE MASS DENSITY OF B-RING

Fitting of the model of Ferrari and Reffet [2013] to the central B-ring at the distance of 105,000 km from Saturn, where most data on the transient thermal regime about the planetary shadow were focused, Reffet et al. [2015] found a slab Bond albedo of A_V = 0.402 ±0.005 for an emissivity nearly unity, in total agreement with the energy balance studied by Pilorz et al. [2015].

Assuming no heat transport by the vertical motion of particles, but solely by conduction through the particles and radiation through voids, the particles have to be relatively conductive to ensure vertical heat transport through the slab. The effective slab conductivity estimated by Reffet et al. [2015] is on the order of 0.06–0.08 W m^{-1} K^{-1} at 80 K. Despite very different approaches but fitted on similar data sets, Reffet et al. [2015] and Pilorz et al. [2015] yield similar slab effective conductivity. The seasonal thermal inertia for the B-ring was found to be 30–35 Jm^{-2} K^{-1} s$^{-1/2}$, comparable to the seasonal thermal inertia of particles measured in the A-ring by Morishima et al. [2016].

The empirical model of Altobelli et al. [2014], using the entire CIRS data set to that date, and including radial scans near the shadow boundaries, yields a thermal relaxation time of 15–25

minutes, almost radially constant for the A-ring and B-ring. Since the thermal relaxation time is expected to be linearly proportional to the slab thermal inertia [Morishima et al. 2011], the radial variation of the slab thermal inertia is likely to be small for these rings.

Assuming that the vertical thermal gradient in the B-ring mainly fluctuates with the slab thickness and that ring and particle properties across the whole ring are similar to the one derived at 105 000 km distance, Reffet et al. [2015] have derived two radial profiles of the B-ring thickness $H_S(R)$ at two different epochs, where B_0 = −15.7° and B_0 = −4.5°. They happen to be highly consistent and exhibit variations in between 1 m and 3 m in the highest optical depth regions of the B-ring (Figure CIRS-14). If this thickness is assumed to be the same as the thickness of self-gravity wakes in the B-ring, it can be combined with their aspect ratios to derive a surface mass density across the thickest regions (B_2 to B_4) of the B-ring. It is found that the surface mass density is about 400 kg m^{-2} in the B_2 region, about 500 kg m^{-2} in the B_4 region and larger than 1000 kg m^{-2} in the B_3 region as self-gravity wakes are observed with difficulty in this dense region.

The resulting minimum mass of the B-ring derived by this method is $M_B = 8.7 \pm 1.7 \times 10^{18}$ kg [Reffet et al. 2015]. The minimum total mass of Saturn's rings, given the estimates of the C-ring, CD-ring, A-ring, and B_1-ring, for a total mass of 5.3×10^{18} kg [Baillié et al. 2011; Colwell et al. 2009; Tiscareno et al. 2007; Esposito et al. 1984], would then be $M_R = 1.4 \pm 0.2 \times 10^{19}$ kg. It is consistent with larger estimates provided by Esposito et al. [1983] and Robbins et al. [2010]. The minimum mass of the B-ring estimated by this method compares rather well to the residual mass of a viscous ring which has evolved over the age of the solar system, i.e., $M_R = 1.5 \times 10^{19}$ kg, whatever the initial (larger) mass is [Salmon et al. 2010].

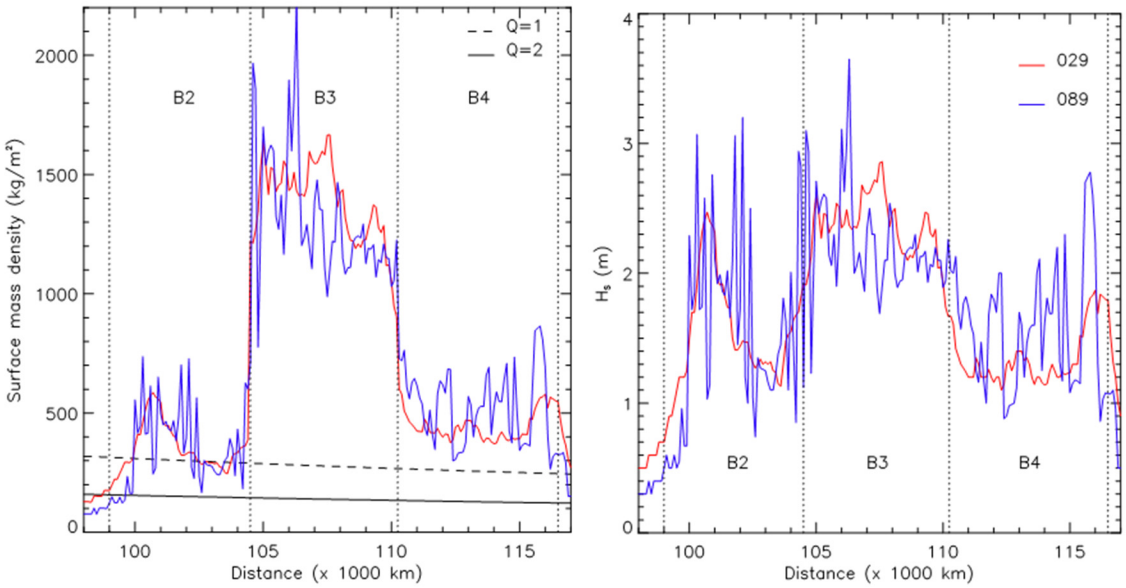

Figure CIRS-14. *Left*: Vertical thickness of the B-ring slab as a function of distance to Saturn. Both profiles have been estimated from vertical gradient measured at B_0 = -15.7 deg (rev. 29) and B_0 = −4.5 deg (rev. 89). *Right*: Radial variations of surface mass density of the B-ring as derived from ring thickness H_S. See Reffet et al. [2015] for details.

SELF-GRAVITY WAKES IN THE A-RING

The quadrupole azimuthal asymmetry first discovered in the A-ring in visible light from the ground [Lumme and Irvine 1976; French et al. 2007] has been since observed with the Cassini remote sensing instruments [Colwell et al. 2006; Hedman et al. 2007; Thomson et al. 2007]. It is caused by the presence of self-gravity wakes forming in this ring close to the Roche limit. As trains of gravitationally bounded particles, separated by gaps of low optical depth [Salo 1995; Robbins et al. 2010], self-gravity wakes are expected to modulate both the filling factor of the instrument field of view and the ring observed temperature along azimuth. These structures were satisfactorily modeled as rectangular bars or elliptical cylinders mainly after the analysis of occultation data [Colwell et al. 2006; Hedman et al. 2007].

Ferrari et al. [2009] showed that the fit with azimuthal variation of the beta factor at different solar elevations was improved using the regularly spaced, infinitely long, opaque elliptical cylinders using the geometric filling factor from Hedman et al. [2007]. In the wake model of Morishima et al. [2014], the temperature distribution over the wake surface is calculated instead of considering the temperatures of individual particles. Wakes are approximately represented by opaque elliptical cylinders as adopted in Hedman et al. [2007] and Ferrari et al. [2009]. The model ignores inter-wake particles for simplicity. The surface of an elliptical cylinder is divided into multiple facets and interactions between facets (inter-wake mutual heating and multiple scattering of photometric light) are calculated using a radiosity method. The ring effective temperature is calculated by summing up the thermal emission from facets that can be seen from the observer.

SURFACE ROUGHNESS OF THE B-RING

Morishima et al. [2017] reanalyzed the seasonal variation of thermal phase curves for the B-ring, first found by Altobelli et al. [2009]. Morishima et al. [2017] approximated the B-ring as a slab covered by craters and the surface roughness of the B-ring was found to be moderate. The modeled phase curves of optically thick rings are shallow if the phase angle change is primarily due to change of observer azimuthal angle. On the other hand, the phase curves are steep if the phase angle change is due to change of observer elevation angle, as inter-particle shadows become visible at higher observer elevation. In addition, the area of shadowed facets increases with decreasing solar elevation angle. These combined effects explain the large seasonal change of the phase curve steepness observed for the B-ring.

Regolith properties deduced from CIRS emissivity roll-off

Ring particles are often assumed to be covered by tiny regolith grains. In rings with low volume filling factor *D*, ring properties can be relatively easily related to the particle and grain properties. Under this assumption, rings are clouds of particles and their thermal emission is a function of the individual particle properties. The ring emissivity can be retrieved from observations and compared to a model which links it to the average emissivity of individual particles and then regolith grains. Rings then are multi-scale worlds made of cm-to-m-sized particles themselves covered by μm-to-

cm-sized grains. Morishima et al. [2012] after the work of Spilker et al. [2005] in the earlier stages of the Cassini mission propose a model to interpret the ring emissivity in terms of regolith grain size and chemical composition.

THERMAL EMISSIVITY ROLL-OFF AT SUBMILLIMETER WAVELENGTHS

The infrared spectrometer provides the thermal radiance *I* (ν) of the ring as a function of wavenumber, ν. If the emissivity ε(ν) is assumed constant over a footprint, using a single temperature approximation, Spilker et al. [2005] derived the ring emissivity as:

$$\varepsilon(\nu) = I(\nu) / \left(\beta_{geo} B(\nu, T_0)\right)$$

where they obtained β_{geo} using Voyager Power & Pyrotechnics Subsystem (PPS) occultation data and the multilayer approximation. The spectral roll off occurs for $\nu < 50$ cm^{-1} for all rings.

While Spilker et al. [2005] analyzed a limited number of CIRS spectra measured in the very early stage of the Cassini mission from relatively large distances, Morishima et al. [2012] analyzed a much larger number of spectra more comprehensively. In their emissivity model, two warm and cold portions, with temperatures T_w and T_c, are considered where f_w is the fraction of the warm portion. A superposition of spectra with two different temperature portions produces a downward convex function of the emissivity when applied to a Planck fit with a single temperature. On the other hand, the emissivity spectrum of water ice has a downward convex function in far-infrared wavelengths. Because these two effects cancel each other out to some degree, degeneracy is generated between the retrieved emissivity spectrum and the temperature distribution. To avoid this issue, Morishima et al. [2012] applied simultaneous fits of the emissivity model parameters (grain sizes) and of hot and cold temperature distributions. They also derived β_{geo} using Cassini UVIS data, taking into account the spacecraft elevation dependence on the photometric optical depth.

The emissivity of Saturn's rings at far-infrared wavelength (Figure CIRS-15) is high basically because of absorption caused by intermolecular vibrations of water ice. A dip seen at 230 cm^{-1} corresponds to the maximum of the imaginary part of the refractive index of the water ice (transverse-optical mode). As found by Spilker et al. [2005], the emissivity decreases with decreasing wavenumber for $\nu < 50$ cm^{-1} because water ice becomes increasingly transparent at longer wavelengths (thus opening a view into the deeper ring particle). The exact wavelength of the roll-off is a strong function of the size of an individual particle, with larger particles having flatter emissivity as the geometric optics limit is approached. No one particle or grain size fits any spectrum and the emissivity is reflective of the collective distribution of ring particle and their regolith grain sizes.

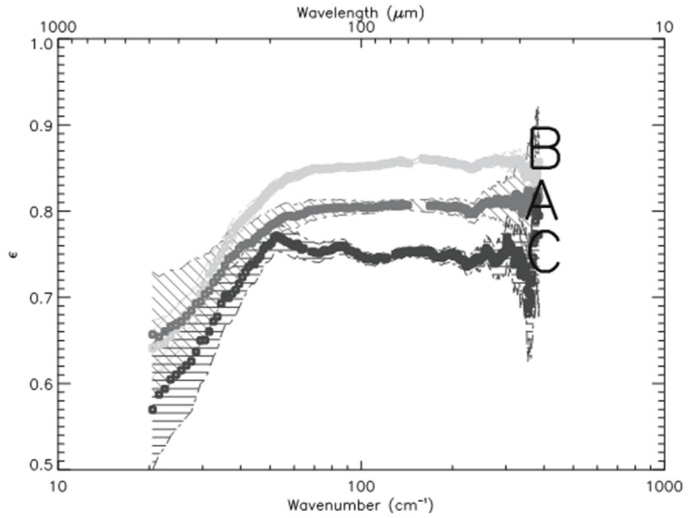

Figure CIRS-15. Emissivity spectra for the A-ring, B-ring, and C-ring. Figure from Spilker et al. [2005].

REGOLITH GRAIN SIZES INFERRED BY EMISSIVITY MODELING

A ring emissivity model was proposed by Morishima et al. [2012] to interpret the ring emissivity in terms of regolith grain size and chemical composition. The single scattering albedos of regolith grains are calculated using the Mie theory [Mie 1908; Bohren and Hoffman 1983], diffraction is removed with the delta-Eddington approximation [Joseph et al. 1976], and the hemispherical emissivities for macroscopic particles are calculated using Hapke's isotropic scattering model [Hapke 1993]. The composition of regolith grains is assumed to be pure water ice *Ih*. The intra-grain porosity of 0.7 is introduced to reproduce the shallow 230 cm^{-1} feature seen in the ring spectra in Morishima et al. [2012]. The maximum ring particle size that CIRS is sensitive to is estimated to be 1–100 cm in most of the rings, although the C-ring shows very different values of maximum grain size, and is dependent on the temperature of the ring. The median size is typically between 100 and 1000 μm. The reason for the temperature dependence of the estimated size distributions, particularly seen in the C-ring, is not clearly understood. Morishima et al. [2012] suggested that it is caused by the effect of eclipse cooling; only small grains are heated to very high temperatures.

The retrieved grain sizes are larger than those estimated from UVIS [Bradley et al. 2010, 2013] and VIMS [Nicholson et al. 2008; Cuzzi et al. 2009; Filacchione et al. 2012; Hedman et al. 2013] reflectances. An interpretation of this discrepancy is that large regolith grains are covered by small grains. At short wavelengths, the incoming light is primarily reflected by these small grains while at longer wavelengths the light can penetrate deeper into the regolith layers.

Exploring possible contaminants using CIRS spectra remains for future work, although the range of wavelengths covered by CIRS is not very suitable for this purpose due to strong water absorptions. Preliminary work [Edgington et al. 2008, unpublished] looked for the presence of silicates, carbon monoxide, and several other simple ices to no avail. This work also sought to determine the relative amounts of amorphous versus crystalline water ice. During Cassini's Solstice

Mission, a great many additional observations at high spectral and higher spatial resolution were acquired. Given this additional data, along with improved calibration of the CIRS data set, a proper statistical analysis and spatial trend analysis is warranteed to look for spatial variations in particle sizes and the presence of contaminant ring material. Another potential area of investigation would couple analysis of the longest wavelengths of the roll-off region with Titan Radar Mapper (RADAR) observations of the rings which probe the deeper particle cores.

Possible polarization effects have been studied. A few CIRS observations where designed to make use of the polarization nature of the FP1 interferometer (accomplished by rotating the spacecraft to three distinct orientations separated by 60°) to look for polarization effects in the far-IR. Theoretically possible with non-spherical thermal emitters, the data were inconclusive as observed patterns could be explained by other physical effects such as thermal opposition surges. These individual observations do not take into account the advantage that the entire CIRS FP1 data set picks off a particular polarization direction. The possibility that there is a polarization signal hidden in the global data set remains to be seen.

Conclusions and future work

Considering the Cassini CIRS data set in its entirety showed us that the ring can be characterized as a thermal system whose properties result from multi-scale phenomena, including the physical properties of individual particles as well as large-scale interactions, resulting in shadowing and thermal transport across the ring. Future analysis will aim at combining the global approach yielding empirical models of the ring thermal behavior, with the forward modeling of individual particles, such as to reject solutions possibly acceptable at one scale but not at the other. The key CIRS ring results are discussed in the next several paragraphs.

The global modeling of all measurements obtained over the illuminated rings yields radial profiles of the ring emissivity and albedo with the highest spatial resolution ever achieved in the thermal infrared. The anisotropy of the temperature distribution with viewing geometry, and in particular the effect of mutual shadowing between particles in regions with higher optical depth, is directly inferred from the global empirical modeling. Thermal surges at low phase angle, most likely resulting from shadow hiding, have been observed in all ring regions, except those with the lowest optical depth like the C-ring background. A contribution to shadow hiding from the particle's regolith cannot be excluded, in particular if regolith properties are driven by the frequency of particle collision, correlated with the ring optical depth. Combining the empirical model of the ring, constrained by all measurements, with dynamical simulations and with realistic temperature distributions on irregular, regolith covered icy surfaces, is the next logical step to disentangle the large-scale properties of the rings from those of its individual constituents.

There is a correlation between the bolometric Bond albedo and the ring optical depth. This is also found by photometric observations and is probably produced by meteoritic bombardment. The areal fractions of fast and slow rotators are similar to each other, although the fast rotator's fraction is larger for thin rings. This produces large range of size distributions for thin rings. A large fraction

of fast rotators is seen in the outer A-ring, suggesting enhanced impact velocities in this region, possibly due to satellite perturbations or strong self-gravitational wakes.

The diurnal thermal inertia is estimated to be about 10 J m^{-2} K^{-1} $s^{-1/2}$ for all the main rings from eclipse cooling data, although the Cassini division shows the lowest values. The low diurnal thermal inertia may indicate a very fluffy surface regolith layer. The thermal skin depth associated with eclipse cooling is on the order of 1 mm. The seasonal temperature variations can provide constraints on thermal inertia of deep interiors of particles, if they do not completely cool down at equinox to their equilibrium temperatures that are determined by the flux from Saturn only. The equinox temperature of the middle A-ring is found to not completely cool down. The seasonal thermal inertia of the middle A-ring particles is estimated to be 30–50 J m^{-2} K^{-1} $s^{-1/2}$, while it is as low as the diurnal thermal inertia for the outer and inner parts of the A-ring. The ring particles in the middle A-ring are likely to have a dense core under a thin fluffy regolith mantle. This indicates that unknown mechanisms confine dense particles in the middle A-ring or that the A-ring has been recently formed (~100 million years) by destruction of a pre-existing icy satellite. The seasonal thermal inertia of the thick B-ring is also found to be of the order of 30–50 J m^{-2} K^{-1} $s^{-1/2}$, assuming no heat transport by the vertical motion of particles. The seasonal inertia of particles in this multi-scale approach is found to be much larger, about 160–200 J m^{-2} K^{-1} $s^{-1/2}$, and the difference is due to the ring porosity that limits heat transfer through the solid phase. At this stage more effort is needed to understand why the thermal inertia of particles is so low, how heat transfer actually happens at their scale, and how deep the thermal waves are actually penetrating and sounding the particles on short and long timescales. Seasonal thermal effects should be able to probe particle interiors. But current thermal models, which attempt to explore them, are still facing an abnormally high porosity which yields a very low bulk density.

The ring particles in the middle A-ring are likely to have a dense core under a thin fluffy regolith mantle.

The particle properties are mostly derived using the multi-particle-layer model of Morishima et al. [2009], which ignores any effects of particle clumping (i.e., finite volume filling factor of a ring). Although this model can reproduce temperatures observed at various observational geometries, it does not accurately model the data in some cases. These failures are most likely all related to effects of particle clumping. Models that handle the effects of particle clumping are also discussed. In models of geometric filling factor and temperature of the A-ring, wakes are represented by elliptical or rectangular cylinders. These models can reproduce azimuthal modulations of geometric filling factor or temperature. The ratio of the vertical thickness to the horizontal width of wakes estimated from CIRS data at the middle A-ring is found to be slightly larger than those from stellar occultations.

Thermal opposition surges are seen in the dense A-ring and B-ring, and C-ring plateaus, but not in C-ring backgrounds. The volume filling factors estimated from the phase curves near the opposition are 0.2 and 0.4 for the A-ring and B-ring and 0.001–0.01 for the C-ring plateaus. The

temperature difference between the lit and unlit faces of the B-ring suggests very efficient heat transport is taking place from the lit face to the unlit face. The multilayer model can reproduce the lit–unlit face temperature difference if ring particles have vertical motion. In the densest part of the B-ring, particles likely bounce near the mid-plane. The lit–unlit face temperature can also be reproduced by a slab-type model in which vertical heat transport is taking place primarily by radiation and conduction, provided ring particles are isothermal. This model also yields a volume filling factor for the B-ring consistent with that estimated from opposition effects, i.e., on the order of 0.3.

The models that take into account the effects of particle clumping are only applicable to rather specific data sets. Universal models that are applicable to various geometries are required. A possible new model is one that directly uses the outputs of *N*-body simulations. Ray-tracing models that are applicable to photometric observations of packed particulate mediums have been developed by several authors [Salo and Karjalainen 2003; Porco et al. 2008; Ciarniello et al. 2015]. Modeling of thermal infrared emission using packed particulate mediums is much more complicated because various heat sources need to be included such as mutual heating. In addition, since the problem is time-dependent (particle spins and particle motion), radiative transfer needs to be solved at every time-step. Full modeling is very challenging and some approximations may be necessary for the first step.

Analysis of CIRS data using currently existing models also have not been fully conducted. For example, we do not clearly know the radial variation of the diurnal thermal inertia. The spatial resolution of the data that we have used were also limited. A part of the issue may be resolved by using FP3 data in addition to FP1 data. FP3 data have so far been used only for the opposition surge of the outer C-ring. During the final phase of the Cassini mission, the spacecraft's orbit carried it high above the planet's north pole and then sent it plunging between the planet and the innermost edge of its rings. In this orbital geometry, the Cassini spacecraft flew closer to some of Saturn's rings than ever before, and this encounter provided unprecedentedly high spatial resolution data. The CIRS instrument resolved some fine structures such as the F-ring, Cassini division, and C-ring plateau region, even with FP1. Future work will also include multi-analysis of data from multiple instruments, combining other temperature indicators provided by the VIMS for the top surface layer, and microwave radiometry for the interior of the particles.

CIRS emissivity spectra give constraints on sizes of regolith grains. The deduced sizes range from 1 μm to 10 cm and are on average larger than those estimated from data at short wavelengths. This may suggest that large grains are covered by small grains or that regolith structure is fractal. Modeling of such structures remains for future work, as does the effect of possible contaminants on CIRS spectra.

Other studies that are related to thermal emission but have not been covered by the present review are orbital migration of ring particles due to thermal effects that include the Yarkovsky effect, the Yarkovsky–Schach effect, and the Pointing–Robertson effect [Rubincam 2006; Vokrouhlický et al. 2007]. Vokrouhlický et al. [2007] found that the total torques on ring particles due to these effects are negative for all rings with a plausible range of thermal parameters that

are consistent with those reviewed in Spilker et al. [2018]. CIRS data of Saturn's rings will be analyzed for decades to come.

Titan

This section contains an introduction which outlines the broad nature of Titan's atmosphere and crust and the nature of thermal emissions from the gases, particulates and surface. Following the introduction is a discussion describing the typical means of modeling Titan spectra to retrieve information, the CIRS Titan science results and their implications organized by the CIRS science objective, the science assessments, and the conclusions and future work. See also book chapters and reviews that include CIRS results [Bézard 2009; Bézard et al. 2013; Flasar et al. 2009, 2014; Lebonnois et al. 2014; Lorenz et al. 2009; Strobel et al. 2009].

Introduction

Titan is the second-largest moon in the solar system (diameter 5150 km), the largest moon of Saturn, and the only moon with a significant atmosphere. The atmosphere is now known to have a bulk composition of ~94.5–98.5% nitrogen (N_2) and 5.5–1.5% methane (CH_4) [Niemann et al. 2010]. With a surface pressure of ~1.5 bar and temperature of ~90 K, and a similar molecular weight to Earth's air, the surface atmospheric density is almost 5× denser than Earth's according to the ideal gas equation. However due to the lower gravity, the scale height (*RT/Mg*) is much greater than Earth (~45 km versus 11 km) leading to a greatly extended atmosphere (~1500 km to the exobase [Yelle et al. 2008]). Titan is tidally locked to Saturn, orbiting with a 15.95-day period, and a substantial eccentricity of 3%. Titan's obliquity relative to Saturn is near-zero, leading to identical solar insolation cycle and seasons.

Titan is the second-largest moon in the solar system (diameter 5150 km), the largest moon of Saturn, and the only moon with a significant atmosphere.

ATMOSPHERIC STRUCTURE

Titan has a mild greenhouse (21 K) and anti-greenhouse effect (9 K) [McKay et al. 1991] leading to a surface temperature of 94 K, considerably warmer than the predicted effective temperature (82 K) for an airless body at 9.5 AU. The greenhouse effect arises from the long-wavelength opacity at ~25–200 μm from collisions primarily of N_2 and CH_4 molecules. The anti-greenhouse effect is due to the high-altitude hazes and condensates that absorb and reflect sunlight in the visible and UV, while being almost transparent in the thermal infrared. Due to these effects, Titan has a similar atmospheric structure to the Earth although caused by different gases. Convection in the lower atmosphere leads to decreasing temperatures up to the tropopause (~45 km, 70 K) with temperatures increasing again in the stratosphere, due to solar heating from methane and aerosols,

up to a well-defined stratopause at ~300 km. Above this altitude the temperature falls through the mesosphere (300–550 km) due to enhanced gas and aerosol cooling, and rises through the thermosphere (550–850 km) due to non-local thermodynamic equilibrium (non-LTE) processes. Above this homopause altitude gases begin to separate and have different scale heights, and ionization has a major effect up to the exobase (1500 km) where gases may escape to space due to Jeans escape [Hunten 1973], sputtering [De La Haye et al. 2007] and possibly slow hydrodynamic escape [Strobel 2008; Yelle et al. 2008].

Titan's global circulation in the stratosphere is dominated by single or dual cell meridional circulations. Following the solstices, warm air in the summer hemisphere rises (to 400–500 km) and circulates to the winter pole, where it cools and descends. Adiabatic compression leads to a hot, elevated stratopause, and a much cooler stratosphere beneath. Near to the equinoxes, a two-cell circulation is briefly in existence, with rising warm air at the equator forming two high-altitude circulation branches towards either pole.

ATMOSPHERIC CHEMISTRY

The dual action of solar UV (primarily Lyman α) and charged particle bombardment (primarily electrons) from Saturn's magnetosphere photolyzes the major atmospheric gases—N_2 and CH_4—leading to radicals of N, C, CH, CH_2, and CH_3 and associated ions. These react and recombine forming larger molecules—primarily hydrocarbons (C_xH_y) and nitriles ($C_xH_y(CN)_z$). The primary photolysis product of methane is ethane (40%, [Wilson and Atreya 2009]):

$$2\,CH_4 + 2\,h\nu \rightarrow C_2H_6 + H_2,$$

leading to escape and permanent loss of hydrogen. Other major photolysis products are acetylene (C_2H_2) and HCN. Small amounts of oxygen reaching Titan mostly from Enceladus lead to trace amounts of CO_2 and H_2O, and a larger amount of CO (50 ppm), which is very long-lived and accumulates over time.

These chemicals diffuse or are transported downwards, creating a vertical concentration gradient that is normally positive upwards. In the cold lower stratosphere, most gases reach saturation and condense onto haze particles (next section), using these as condensation nuclei, and falling out of the atmosphere towards the surface (some re-evaporation may occur). The tropopause thus acts as a cold trap for both methane in the upward sense, and other gases in the downward sense. The few non-condensing gases are: N_2, H_2, CO, and C_2H_4, plus light noble gases (Ne, Ar).

Due to the Hadley circulation (previous section) the minor gases are entrained, and become decaying tracers of atmospheric motions with lifetimes varying from hours to decades or longer. Many minor gas species are highly enriched in the stratosphere over the winter pole, as first detected by Voyager.

PARTICULATES

Two types of particulates are common in Titan's atmosphere: 1) aerosols, defined for our purposes as photochemically-produced microscopic organic particles and assumed to be agglomerations of macromolecules bonded by Van Der Waals forces as seen in terrestrial smog, smoke and laboratory simulations (tholins); and 2) condensates (liquid and solids) formed by condensation of trace gases (methane, ethane, etc.) into small droplets (liquid) or grains (ice) similar to terrestrial tropospheric and stratospheric clouds. Condensates can be, and likely are, mixtures of several molecular types with similar freezing/boiling points. Further grain-surface photochemistry may change the composition (see the section entitled Surface).

SURFACE

Titan's surface was only coarsely imaged as late as 1996 [Smith et al. 1996] using the Hubble Space Telescope (HST), and subsequently with ground-based telescopes employing adaptive optics. Detailed imaging awaited the Huygens probe, which descended to Titan's surface in 2005 [Tomasko et al. 2005]. The Cassini orbiter followed up with mapping at visible (ISS), near-IR (VIMS) and RADAR wavelengths; the latter providing the most detailed morphological picture. RADAR was the key to discovering Titan's dune fields [Lorenz et al. 2006], polar lakes and seas [Stofan et al. 2007], and surface cratering [Neish and Lorenz 2011]. Overall, Titan's topography remains low in relief [Lorenz et al. 2013], with the tallest surface prominences reaching only 1.4 km [Lopes et al. 2013]. Proposed geologic activity remains controversial [Nixon et al. 2018]. Key goals for CIRS included measurement of an expected equator-to-pole thermal gradient and diurnal variation due to insolation effects, and any possible local differences over the seas, dunes and impacted terrain (Xanadu) due to differences in altitude and thermal inertia, related to porosity and composition.

Spectral modeling and inversion

Once CIRS spectra have been calibrated, and usually averaged together (co-added) to increase the signal-to-noise (S/N) ratio, they are modeled using a radiative transfer program to retrieve atmospheric quantities such as temperature, gas abundances, and particle column densities. The CIRS team used multiple radiative programs—for example, ARTT Coustenis et al. [2007], NEMESIS Irwin et al. [2008]—and other modeling codes developed at the University of Maryland, Paris Observatory, NASA Goddard Space Flight Center (GSFC), and elsewhere, to retrieve atmospheric and surface information.

The process of modeling a spectrum usually follows these principal steps:

1. Define a reference atmospheric profile of vertical temperature, gas abundances, and particle sizes and number densities.

2. Run a forward model for the reference atmosphere and compare to the CIRS spectrum.

3. Adjust model parameters (reference atmosphere) iteratively and rerun forward model, until a fit to the spectrum is obtained, usually defined as reaching the noise threshold, or some other pre-determined measure of convergence.

In many cases, atmospheric gas abundances are obtained in a two-step process: (i) model the emission of a well-mixed gas of known (or assumed) abundance (often methane) to retrieve atmospheric temperatures; and (ii) fix the temperature profile and model other parts of the spectrum to obtain gas abundances. However, this paradigm is often modified by assuming or ingesting temperatures from other sources such as the Huygens probe, or radio occultation measurements. In other cases, gas or particle abundances and temperatures are obtained simultaneously.

Steps of the model process are described in the following section.

REFERENCE ATMOSPHERE

The first step is to construct an initial model atmosphere that includes temperature profiles and vertical profiles of gases and aerosols. An excellent starting point is the vertical profile data recorded by the Huygens probe, which provided in situ measurements at the landing site coordinates (10.3° S, 192.3° W) of Titan's temperature profile, gas abundances, and an aerosol altitude profile below 150 km [Fulchignoni et al. 2005; Niemann et al. 2010; Tomasko et al. 2005]. Further reference temperatures profiles are available from Cassini CIRS [Achterberg et al. 2008a, 2011] and radio occultations [Schinder et al. 2011a, 2012]. The temperature profiles are combined with trial gas abundances based on previous measurements or photochemical model predictions to create an a priori (initial-guess) profile for Titan's atmosphere.

FORWARD MODEL

The outgoing spectral radiance along a single atmospheric path is obtained by evaluating the Schwarzchild integral for emission:

$$I_{\tilde{\nu}} = \int_0^{z_\infty} \frac{\partial \tau_{\tilde{\nu}}(z_\infty, z)}{\partial z} B_{\tilde{\nu}}\big(T(z)\big) dz, \qquad \text{(Eq. 1)}$$

where $I_{\tilde{\nu}}$ is the outgoing radiance, $\tau_{\tilde{\nu}}$ is the transmittance from height z to the top of the (sensible) atmosphere at height z_∞, $B_{\tilde{\nu}}(T)$ is the Planck function (local thermodynamic equilibrium, or LTE, as assumed), and the subscript $\tilde{\nu}$ indicates wavenumber. Including the surface with an emissivity ε_s, and dropping the wavenumber subscripts for convenience, the outgoing intensity is:

$$I = \int_0^{z_\infty} \frac{\partial \tau(z_\infty, z)}{\partial z} B\big(T(z)\big) dz + \varepsilon_s B(T_s)\tau_s + (1-\varepsilon_s)\tau_s \int_{z_\infty}^{0} \frac{\partial \tau(0,z)}{\partial z} B\big(T(z)\big) dz, \qquad \text{(Eq. 2)}$$

where τ_s is the transmittance evaluated from the surface to the top of the atmosphere. Note that the third term accounts for the down-welling radiation which is reflected from the surface and suffers extinction on return; this term vanishes when the surface emissivity is unity. The transmittance is defined as: $\tau_{\tilde{\nu}} = \exp(-\chi_{\tilde{\nu}})$ where $\chi_{\tilde{\nu}}$ is the spectral opacity due to all sources in the atmosphere

integrated over the path. The radiative transfer program evaluates the discretized form, replacing the integral by a summation over *N* atmospheric layers, e.g., for unit surface emissivity:

$$I_\infty = B_s\tau_{N_L} + \sum_{l=1}^{N_L}\left[B_l exp\left(-\sum_{i=1}^{l}\Delta\chi_i\right)\right]. \quad \text{(Eq. 3)}$$

The opacity increment at each layer $\Delta\chi_i$ is typically the sum of three sources: $\Delta\chi_i = \Delta\chi_{L,i} + \Delta\chi_{C,i} + \Delta\chi_{P,i}$, which are the opacities due to spectral lines, collision-induced absorption (CIA) and particles, respectively. These are:

$$\Delta\chi_{L,i}(\tilde{\nu}) = \sum_{j=1}^{N_g}\left[k_j(\tilde{\nu})q_{ij}\right]\rho_i\,\Delta z_i \quad \text{(LINES)} \quad \text{(Eq. 4)}$$

$$\Delta\chi_{C,i}(\tilde{\nu}) = \sum_{j=1}^{N_g}\sum_{k=1}^{N_g}\alpha_{jk}\,(\tilde{\nu})q_{ij}q_{ik}\left(\frac{p_i}{p_0}\right)^2\left(\frac{T_0}{T_i}\right)^2\Delta z_i \quad \text{(CIA)} \quad \text{(Eq. 5)}$$

$$\Delta\chi_{P,i}(\tilde{\nu}) = \sum_{j=1}^{N_P}\sigma_j\,(\tilde{\nu})n_{ji}\Delta z_i \quad \text{(PARTICLES)} \quad \text{(Eq. 6)}$$

where *kj* is the absorption co-efficient (per unit mass) due to spectral lines for the j^{th} of N_q gases in the atmosphere, q_{ij} is the volume mixing ratio of each gas at each level, ρ_i is the total atmospheric mass density of the layer, Δz_i is the thickness of the layer, α_{jk} is the spectral CIA coefficient for the (*j,k*) gas pair normalized to nominal pressure p_0 and temperature T_0, p_i and T_i are the pressure and temperature of the layer respectively, σ_j is the extinction cross-section of the j^{th} particle type and n_{ji} is the number density of each particle type in the layer. The exact method of computing the spectral line absorption coefficient *k* varies: it may be a line-by-line model, or more usually a band model of correlated-k technique, which preserves accuracy but at much shorter computational time.

SPECTRAL LINE DATA

Infrared spectral line data are taken from the standard line atlases: GEISA [Jacquinet-Husson et al. 2016] and/or HITRAN [Rothman and Gordon 2013], supplemented by additional line lists provided by colleagues for some gases and bands that have been measured recently, but not yet included in the standard atlases. The CIA coefficients of are those of Borysow and colleagues as detailed in [Teanby et al. 2006b]. Extinction cross-sections for stratospheric aerosols are often based on laboratory tholin coefficients measured by Khare et al. [1984a, 1984b], but more recent laboratory work and CIRS-derived coefficients are now available [Khare et al. [1984a, 1984b]. A list of principal detected infrared bands is given in Table CIRS-5. See also Figure CIRS-16.

Table CIRS-5. Principal gases in Titan's stratosphere, and infrared spectral bands seen by Cassini CIRS.

	Gas Name	Chemical Formula	Emission Bands Detected in Mid-/Far-IR (center or range in cm^{-1})	VMR (equator at 5 mbar)
Major Species	Nitrogen	N_2	~100 (collision-induced opacity)	9.85×10^{-1}
	Methane	CH_4	60–140 (pure rotations); 1304 (n4)	1.40×10^{-2}
	Argon	*Ar*	*none*	
	Hydrogen	H_2	355 and 585 (dimers)	1.00×10^{-3}
Hydrocarbons	Acetylene	C_2H_2	729 (n5)	3.00×10^{-6}
	Ethylene	C_2H_4	949 (n7)	1.50×10^{-7}
	Ethane	C_2H_6	822 (n9), 1379 (n6), 1468 (n8)	1.00×10^{-5}
	Propyne	C_3H_4	328 (n10), 633 (n9)	7.00×10^{-9}
	Propene	C_3H_6	913 (n19)	$2{:}00 \times 10^{-9}$
	Propane	C_3H_8	748 (n21), 870 (n8), 922 (n16), 1054 (n15), 1158 (n7), 1376 (n13), 1472 (n19)	5.00×10^{-7}
	Diacetylene	C_4H_2	220 (n9), 628 (n6)	1.40×10^{-9}
	Benzene	C_6H_6	674 (n4)	5.00×10^{-10}
Nitriles	Hydrogen Cyanide	HCN	40–100 (pure rotations), 712 (n2)	1.00×10^{-7}
	Cyanoacetylene	HC_3N	499 (n6), 663 (n5)	4.00×10^{-10}
	Cyanogen	C_2N_2	233 (n5)	(north only)
Oxygen Species	Carbon Monoxide	CO	50–100 (pure rotations)	4.50×10^{-5}
	Carbon Dioxide	CO_2	667 (n2)	1.40×10^{-8}
	Water	H_2O	80–300	1.00×10^{-10}

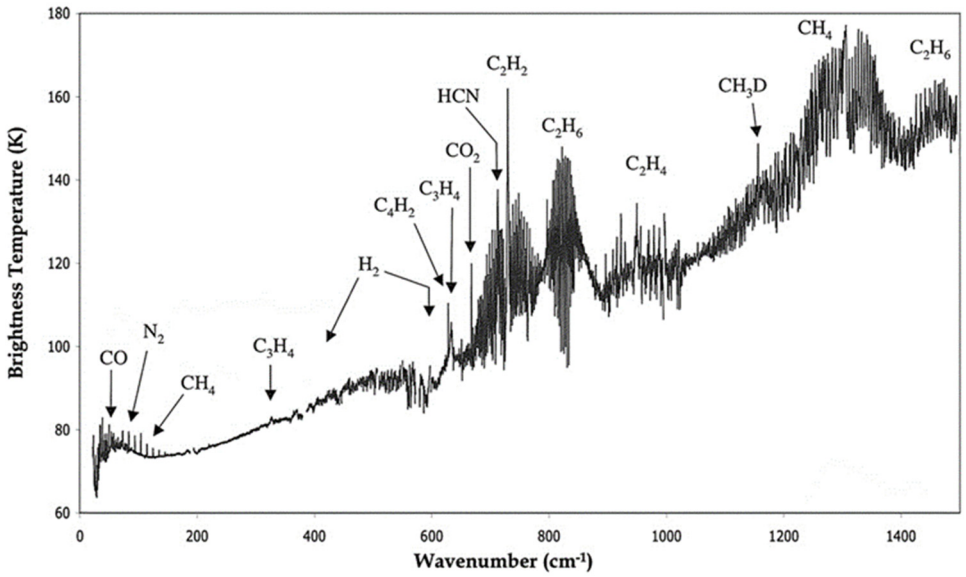

Figure CIRS-16. A complete composite unapodized CIRS spectrum in brightness temperature taken during TB at medium resolution (1.7 cm^{-1}) at mid-latitudes. Figure from Coustenis et al. [2007].

RETRIEVAL/INVERSION

Coupled to the forward model, many radiative transfer models also include a retrieval (or inversion) methodology—for example, Rodgers [2000], which attempts to find the set of model parameters $\underline{x}$ which best fits the spectral data, $\underline{y}$. The measurement process may be written as: $F(\underline{x}) = \underline{y} + \varepsilon$, where F is the physics and ε is the measurement error. The inverse problem is therefore to find a self-consistent atmospheric state $\underline{\hat{x}}$ such that $F(\underline{\hat{x}}) = \underline{y} \pm \varepsilon$. The retrieval proceeds by defining a goodness of fit metric similar to a chi-squared test, and sometimes called the cost function, that is minimized to achieve a best fit atmospheric state $\underline{\hat{x}}$; e.g., the cost function ϕ used by NEMESIS:

$$\phi = \left(\underline{y} - F(\underline{\hat{x}})\right)^T \underline{S}_{\varepsilon}^{-1} \left(\underline{y} - F(\underline{\hat{x}})\right) + (\underline{\hat{x}} - \underline{\hat{a}})^T \underline{S}_a^{-1} (\underline{\hat{x}} - \underline{\hat{a}}), \quad \text{(Eq. 7)}$$

is comprised of two terms, the first being the traditional χ^2 difference between the model and data spectra, while the second is a constraint term that is proportional to the square of the deviation between the solution vector and the a priori (best-guess) vector $\underline{\hat{a}}$, required to obtain a solution to the ill-posed problem. The retrieval procedure iterates to solve the non-linear problem, until the cost function or other fitness measure ceases to decrease appreciably (converges). This combination of forward model and retrieval scheme is a powerful tool to retrieve values and error estimates for the temperature, gas abundance profiles, and haze opacities from CIRS spectral data.

Titan's surface

Titan's surface temperature can be directly sensed in the far-infrared through a window of low opacity near 530 cm^{-1} (19 μm), as discovered by Voyager 1 [Flasar et al. 1981; Hanel et al. 1981; Samuelson et al. 1981]. This wavelength is sensed by CIRS FP1, which being a single pixel of relatively large angular diameter, places some limits on resolution and mapping capability. Nevertheless, CIRS was able to significantly expand on the science of Voyager, giving global context for the Huygens measurements, and comparison for RADAR temperature measurements at longer wavelengths [Janssen et al. 2009].

LATITUDINAL VARIATION

The first surface temperature results from CIRS were published by Jennings et al. [2009], who averaged data from 43 flybys of the prime mission (2004–2008). They found T = 93.7 ±0.6 K at the Huygens landing site, in good agreement with the in situ measurements, and also the maximum recorded at any latitude. The temperature decreased to 90.5 ±0.8 K at 87° N and 91.7 ±0.7 K at 88° S, in broad agreement with the season (late northern winter).

TEMPORAL CHANGES

Jennings et al. [2011] followed up on the earlier work, showing the first time-resolved measurements covering two time periods: 2006–2008 (L_S = 335°) and 2008–2010 (L_S = 0°), the latter coinciding with northern spring equinox (NSE) in 2009. By the time of NSE, the temperature distribution had become symmetric, with polar temperatures in both hemispheres leveling off at ~91 K, and an equatorial maximum of 93.4 K. A slight phase lag relative to solar insolation of ΔL_S ~9° was recorded, consistent with the observations of Voyager 1, and general circulation modeling (GCM).

Cottini et al. [2012b] followed up with a comprehensive analysis of data from 2004–2010, this time dividing the data temporally into three two-year periods. Agreement with HASI was again noted at the Huygens landing site, and changes of several degrees near the poles were in good agreement with Jennings et al. [2011]. Cottini et al. [2012b] were also able to detect diurnal variations in surface temperature, based on data from −20° to +20° latitude. A slow warming of ~1 K was observed from daybreak to late afternoon, followed by a plateau, and then a more rapid cooling from midnight to dawn. By comparing to models from Tokano [2005], the authors found consistency with a thermal inertia of 300–600 J m^{-2} $s^{-1/2}$ K^{-1} and albedo 0.3, in agreement with a surface crust of porous icy material.

A surface temperature update was published by Jennings et al. [2016], who divided the period 2004 to 2014 into five two-year periods (Figure CIRS-17). During this time the north polar temperature rose by about 1 K from 90.7 ±0.5 to 91.5 ±0.2 K, while that at the south pole dropped by a larger amount from 91.7 ±0.3 to 89.7 ±0.5 K. The low latitude temperature maximum stayed constant at 93.65 ±0.15 K, while moving northwards from 19° S to 16° N. In general, temperature changes were in agreement with GCM models, excepting in the north polar regions from 2014 onwards, where the rise was about 1 K less than expected. This anomaly was tentatively attributed to surface cooling through increased precipitation and methane evaporation. Recently Jennings et al. [2019] extended the analysis to the end of mission in September 2017.

VARIATION WITH TOPOGRAPHY AND TERRAIN

A search for localized temperature differences has been made by members of the CIRS team including V. Cottini and D. E. Jennings, including over the northern lakes/seas, and over low-latitude albedo features such as Xanadu with no conclusive evidence to date—unlike the thermal anomalies seen by RADAR [Janssen et al. 2009]. This has been attributed to the much lower S/N and larger spatial resolution footprint of CIRS that may not be sufficient to see small temperature contrasts over small features, including lakes and seas.

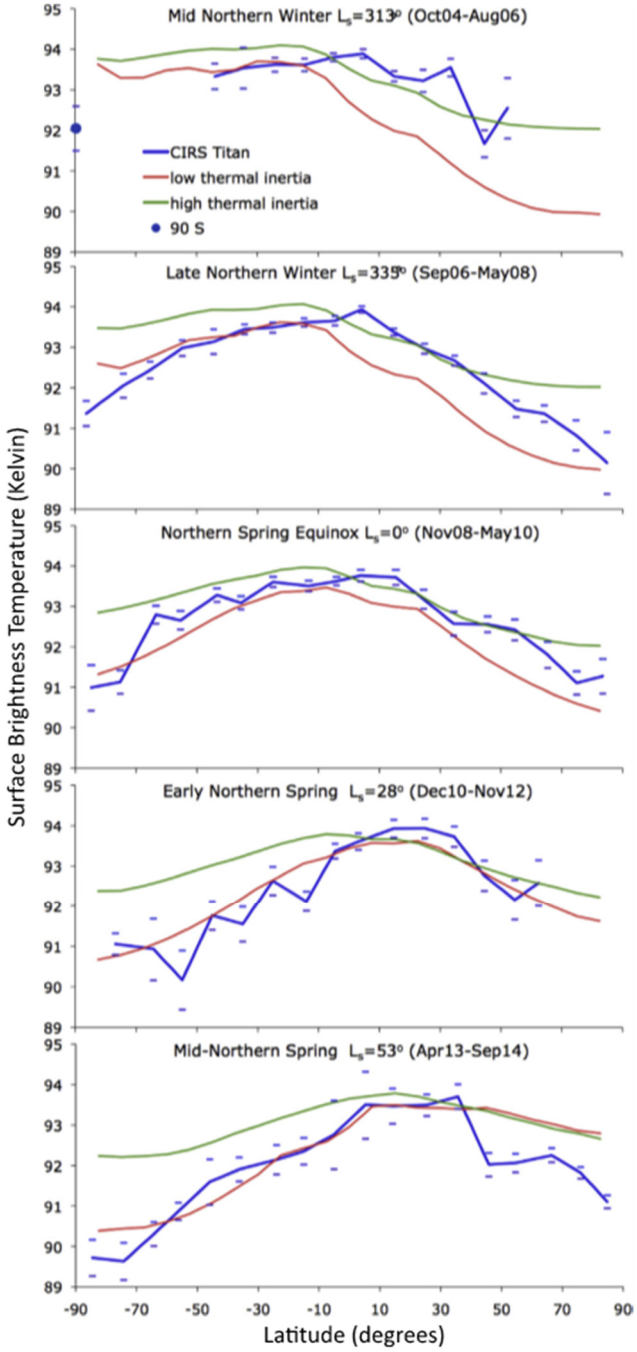

Figure CIRS-17. Measured surface brightness temperatures (blue) on Titan compared with GCM predictions, for five approximately two-year periods during the Cassini mission. The error bars are two standard deviations, calculated from the average that produced each data point. Variation in the size of the error bars is due primarily to differences in the number of spectra averaged. The two GCM curves [Tokano 2005] correspond to low thermal inertia (red) and high thermal inertia (green). Two of the periods, L_S = 313° and 28°, did not have sufficient data to completely map the high latitudes. The single data point at 90° S for L_S = 313°, added here to extend the coverage to the south pole, was from June 6, 2005. Figure from Jennings et al. [2016].

Atmospheric dynamical state

CIRS has mapped Titan's atmospheric temperatures primarily through two spectral regions: the ν_4 band of methane centered on 1305 cm^{-1} (visible on FP4) that sense the stratosphere, and the far-infrared (100–400 cm^{-1}) that gives temperatures in the troposphere. By assuming abundances of CH_4 and H_2, typically from Huygens Gas Chromatograph Mass Spectrometer (GCMS), the temperatures may be retrieved. Temperature (and gas abundance) retrievals use either one of two observing geometries: nadir viewing, where the sightline intercepts the surface, although not necessarily normal (90° to surface); and limb, where the line of sight passes above the surface (tangential). Limb viewing is often preferable for two reasons: (i) the emission is usually strongly localized at the tangent point altitude, allowing for more precise altitude sensing; and (ii) the longer path length compared to nadir viewing increases S/N, allowing retrievals to proceed to higher altitudes.

Limb viewing on Titan encounters a problem not usually significant on the Earth: the larger scale height of the atmosphere causes the depth of the sensible atmosphere to be greatly extended relative to the solid body diameter. This means that the weighting function extends significantly to either side of the tangent point, and therefore latitudinal/longitudinal variations in composition and temperature are important. This causes problems for 1-D radiative transfer models (such as NEMESIS), which cannot capture the 2-D nature of the problem (Figure CIRS-18), although at least one full 2-D temperature retrieval model has now been developed [Achterberg et al. 2008a].

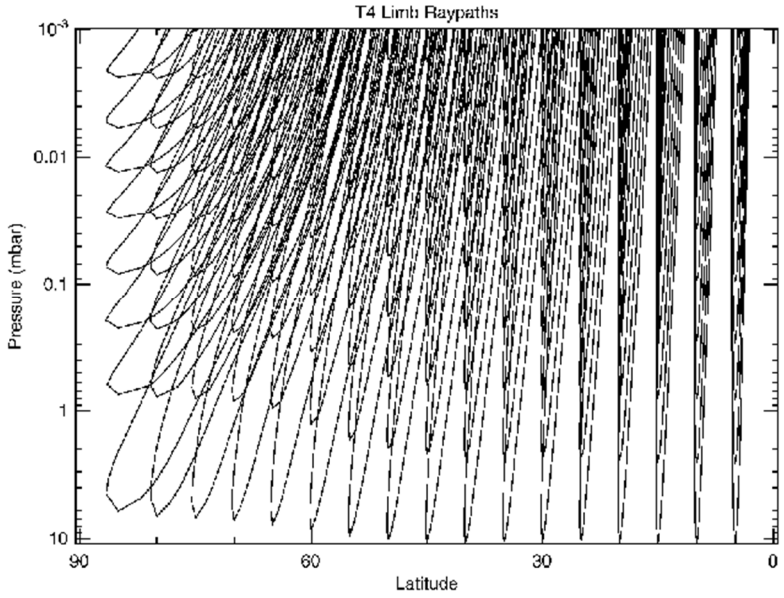

Figure CIRS-18. Ray paths for limb measurements acquired on the T4 Titan flyby, illustrating the nature of the 2-D retrieval problem. Tangent views towards high latitudes traverse a significant range of latitudes. The equatorward branch of each trajectory extends from the spacecraft to the tangent point of the ray, while the poleward branch is the extension of the ray path beyond the tangent point. Figure from Achterberg et al. [2008a].

GLOBAL TEMPERATURE MAPPING

The first maps of Titan's global temperatures were published by Flasar et al. [2005a], showing the first Titan results from Cassini CIRS. The stratopause was distinct at ~310 km (186 K) at low latitudes, and showed a cooling of 4–5 K towards the south pole. The northern hemisphere above 60° N was not measured. Shortly thereafter, Huygens HASI results [Fulchignoni et al. 2005] were to show disagreement with the CIRS low latitude stratopause altitude, a discrepancy that has long persisted, although may recently have been resolved [Lellouch et al. 2014].

The first and so-far only model to successfully retrieve the 2-D atmospheric structure on Titan was devised by Achterberg et al. [2008a]. The authors showed the significant errors that can occur in 1-D models, by comparing to a fully 2-D model (Figure CIRS-19). Temperatures were retrieved from 90° S to 60° N and 5 to 0.2 mbar from nadir mapping data, and from 75° S and 85° N and 1 to 0.005 mbar from limb data. The higher-altitude limb data allowed the stratopause to be fully captured, and showed that it was 20 K warmer in the northern polar atmosphere than at low latitudes (<40° N) and higher by about 100 km (0.01 mbar N polar, versus 0.1 mbar low latitudes) (Figure CIRS-20). This is in agreement with GCM models [Lebonnois et al. 2009, 2012] that predict subsidence in the stratosphere over the winter pole and consequent adiabatic warming.

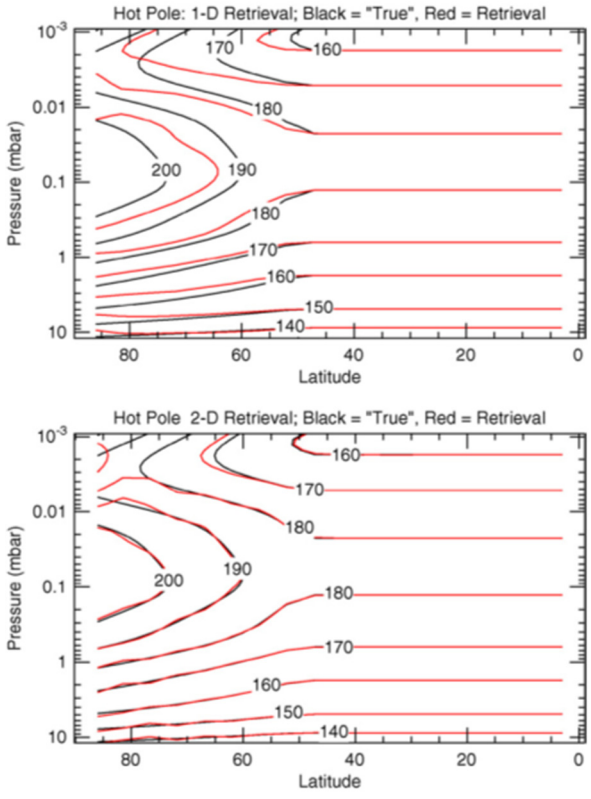

Figure CIRS-19. One- and two-dimensional retrieval results on synthetic data with a warm pole. The one-dimensional retrieval does not recover the polar warm spot well. Figure from Achterberg [2008a].

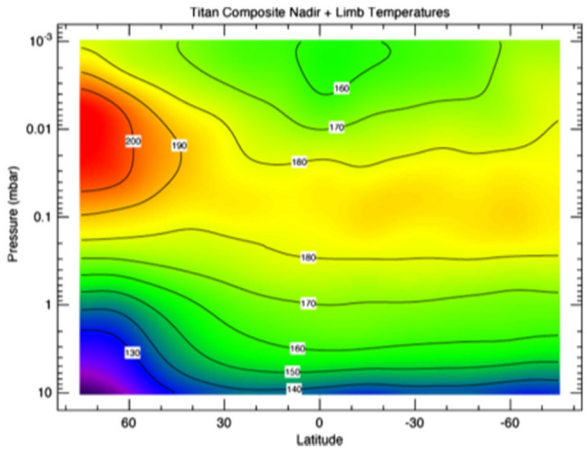

Figure CIRS-20. Zonal mean temperatures from all limb and nadir maps. Retrieved temperatures were averaged in 5° latitude bins, then smoothed with a 10° boxcar function applied three times. Contours are labeled in K. Figure from Achterberg et al. [2008a].

Winds and Jets

The first CIRS derivation of the stratospheric wind was shown in Flasar et al. [2005a], with zonal winds reaching 160 m/s in mid-northern latitudes above 200 km (1 mbar). Achterberg et al. [2008a] also applied the thermal wind equation to derive zonal winds, finding a jet of 190 ms^{-1} at 30–60° N, and peaking near 1 mbar (Figure CIRS-21).

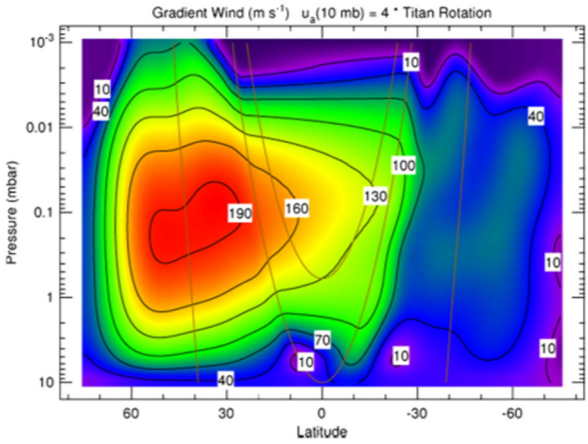

Figure CIRS-21. Zonal winds calculated from the temperatures in Figure CIRS-19 from the gradient wind equation, assuming solid-body rotation at the 10 mbar level at four times Titan's rotation rate. Wind speed contours (black lines) are labeled in ms^{-1}. The gray lines indicate cylindrical surfaces parallel to the rotation axis along which the gradient wind equation is integrated. Equatorward and above the gray line tangent to the equator at 10 mbar, the winds are unconstrained by the gradient wind equation, and have been linearly interpolated on constant pressure surfaces. Figure from Achterberg et al. [2008a].

ATMOSPHERIC ROTATION AXIS

A curious and hitherto unknown phenomenon was observed at the end of the prime mission by Achterberg et al. [2008b]—that isotherm contours plotted in a polar frame are not concentric about the solid body pole, but offset by ~3.5° (Figure CIRS-22). This axial offset was observed most clearly in the north due to the steeper temperature contours, but was also observed in the opposite sense in the south. The atmospheric tilt was later confirmed in other datasets, including an analysis of Titan's brightness banding in ISS images [de Kok et al. 2010b; Roman et al. 2009] and in composition contours of HCN gas from CIRS [Teanby et al. 2010a].

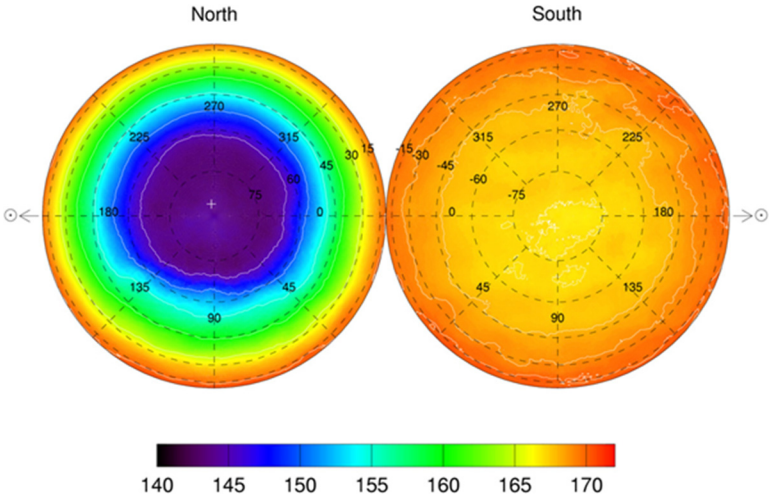

Figure CIRS-22. Polar projection maps of retrieved temperatures at the 1 mbar level. The northern hemisphere is shown on the *left* and the southern hemisphere on the *right*. The color-coded temperature scale in kelvins is shown at the bottom. The superposed grid represents latitude and west longitude in a Sun-fixed frame with the longitude of the subsolar point at 180° W, such that the Sun direction is towards the left and right edges of the figure. Temperature contours are plotted at intervals of 5 K in the northern hemisphere, and 1 K in the southern hemisphere. The fitted axis of symmetry is indicated by a white cross (+). Figure from Achterberg et al. [2008b].

In 2008, it was unclear whether this axis was fixed in a solar frame, or a sidereal (inertial) frame, and Achterberg et al. [2008b] suggested that the observed pole tilt might represent a compromise between two competing effects. The first is the need to maintain Titan's global super-rotation, which requires the upward transport of angular momentum. For an axisymmetric circulation the most favorable configuration for achieving this with upwelling at the equator. The second is the transport of heat by a Hadley circulation, which is most efficient when the upwelling is centered about the subsolar latitude. If this hypothesis were correct, the axial tile should remain fixed in the solar frame. However, more recent, unpublished work by the same authors, which includes observations from the remainder of the Cassini mission, indicates that the axial tilt, remains fixed in the inertial frame. The origin of the tilt still lacks an explanation.

GLOBAL ENERGY BALANCE

Li et al. [2011b] considered whether Titan is in overall thermal equilibrium: as it should be if there is no significant internal energy source. One the strengths of CIRS is the very broad spectral coverage, which includes almost the entire Planck function of cold outer solar system bodies. By carefully integrating across the entire spectrum and accounting for emission angle, Li and colleagues found a global power emission of (2.84 ±0.01) × 10^{14} watts. This compares very closely to the global absorbed solar energy of (2.89 ±0.12) × 10^{14}, which has a significantly larger associated error due to the bond albedo, and places any possible thermal imbalance at ≤ 6%.

In a follow-up paper, Li [2015] searched for temporal variability of the emitted power. In the northern hemisphere, the radiant energy dropped from 2007–2009, then increased 2009–2013, whereas in the southern hemisphere, the power continuously dropped by eventually 5% from 2.40 to 2.28 W/m^2 (Figure CIRS-23). This drop was attributed to seasonal variation. Taken together, the overall global power drop was 2.5%: much less than the decrease (13%) in the solar constant at Titan in the same period, showing the significant thermal inertia of Titan's atmosphere.

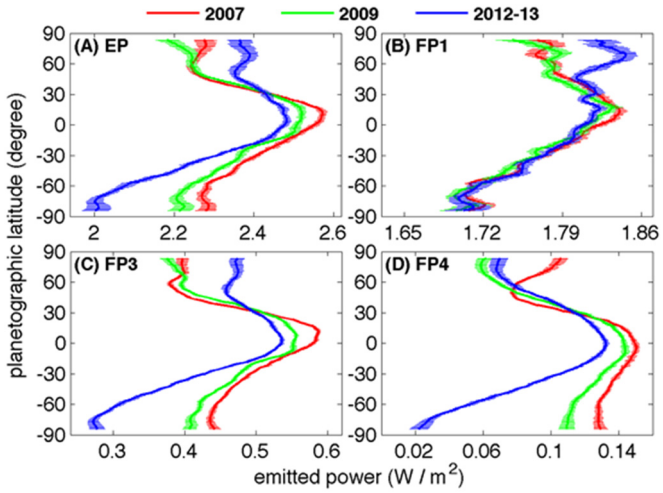

Figure CIRS-23. Meridional distribution of Titan's emitted power. Panel (A): total emitted power. *Panels (B), (C), and (D):* are thermal radiance recorded by the focal planes FP1, FP3, and FP4, respectively. The thick line is the profile of the emitted power and horizontal lines represent the uncertainties. The estimated uncertainty is combined by the uncertainty related to the filling observational gaps and the uncertainty related to the CIRS data calibration. Figure from Li [2015].

A more detailed picture of the global energy balance was presented by Bézard et al. [2018], who developed a seasonal radiative-dynamical model. Constrained by gas and haze data from CIRS and Huygens Descent Imager/Spectral Radiometer (DISR), the model was capable of investigating the net heating and cooling rates at varying latitudes as a function of time. A significant revision downward of the radiative relaxation time in the stratosphere was proposed, and the change in the solar flux due to Saturn's orbital eccentricity was found to be enough to explain a 4 K drop in equatorial temperature at 1 mbar noted between 2009 and 2016. At mid-latitudes on the other hand, the model predicted changes in temperature much larger than observed, which put new constraints on the vertical mixing.

SEASONAL CHANGE

Achterberg et al. [2011] followed up on the original work of [Achterberg et al. 2008a], showing time variation in the stratospheric temperatures from 2004–2009 (L_S 293° to 4°, from late northern winter to just after equinox). Significant cooling (20 K) of the northern stratopause had occurred, consistent with a weakening of the descending branch of the stratospheric circulation cell. Smaller changes were noted elsewhere in the atmosphere.

Teanby et al. [2012a] reported rapid changes in the south polar temperature field shortly after equinox (Figure CIRS-24). They measured elevated mesospheric temperatures in early 2010, which were indicative of south polar subsidence. This is opposite to the south polar upwelling inferred at the start of the mission and was the first observation of Titan's circulation reversing. The reversal was extremely rapid and was evident in both temperature and composition 2-D cross-sections.

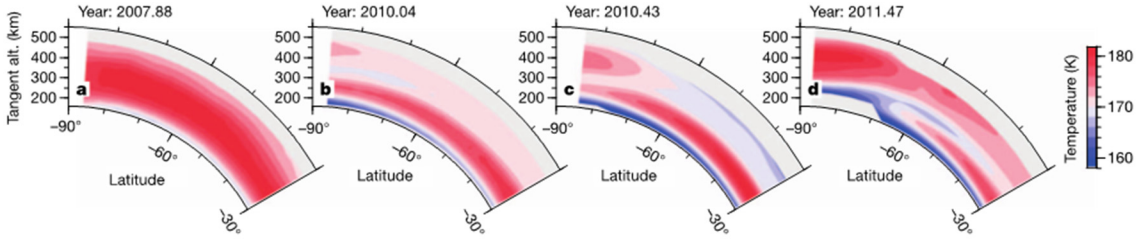

Figure CIRS-24. South polar seasonal temperature changes. Cross-sections were derived from low-spectral-resolution limb-mapping sequences and cover pre-equinox (a) and post-equinox (b–d) periods. Substantial stratospheric (300 km) cooling occurs after the equinox, consistent with reduced total solar flux during this time, as Titan moves towards southern winter. After the equinox (after mid-2009), there is evidence for high-altitude (450 km) polar warming relative to more equatorial latitudes. This is initially present as a small (2 K) temperature anomaly almost immediately proceeding the equinox (b), which increases to 6 K (c) and then to 8 K (d) in subsequent sequences. This implies that the mesospheric circulation has reversed and is now subsiding at the south pole. The strongest polar warming occurs in the most recent observation, indicating the fastest subsidence speeds. The gray regions indicate latitudes and altitudes where observations exist but have insufficient signal-to-noise ratios for an accurate temperature determination. Contour spacing is 2 K, which is the maximum uncertainty for this altitude range. These changes are confirmed by additional single-latitude observations at both high and low spectral resolution. Figure from Teanby et al. [2012a].

Teanby et al. [2017] reported another new discovery about Titan's winter polar vortex, this time in the south, during the early winter time period that Cassini had not been able to observe in the north (happening in 2002 just prior to arrival of the spacecraft). Previously, a hot elevated stratopause had been seen in the late winter vortex in the north, and also in the early winter vortex in the south. Abruptly however, in 2012 three years post-equinox, the mesosphere in southern winter vortex cooled dramatically, and did not recover its previous temperature until 2015. This phenomenon, not seen elsewhere in the solar system, was interpreted as being due to the huge enrichment occurring in trace gases, which were efficiently cooling the mesosphere. This observation provided a unique glimpse at the interplay between thermodynamic and radiative effects on controlling atmospheric temperature (Figure CIRS-25).

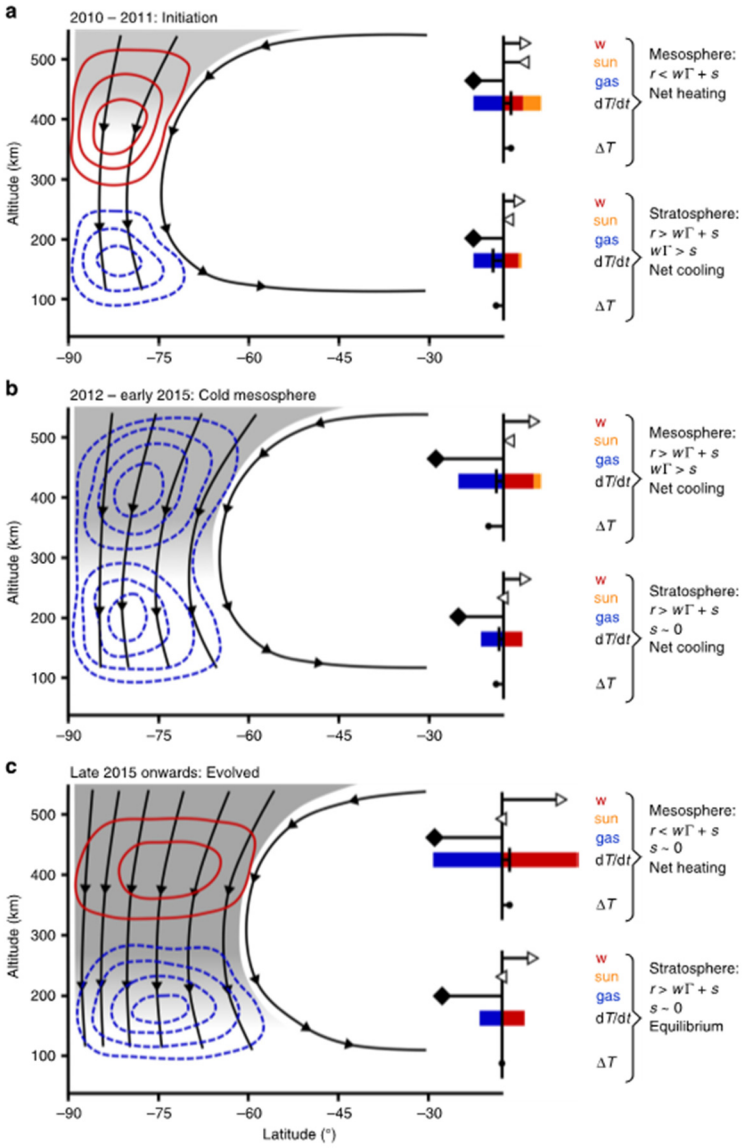

Figure CIRS-25. Schematic of the three stages of Titan's vortex evolution. Shaded areas represent trace gas abundance, which increases with time due to the subsiding flow (black streamlines). Red contours indicate hot anomalies and blue-dashed contours represent cold anomalies. Inset bar plots in each panel represent mesospheric and stratospheric heating and cooling processes; right-pointing triangles indicate subsidence speed w, which drives adiabatic heating rate wΓ (red bar); left-pointing triangles indicate solar heating rate s (orange bar); and diamonds indicate trace gas relative abundance, which drives long-wave radiative cooling rate r (blue bar). The overall net heating rate ∂T/∂t = −r + wΓ + s (vertical line) produces either a hot or cold temperature anomaly ΔT (filled circle). Estimated long-wave cooling rates range from 0.75 to 3.3 K per day in the mesosphere (~0.01 mbar, 400 km) and 0.04–0.17 K per day in the stratosphere (~1 mbar, 175 km). The three stages are: *Panel a*: vortex initiation, with a hot mesosphere driven by modest subsidence-induced adiabatic heating combined with weak cooling from trace gases; *Panel b*: cold mesosphere, caused by enhanced net cooling from increased trace gas opacity; and *Panel c*: evolved vortex, with a hot mesosphere driven by strong subsidence-induced adiabatic heating that exceeds enhanced cooling from trace gas enrichment. Figure from Teanby et al. [2017].

Gas composition and chemistry

The gas composition of Titan's atmosphere is highly informative in many respects: it yields information on the chemistry, it acts as a tracer of dynamical motions, and informs about the possible composition of aerosols and condensates. As previously mentioned, measurement of the gas abundances through thermal infrared emissions is contingent on first knowing the temperature profile, either through external (non-CIRS) measurements or models, or through CIRS modeling based on a prior well known/well mixed gas such as CH_4, CO, or H_2. However, in some instances these well-known gas abundances are instead the object of study, necessitating a joint retrieval which complicates the analysis.

GLOBAL GAS DISTRIBUTION

The first latitudinal trends in Titan's gases from CIRS data were published in Flasar et al. [2005a], showing similar qualitative trends in the lower stratosphere to those seen in Voyager flyby data 24 years earlier, i.e., short-lived trace gases (HCN, HC_3N, C_4H_2) showed sharp increases towards the north pole by 1–2 orders of magnitude, while longer-lived gases (such as CO_2 and C_3H_4) showed smaller increases or none at all. C_2H_4 showed an unexpected decrease from 0 to 60° N, which remains unexplained. Shortly thereafter, a focused follow-up study of the latitudinal variation of nitriles by Teanby et al. [2006] using medium resolution nadir spectra confirmed the trends reported in the 2005 paper.

The year 2007 was a watershed year for CIRS Titan results, with publications by Coustenis, Teanby, Vinatier and de Kok describing gas composition measurements.

Coustenis et al. [2007] modeled observations encompassing the first half of the Cassini prime mission (2004–2006), and including medium (2.5 cm^{-1}) and high (0.5 cm-) spectral resolution observations. All previous gases seen by Voyager IRIS and the Infrared Space Observatory (ISO) were detected, including a robust confirmation of benzene, tentatively detected by ISO [Coustenis et al. 2003]. Latitudinal variations of all species were mapped (Figure CIRS-26), showing the greatest polar increases for HCN, HC_3N, C_4H_2, C_3H_4, and C_6H_6. The D/H ratio was measured from CH_3D, and found to be $(1.17 \pm 0.25) \times 10^{-4}$.

The first results from analysis of CIRS limb observations, yielding vertical-latitudinal profiles of HCN, HC_3N, and C_2H_2, were shown in the paper of Teanby et al. [2007], and was also the first to include CIRS data covering 60–90°N. It clearly revealed for the first time the 2-D structure of the atmospheric trace gas concentrations, and dramatically showed the difference in distributions between the three decaying tracers of differing lifetimes (Figure CIRS-27). The longest-lived species, C_2H_2 showed only marginal polar enhancement, while the shortest-lived species, HC_3N showed the steepest vertical gradient at low latitudes, and the most intense enhancement over the northern (winter) pole where the descending branch of stratospheric global circulation was occurring. The intermediate lifetime species, HCN, showed the most interesting and unexpectedly distribution, with a tongue of enriched air reaching from the lower N polar stratosphere back

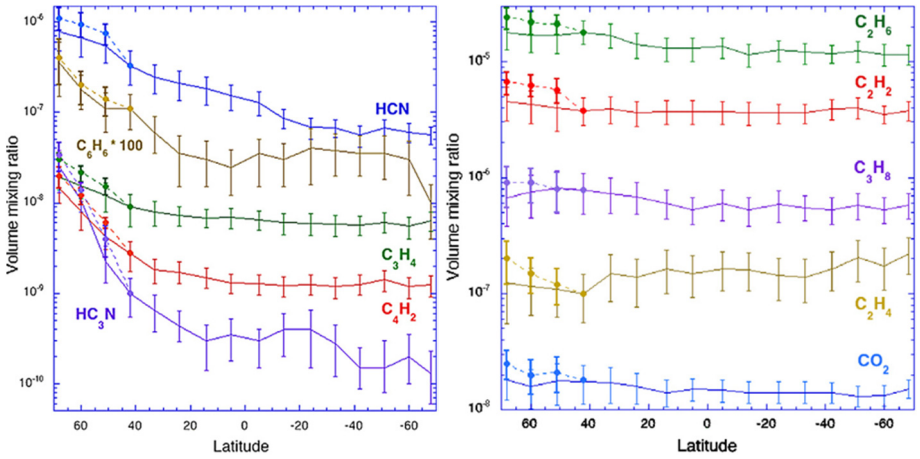

Figure CIRS-26. Meridional variations in the composition of trace gases in Titan's stratosphere and associated error bars. The latitudes indicated take into account the latitude smearing effect. The abundances shown are the averages of the results from fitting tours TB–T10. In dotted lines are shown the results at high northern latitudes when using the limb-based profiles instead of the nadir-based ones, highlighting the uncertainty on the higher northern inferences. Figure from Coustenis et al. [2007].

equatorwards. This was interpreted as the returning branch of the stratospheric circulation, seen clearly for the first time outside of GCM models.

Vinatier et al. [2007a] retrieved temperatures and vertical profiles for a wider array of gases at two latitudes on Titan—15° S and 80° N—from early flybys in 2004–2005. The temperature profiles confirmed the existence of a well-defined stratopause on Titan that was elevated (380 km versus 310 km) and hotter (207 K versus 183 K) in the north, in agreement with model expectations. The gas distributions largely confirmed the predicted picture from photochemical and dynamical models, however, there were unexpected details. Two of the heavier gases (C_3H_4 and C_4H_2) showed a minimum at 300 km in the north, perhaps related to haze formation. C_2H_4 showed a decreasing profile with altitude in the south: the opposite trend to other species, and possibly indicative of a secondary formation peak at low altitudes.

Oxygen-containing molecules were the focus of work by de Kok et al. [2007a], who retrieved a global mean abundance of CO equal to 47 ±8 ppm, and an upper limit for H_2O of 0.9 ppb, from CIRS FP1 far-IR spectra. CO_2 was found to have a typical abundance of 15 ppb in the lower stratosphere (100–200 km) with little latitude variation, in agreement with its expected long photochemical lifetime.

Teanby et al. [2008a] made a more detailed study of the northern polar vortex, this time using limb observation data to find the vertical gas distributions. A primary focus was to infer dynamical information from the distribution of trace gas species. A clear mixing barrier was detected at the edge of the northern vortex, preventing the enriched air from mixing laterally into the mesosphere at lower latitudes. However, at the base of the vortex, a tongue of tracer-enriched was spotted extending to lower latitudes, suggesting cross-vortex mixing and a residual polar circulation:

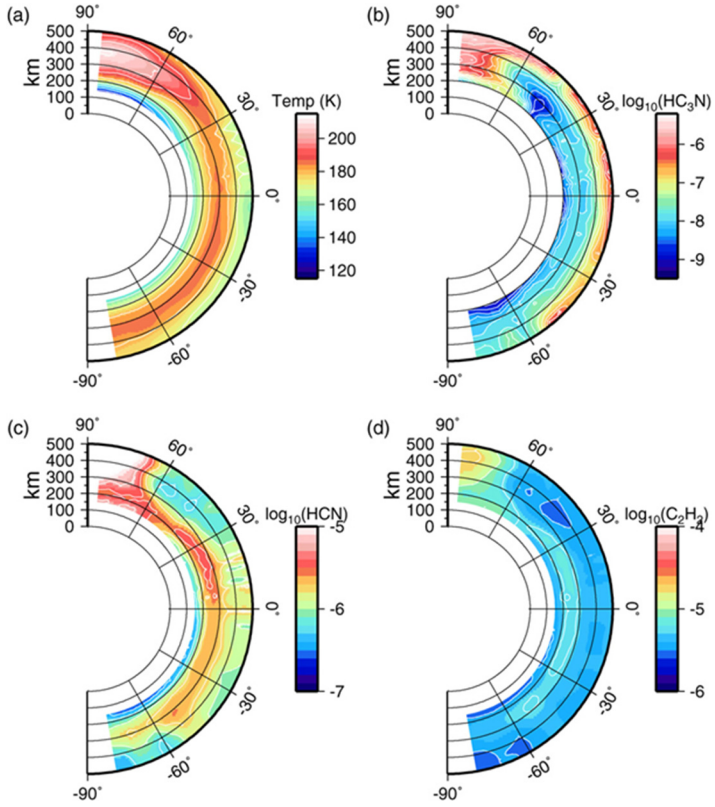

Figure CIRS-27. Cross-sections through Titan's atmosphere obtained using the three low resolution mapping sequences displaying temperature, HC_3N, HCN, and C_2H_2 abundance. Temperature is increased over the northern winter pole in the upper stratosphere and mesosphere and the stratopause is elevated with respect to the equator. The stratopause in the south also appears to be slightly higher than at the equator. The lower stratosphere in the north is much colder than at the equator. HC_3N shows a massive enrichment over the north pole, which appears to be confined to latitudes above 60° N. There is a suggestion of a tongue of enriched air extending from the north to the south at 200 km and 60° N. Note that HC_3N retrievals are not reliable southward of 50° N as the signal from HC_3N is too small. HCN is also enriched in the north, but the most striking feature is the layer of HCN enriched air at 200–250 km extending from the north pole to lower latitudes, which is suggestive of entrainment of enriched air in a meridional circulation cell. C_2H_2 appears to be well mixed throughout the atmosphere and does not vary significantly with latitude. There appears to be some slight enrichment over the north pole, which may be an artifact due to the correlation between HCN and C_2H_2 retrievals. Figure from Teanby et al. [2007].

features not reproduced in contemporary GCM models. Evidence was also seen for possible polymerization of C_2H_2 to C_4H_2.

A 2-D circulation model (CM) appeared soon thereafter, due to the work of Crespin et al. [2008] at the Institute Pierre-Simon Laplace, and with extensive collaboration from CIRS investigators. This model attempted to replicate the temperature fields measured by Achterberg, and vertical gas distributions retrieved by Vinatier and Teanby, especially. This represented an important step forward in modeling the new Cassini data, and provided an explanation for some of the observed phenomena. For example, the low-altitude increase in C_2H_2 was explained as the

presence of a long-lived, non-condensing gas species in the returning branch of the global circulation cell. However, some difficulties were encountered, such as the inability of the model to replicate a well-defined stratopause, and to reproduce the amplitude of the residual (previous season) winter polar enhancement in the south. These model deficiencies were important in pointing the way to further future work.

Hydrocarbon and nitrile composition from CIRS far-infrared spectra were first reported by Teanby et al. [2009c], who aggregated data from the first four years of the Cassini mission, encompassing the entirety of the prime mission (2004–2008). Three gases previously seen in this spectral region (200–400 cm^{-1}) by Voyager IRIS were detected: C_3H_4, C_4H_2, and C_2N_2, the last of which (cyanogen) is not seen in the mid-infrared spectrum of CIRS (600–1400 cm^{-1}). The abundance of C_3H_4 was about 2× greater than inferred from mid-infrared data, suggesting that coefficients for one or other of the bands were incorrect. For the first time, C_2N_2 was detected at low latitudes, where its abundance ($5.5 \pm 1.4 \times 10^{-11}$) is amongst the lowest of any gas detections by CIRS. Like other nitriles (HCN, HC_3N), cyanogen showed a greater polar enhancement than hydrocarbons with similar lifetimes, suggesting that chemical processes were missing from contemporary models.

In a study by Coustenis et al. [2010], the 2007 survey was expanded to include nadir data from all flybys of the Cassini prime mission (2004–2008), and including latitudes 90° S to 90° N, and also using revised spectroscopic parameters for C_2H_2, C_2H_6, and HCN to improve accuracy of results. By and large, the results were in agreement with GCM predictions [Crespin et al. 2008], but discrepancies were noted, such as lack of observational support for a secondary circulation cell.

Vinatier et al. [2010b] provided a comprehensive look at vertical profiles of a nearly-complete suite of Titan gases in the CIRS spectrum (C_2H_2, C_2H_4, C_2H_6, C_3H_8, CH_3C_2H, C_4H_2, C_6H_6, HCN, HC_3N, and CO_2) including first-ever maps of the 2-D distribution of C_2H_4, C_2H_6, C_3H_8, C_6H_6 and CO_2 at nine latitudes from 56° S to 80° N (Figure CIRS-28). This confirmed earlier results [Vinatier et al., 2007a], such as the decreasing abundance of C_2H_4 with altitude, in contrast to other gas species. Other previously unknown details of the gas distribution emerged, including depleted regions of C_2H_2, HCN, and C_4H_2 at 400 km (0.01 mbar) and 55° N. In contrast an enhanced region of CO_2 was seen at 30–40° N between 2–0.7 mbar. Finally, nearly all molecules showed a local minimum in abundance at (300 km, 80° N) in contrast with GCM models that predicted vertically constant profiles inside the vortex.

Far-infrared spectral lines of HCN were modeled by Teanby et al. [2010b] to confirm the earlier polar enhancement derived from mid-infrared spectral emissions [Teanby et al. 2007]. The data also supported the conclusion of Teanby et al. [2009c] that nitriles were missing a chemical sink in current photochemical schemes, since the emission versus lifetime distribution did not match that of hydrocarbons. In addition, the abundance of CO was re-derived and found to be: 55 ±6 ppm at 20 mbar, in good agreement with de Kok et al. [2007a].

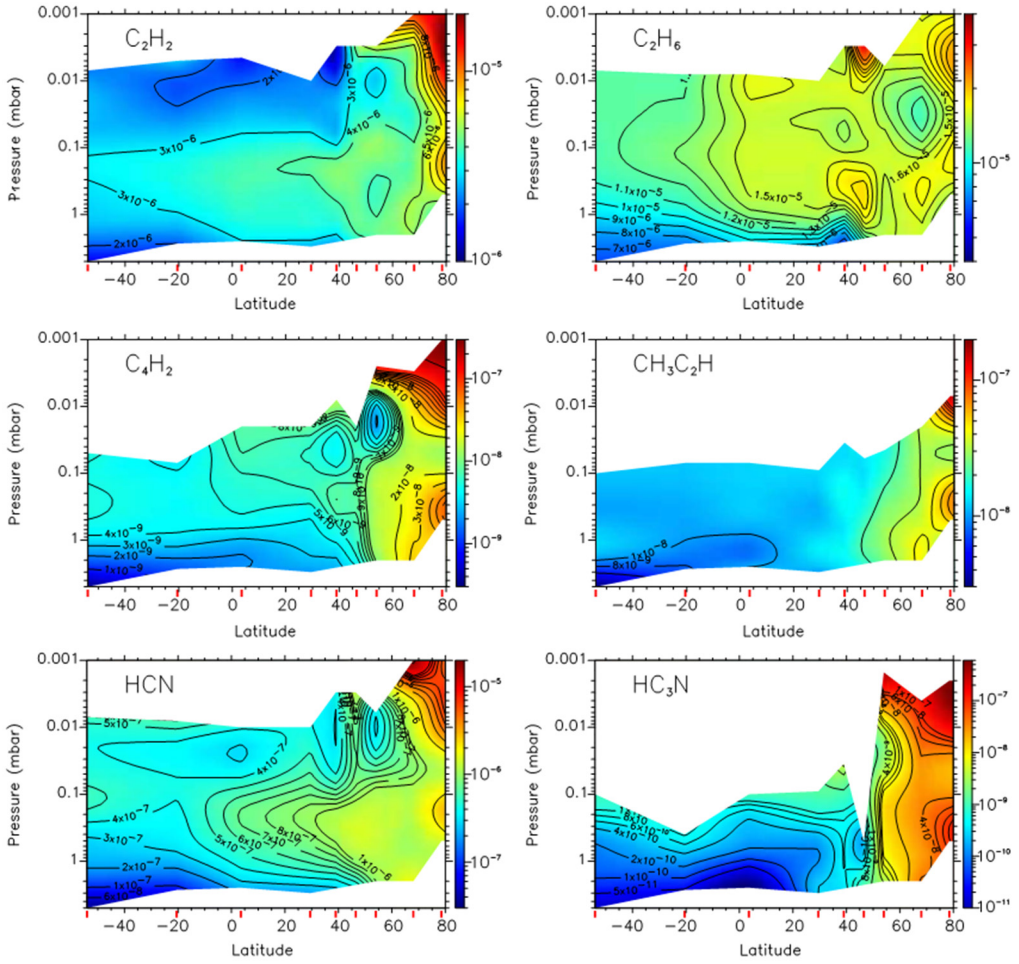

Figure CIRS-28. Latitude/pressure map of mixing ratios of C_2H_2, C_2H_6, C_4H_2, CH_3C_2H, HCN, and HC_3N. The regions of insufficient information content appear in white. Latitudes of the observed spectra are displayed as red vertical bars on the latitude axis. Figure from Vinatier et al. [2010b].

The global abundance of H_2 was the objective of a study by Courtin et al. [2012], who modeled the H_2–N_2 dimer S_0 (0) feature around 355 cm^{-1} seen on CIRS FP1 using data from 2006–2007. The mean abundance found was (9.6 ±2.4) × 10^{-4}, in good agreement with the Huygens GCMS value of (1.01 ±0.16) × 10^{-3} [Niemann et al. 2010]. This value is however some 4× lower than the ionospheric value: (4.05 ±0.03) × 10^{-3} at ~1200 km [Waite et al. 2005], which causes significant difficulty for modeling to explain. Interestingly, the CIRS measurements of the hydrogen abundance showed some evidence of increase towards the poles (Figure CIRS-29), by 30–70%, which would only make sense if it was due to downward transport in the presence of a vertically increasing hydrogen profile, as implied by the joint CIRS-GCMS-INMS results. Whether or not such a large hydrogen gradient is consistent with photochemical timescales from modeling remains an open question.

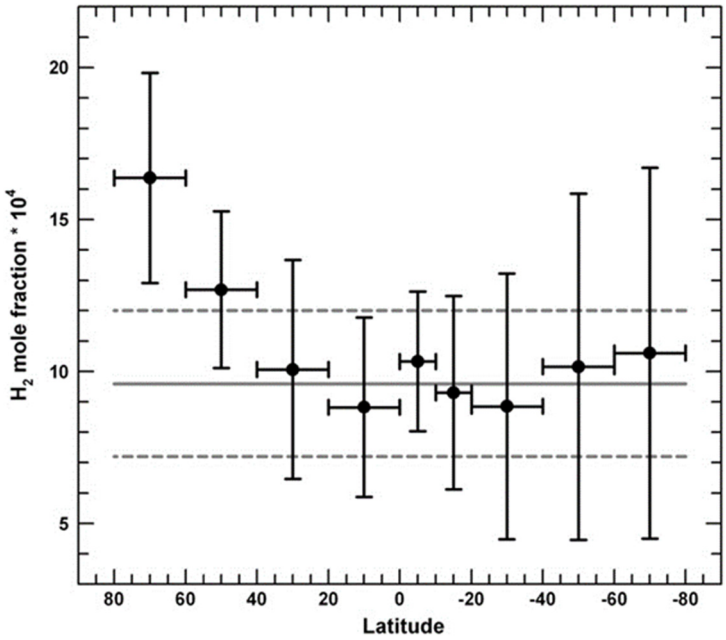

Figure CIRS-29. Values of the H_2 mole fraction (in unit of 10^4) derived from the CIRS average spectra in the nine latitude bands. The horizontal lines represent the global average value we derived, $(9.6 \pm 2.4) \times 10^{-4}$. Figure from Courtin et al. [2012].

Cottini et al. [2012a] made the first measurement of water latitude distribution from Cassini CIRS far-IR data, following the upper limit published by de Kok et al. [2007a] and a southern hemisphere average by Teanby et al. [2009b]. Globally, nadir measurements yielded an abundance of 0.14 ±0.05 ppb for an altitude of 97 km for a well-mixed vertical profile, somewhat lower than previously inferred from ISO (0.4 ppb). Two vertical profile points were also retrieved (Figure CIRS-30), showing a steep gradient that was in agreement with some photochemical models. No latitude variation was noted in the data.

In 2014, an interesting result emerged from the work of Lellouch et al. [2014] to constrain the abundance of methane, normally assumed to be constant with latitude in CIRS analysis, and fixed to the Huygens probe GCMS values [Niemann et al. 2010]. Lellouch and colleagues sought instead to retrieve the atmospheric temperature and the abundance of CH_4, via simultaneous modeling of mid-infrared rovibrational lines and far-infrared pure rotational lines. The result was unexpected, showing a variation in the abundance of methane from 1.0 to 1.5% at 85 km (15 mbar) in the lower stratosphere, a large fluctuation that was difficult to explain. Intriguingly, the low value (1.0%) near the equator allowed a temperature profile that agreed for the first time with Huygens HASI measurements, at the cost of losing agreement with GCMS. An explanation was offered for the mid-latitude increases in methane abundance as being due to tropospheric convection events percolating and persisting into the stratosphere.

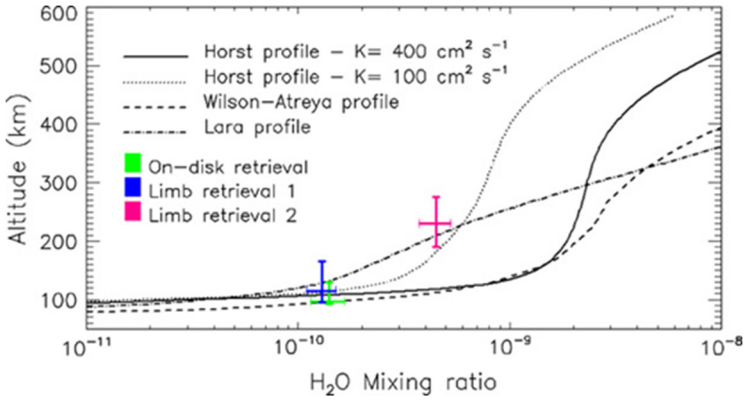

Figure CIRS-30. Water vapor mole fraction retrieved from CIRS on-disk and two limb observations assuming a water profile constant with altitude over the condensation level. Water profiles from three photochemistry models are also shown for comparison. The Hörst et al. [2008] water vapor profile was derived assuming two different eddy diffusion coefficients—100 cm^2 s^1 and 400 cm^2 s^1 (the second being the one recommended in their model; dotted curve plus solid curve). Also the profiles in Wilson and Atreya [2004] (dashed curve) and in Lara et al. [1996] (dot-dash curve). Figure from Cottini et al. [2012a].

Titan's water abundance was further constrained by the work of Bauduin et al. [2018], who analyzed a unique set of distant (~10^6 km) observations of Titan by CIRS, taken so that the entire moon was contained inside the FP1 pixel. This was done for intercomparison purposes with earlier studies using ISO and Herschel data, where Titan was similarly unresolved from the Earth-orbiting telescopes. Bauduin and colleagues found that the original discrepancy of a factor ~5 between Herschel (0.023 ppb at 12.1 mbar) and CIRS (0.14 ppb at 10.7 mbar) was sustained in the reanalysis, opening the possibility of seasonal change in the water abundance.

Lombardo et al. [2019] used a new line list for propene, first detected by Nixon et al. [2013a] to make the first spectral retrievals for this gas species. The results indicate that propene has a significantly different latitudinal profile from the other C_3H_x species: propyne and propane. Instead of being concentrated over the winter pole, the greatest abundance was found at the equator. Differences from photochemical model predictions were also found.

SEASONAL CHANGES

The paper of Teanby et al. [2008b] marked the start of papers focused on a new dimension of the dataset: seasonal changes in the gas distributions, from (L_S = 293°–328°). Teanby and colleagues used nadir spectra at medium (2.5 cm^{-1}) and high spectral resolution (0.5 cm^{-1}) to elucidate spatial and temporal changes in the abundances of C_2H_2, C_3H_4, C_4H_2, HCN, and HC_3N. A major new result was the gas distribution for the north polar region, showing that abundances continued to increase right up to 90° N (Figure CIRS-31). No secondary circulation cell was seen at the south pole, in contrast to GCM models predictions. A decline in southern gases was noted, as the residual southern winter enhancement faded.

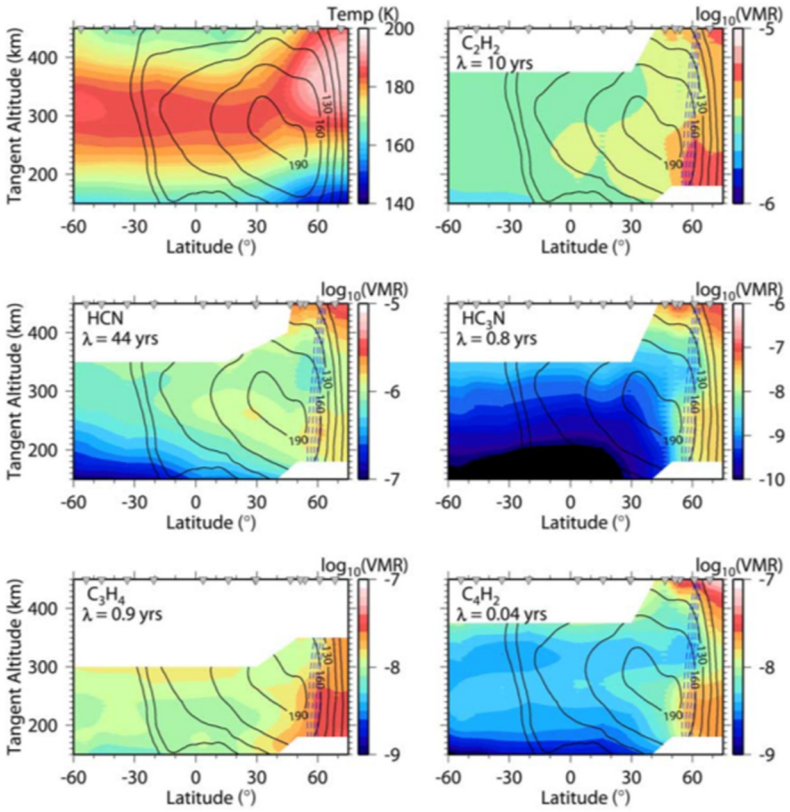

Figure CIRS-31. Cross-sections of temperature and composition through Titan's atmosphere. Composition is given as a volume mixing ratio, and the positions of the observed profiles are denoted by inverted triangles at the top of each plot. Contours indicate the vortex zonal wind speeds (in m s^{-1}) derived by Achterberg et al. [2008a], and blue dashed lines show the region with the steepest horizontal potential vorticity gradient, which indicates a dynamical mixing barrier (see Figure CIRS-5 and the section entitled Jupiter). Altitudes with low signal to noise or where the atmosphere becomes opaque are not plotted. VMR is the volume mixing ratio, and lambda is the photochemical lifetime at 300 km. Figure from Teanby et al. [2008b].

Teanby et al. [2009b] elaborated on the previous work, and showed that nitriles have different enhancements over the winter pole compared to hydrocarbons of similar photochemical lifetimes, which suggests some missing reactions in chemical models. A further update to seasonal and temporal trends in gas abundances was published by Teanby et al. [2010c], enlarging the dataset to include the six-year period from 2004–2010. Post-equinox (August 2009), increases in gases at both poles was seen, the first tentative evidence that Titan was transitioning to a two-cell circulation.

Seasonal changes in temperature and composition were also reported by Bampasidis et al. [2012], who modeled CIRS high resolution (0.5 cm^{-1}) nadir spectra from 50° S to 50° N, and spanning a time range from 2006–2012. At northern latitudes, the temperature profile evolved during the time period from a strong positive gradient to a more isothermal profile, with a cooling mesosphere and warming stratosphere. A maximum in the polar trace gas enrichment was found at the time of northern spring equinox (August 2009), followed by a sharp decrease as the polar descending circulation weakened and gases began to dissipate.

The first clear evidence for reversal of the stratospheric circulation was reported by Teanby et al. [2012a], who reported a build-up in trace gases over the south pole, some two years after equinox. A primary result was that the transition was very rapid, taking less than six months. The gas enrichments were used to estimate subsidence velocities within the vortex. Furthermore, gas and temperature distributions showed that upper atmosphere circulation must extend too much higher altitudes than previously thought: 600 km or more. This placed an imperative for revision of GCM models that did not at the time reach to such altitudes. In addition, the data suggested that the detached haze layer at ~500 km could not be solely generated by the circulation.

Coustenis et al. [2013] tackled the important question of intercomparison of findings from Cassini CIRS and Voyager IRIS, spanning a full Titan year, albeit with incomplete coverage. Temperature profiles and gas abundances in the lower stratosphere were measured and compared between 1980 and 2010, one Titan year apart. The results indicated little inter-annual variability, although the detailed distributions of the shortest-lived molecules C_3H_4 and C_4H_2 did exhibit differences.

Most recently, Vinatier et al. [2015] provided an update on the vertical profiles for the majority of Titan gas species seen in the CIRS data (Figure CIRS-32), using data from 2006–2013, focusing on seasonal changes. This provided a clear picture of the changes occurring in seasonal circulation, most especially around equinox, when the two-cell system persisted for just six months (January 2010–June 2010). By 2011, the single-cell winter circulation pattern had become established, reversing the direction of the circulation seen at the start of the mission. A sudden unexpected temperature drop was seen soon afterwards above the south pole, hypothesized to be due to enrichment in trace gases acting as coolants. In late 2012, a detached haze layer was seen in the CIRS data at 320–330 km, corresponding to the altitude of the detached haze layer seen by Cassini's cameras in the UV.

Seasonal change in Titan's temperatures and gases at high latitudes was studied by Coustenis et al. [2016], focusing especially on the comparison of ±50° and ±70° from 2010–2014, following Coustenis et al. [2010] (Figure CIRS-33). For the longest-lived hydrocarbons there was minimal change at all latitudes prior to 2013, with a small trend for increase in the south thereafter. At 70° S there was a strong enhancement in heavier hydrocarbons from late 2011 (equinox), including the appearance of HC_3N and C_6H_6 that were undetectable at this latitude at earlier times. A possible link between the gases and haze formation was postulated.

Sylvestre et al. [2018] followed up on the work of Teanby et al. [2009c], this time searching for seasonal changes in Titan's gases via the far-infrared spectrum. The heavy molecules C_3H_4, C_4H_2, and C_2N_2 were measured, showing a dramatic increase in abundance over the south pole in a short period from 2012–2013, while north polar abundances remained nearly unchanged. However, at northern mid-latitudes the shorter-lived species C_4H_2 and C_2N_2 did exhibit a decrease, while C_3H_4 did not. These results provide further constraint on photochemical and dynamical models.

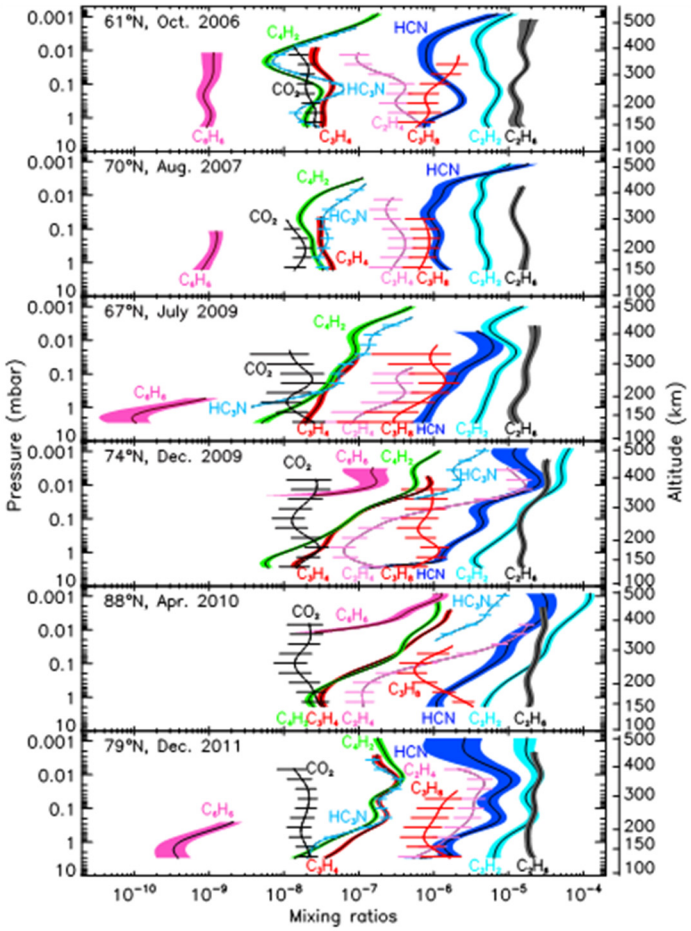

Figure CIRS-32. Seasonal variations of the mixing ratio profiles of C_2H_2 (cyan), C_2H_4 (pink with horizontal bars), C_2H_6 (gray), C_3H_8 (red with horizontal bars), C_3H_4 (red envelope), C_4H_2 (green), C_6H_6 (pink envelope), HCN (dark blue), HC_3N (blue with horizontal bars), and CO_2 (black with horizontal bars) at the north pole, derived from 0.5 cm^{-1} resolution limb spectra. Envelops and horizontal bars give the 1 r error bars. Figure from Vinatier et al. [2015].

A follow-up to the trends in seasonal changes of trace gases reported by Coustenis and colleagues in 2010 and 2016 was made by Coustenis et al. [2018], who focused on the polar regions 60°–90° north and 60°–90° south from CIRS nadir data. Notably different behavior was found for the onset of southern winter gas enhancement, which began in 2012, versus the decline in northern winter enhancement, beginning in 2015. The asymmetry in heating was dramatically evidenced in lower stratospheric temperatures: from 2013–2016 the north, entering spring, showed a mild temperature increase of 10 K, while the south, tending towards winter showed a more dramatic decrease of 25 K in the same period.

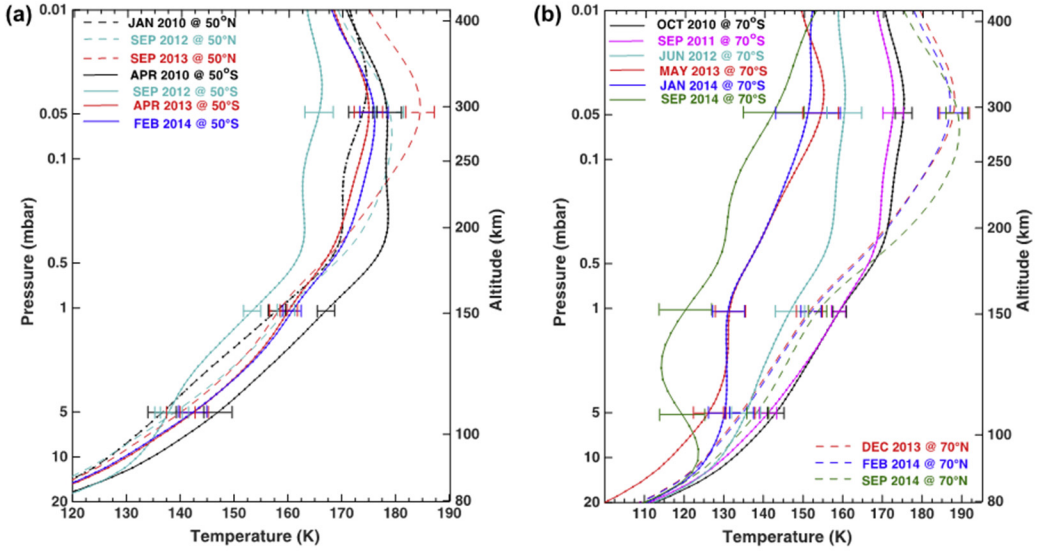

Figure CIRS-33. Seasonal change in Titan's temperatures and gases at high latitudes. (a): temperature variations at 50° S (solid lines) and 50° N (dashed lines) in Titan's stratosphere from January 2010 until February 2014; (b): temperature profiles of Titan at 70° S (solid lines) and 70° N (dashed lines) with dates ranging from October 2010 to September 2014 (in different colors).The pressure/altitude ranges probed by these profiles vary with latitude, but are generally in the 0.1–20 mbar region. The 3-r error bars on the temperature are plotted at 0.05, 1, and 5 mbar (see text for details). As can be seen, the stratospheric temperatures in the 0.1–1 mbar pressure range dropped by about 40 K near the southern pole within the past four years. At the same time, the temperatures in the north had not indicated similar dramatic changes, but rather an increase in temperature is found since February 2014, as the north moves into summer. The dashed lines, thus, show that within about seven months since December 2013, the NORTH POLE had warmed up by about 6 K. Figure from Coustenis et al. [2016].

SEARCH FOR NEW GAS SPECIES

Nixon et al. [2009a] made a detailed survey of the CIRS mid-infrared spectrum of Titan, searching for previously unseen gas species, and focusing especially on the region from 850–1050 cm^{-1} where there are few strong emissions. While a null result was obtained, numerous weak bands of propane (C_3H_8) were seen clearly for the first time that were not present in existing line lists used by the team, prompting a renewed round of laboratory work to provide line parameters.

In a follow-up paper, Nixon et al. [2010b] computed upper limits for several of gases expected to be found on Titan, from dedicated search observations (FP3/4 pair mode) at latitudes 25° S and 75° N. By comparing the results to photochemical model predictions they concluded that NH_3 and CH_3OH are likely present at levels far below the CIRS detection threshold, while CH_3CN, CH_2CCH_2 and H_2CO are closer to detection limits. In a later paper, Nixon et al. [2013b] added upper limits for biologically important sulfur and phosphorus-bearing compounds: H_2S and PH_3.

The first, and to this date only, new gas species detection on Titan from Cassini CIRS data was announced by Nixon et al. [2013a], following the availability of new propane line parameters from

several sources. This enabled the isolation of a propene (C_3H_6) emission at 912 cm^{-1} from stronger over-lying propane and ethylene bands (Figure CIRS-34), with an abundance of 2–4 ppb depending on altitude. This detection marked the completion of the triad of C_3H_x hydrocarbons, although the search for isotopologues such as allene (CH_2CCH_2) and cyclopropane (c-C_3H_6) continues.

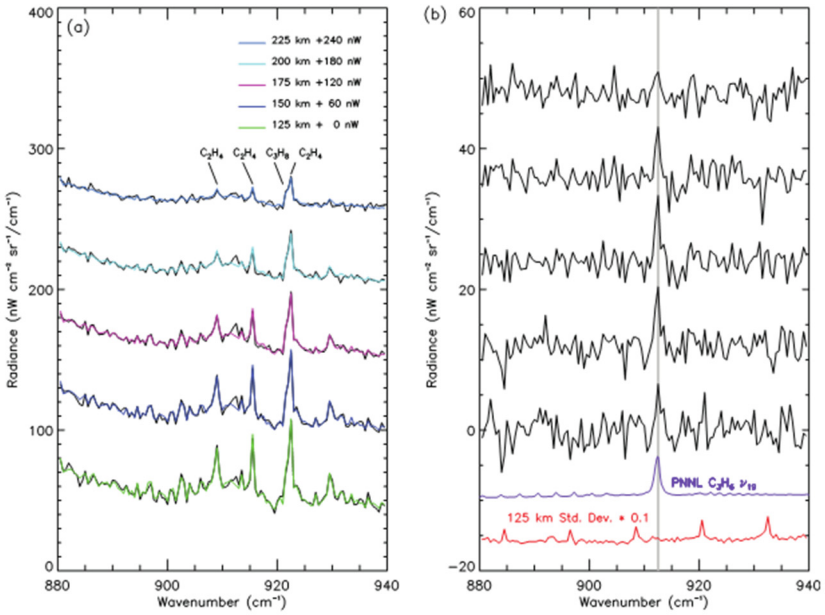

Figure CIRS-34. New gas species detection on Titan from Cassini CIRS data. (a) Co-added data spectrum (black) from weighted average of lowest (125 km), middle (175 km), and topmost (225 km) vertical bins. Also shown are the model spectra with propane (red) and without propane (blue) from the JPL pseudo-line list. (b) Residuals from subtracting data–model: blue line is model without propane and red line is with propane. The purple line shows the smoothed laboratory absorbance spectrum of propene recorded at PNNL, scaled by 1 × 10^4 and offset by −10. The detection significance is ~5 σ. Figure from Nixon et al. [2013a].

A detailed study was made by Jolly et al. [2015] to search for dicyanoacetylene (C_4N_2) in the far-infrared spectrum of CIRS, based on both theoretical expectations for its presence, and also the tentative identification of the ice at 478 cm^{-1} from Voyager IRIS data. Previous searches for the v8 band gas emissions at 472 cm^{-1} had been unsuccessful, causing a dilemma: how could there be ice clouds without vapor? New laboratory work indicated that the ν_9 band at 107 cm^{-1} was in fact stronger than ν_8, and a better candidate for detection given the better S/N in this part of the spectrum. However, only an upper limit on non-detection of 5–7 × 10^{-10} at the 1 σ level was found, leaving the question open about the origin of C_4N_2 ice.

ISOTOPIC RATIOS

Bézard et al. [2007] made a distinguished first detection of the first known double isotopologue on Titan: $^{13}CH_3D$ (Figure CIRS-35). By modeling the emission to measure the gas abundance they were able to estimate isotopic ratios of: $^{12}C/^{13}C$ = 82 (+27/−18) and D/H = (1.32 +0.15/−0.11) × 10^{-4}.

The carbon ratio was in good agreement with the terrestrial ratio (89), however the D/H appeared slightly lower than terrestrial (1.56×10^{-4}), though still substantially higher than in the giant planets, in accordance with expectations.

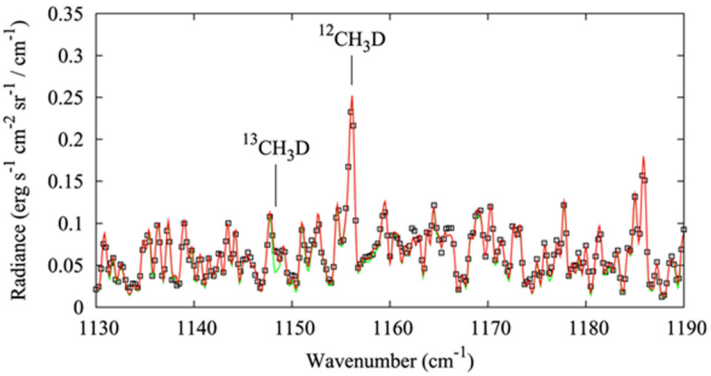

Figure CIRS-35. Comparison between a CIRS spectral selection centered at 15° S (symbols) and synthetic spectra calculated with (red line) and without (green line) $^{13}CH_3D$ line opacity, assuming a $^{12}C/^{13}C$ ratio of 89. Spectral resolution is 0.52 cm^{-1} (apodized). Both calculations use the same haze model, a CH_4 mole fraction of 1.4% and a CH_3D mole fraction corresponding to D/H = 1.34°ø 10^{-4}. Figure from Bézard et al. [2007].

Isotopic ratios in HCN were presented by Vinatier et al. [2007b] from CIRS limb spectra near 700 cm^{-1} on two early flybys. Abundances of HCN, $H^{13}CN$ and $HC^{15}N$ were individually measured, yielding isotopic ratios: $^{13}C/^{12}C = 75 \pm 12$, consistent with the current GCMS measurement at the time (82 ±1); and $^{14}N/^{15}N = 56 \pm 8$, lower than the value measured by GCMS in N_2 (183 ±5), but consistent with previous determinations in HCN from ground-based submillimeter investigations, and confirming that nitrogen-15 is preferentially depleted from the atmospheric reservoir in N_2 and incorporated into HCN.

The year 2008 proved to be a bumper year for new isotopic measurements, with four papers based on CIRS data. Coustenis et al. [2008] made the first detection of C_2HD, enabling for the first time the measurement of D/H in this chemical species. The modal value of $(2.09 \pm 0.45) \times 10^{-4}$ was significantly lower than the D/H in methane found by Bézard et al. [2007]: 1.56×10^{-4}, indicating possible fractionation from the parent (CH_4) to daughter molecule via photolysis or chemical selection.

Jennings et al. [2008] provided the first detection of carbon isotopes of HC_3N, most especially the strong detection of $H^{13}CCCN$ at 658.7 cm^{-1}, well separated from the main gas at 663.3 cm^{-1}. The derived isotopic ratio $^{12}C/^{13}C = 79 \pm 17$ was in good agreement with the terrestrial inorganic standard (89), and confirmed the growing body of evidence that carbon does not incur photochemical fractionation in Titan's atmosphere.

In a companion paper, Nixon et al. [2008b] showed the first detection of CO_2 isotopes on Titan, including both $^{13}CO_2$ and $CO^{18}O$. The carbon ratio ($^{12}C/^{13}C$) was 84 ±17, again in agreement with terrestrial levels, while the oxygen ratio ($^{16}O/^{18}O$) showed some evidence for enrichment: 346 ±110, versus the terrestrial 506. This value was later revised upwards to 380 ±142 by Nixon et

al. [2009b] using a more sophisticated and accurate model for the detector responses, moving the oxygen ratio closer to consistency with terrestrial values.

First remote-sensing measurements of the $^{12}C/^{13}C$ ratio in prominent hydrocarbons: methane, ethane, and acetylene were made by Nixon et al. [2008a], using CIRS high-resolution limb spectra. The results were: 76.6 ±2.7, 84.8 ±3.2, and 89.8 ±7.3 for CH_4, C_2H_2, and C_2H_6, respectively. While the acetylene and ethane values were close to terrestrial, the methane value was markedly lower: a perplexing result, lower even than the GCMS value (at the time) of 82.3 ±1 [Niemann et al. 2005]. Possible explanations were offered in terms of line strength errors or else some strong fractionation effect, however, unknown systematic errors may have contributed.

Following small irregularities in the modeling of the strong ν_8 band of diacetylene (C_4H_2), Jolly et al. [2010] were able to identify the carbon-13 isotopologue: $H^{13}CCCCH$ at 622.3 cm^{-1} (Figure CIRS-36). By modeling emission and comparing to the main isotopologue, a ratio $^{12}C/^{13}C$ = 88 ±7 was derived. This is in good agreement with the ratio in C_2H_2 [Nixon et al. 2008] and also the terrestrial and giant planet values, confirming an emerging picture that carbon undergoes very little isotopic fractionation across the solar system, in comparison to hydrogen and nitrogen.

Nixon et al. [2012] attempted a more accurate measurement of $^{12}CH_4/^{13}CH_4$ to resolve the uncertainty, this time including the other known methane isotopologues: $^{12}CH_3D$ and $^{13}CH_3D$. The

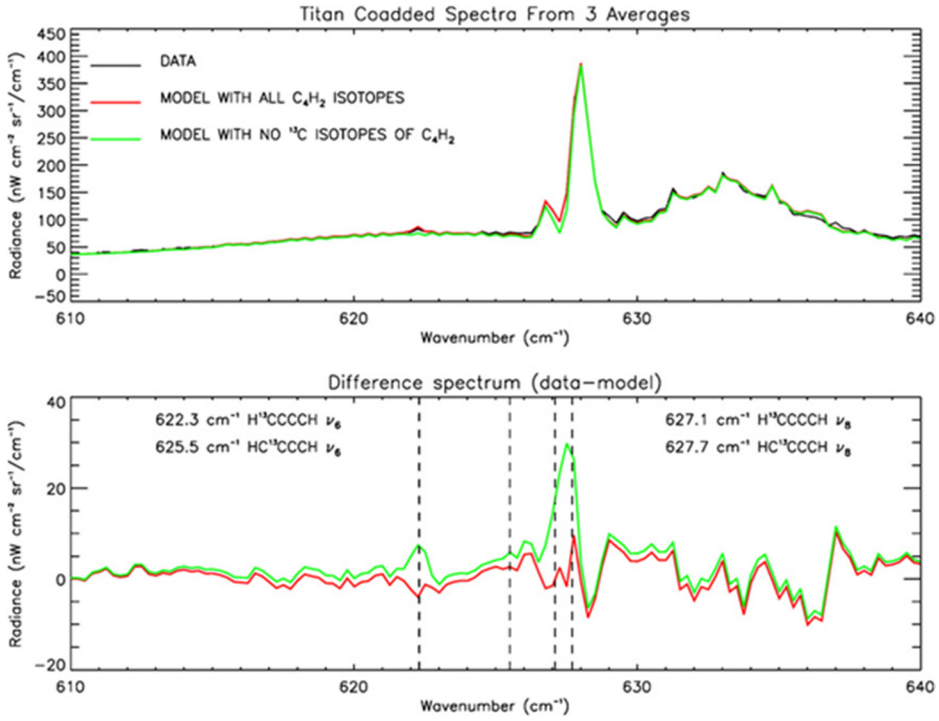

Figure CIRS-36. Modeling emission and comparing to the main isotopologue. *Top*: mean observed spectrum of Titan, compared to model spectra with and without the contribution of ^{13}C isotopologues of C_4H_2. *Bottom*: residual emission obtained after subtracting the observed spectrum and both model spectra. Figure from Jolly et al. [2010].

$^{12}C/^{13}C$ from these new measurements: 86.5 ±8.2 was now in much closer agreement with Huygens GCMS, also revised upwards to 91.1 ±1.4, and both in agreement with terrestrial (89), removing any need for significant fractionation. D/H was also measured to be (1.59 ±0.33) × 10^{-4}, in good agreement with the Huygens GCMS value in H_2: (1.35 ±0.30) × 10^{-4}. By considering the limited divergence of these ratios from primordial values, the authors were able to place an upper bound on the age of Titan's atmosphere of 1600 million years.

Hazes and condensates

In this section, we discuss the rich information derived from CIRS data regarding hazes and condensates in Titan's atmosphere. Although the definitions are sometimes blurred, we will here use the term haze in a narrow sense to mean photochemically-derived, refractory organic particles that are heterogenous in size, composition, and structure at the microscopic level. We use "condensate" to refer to clouds of droplets of ice particles of relatively pure substances that have reached their condensation/freezing point. We note that haze particles are thought to act as nuclei for condensation, and would, therefore, be present in the cores of condensate cloud droplets, although at that point, undetectable. In addition, condensates may undergo photochemical reactions and change their composition, as described the following sections.

HAZE

The first paper tackling the derivation of haze properties from CIRS data was the work of de Kok et al. [2007b], who studied far-infrared (10–600 cm^{-1}) spectral limb data. The authors were able to measure the fractional scale height of the main, ubiquitous haze, in addition to identifying three specific spectral components that could be modeled with Gaussian signatures at 140, 190, and 220 cm^{-1}. These spectral features were localized in both latitude and altitude on Titan, and were in fact condensates of unknown composition, with B and C being seen preferentially in the northern (winter) hemisphere. Haze B appeared to be the re-detection of a strong feature seen by Voyager IRIS, whose composition remains uncertain (Figure CIRS-37).

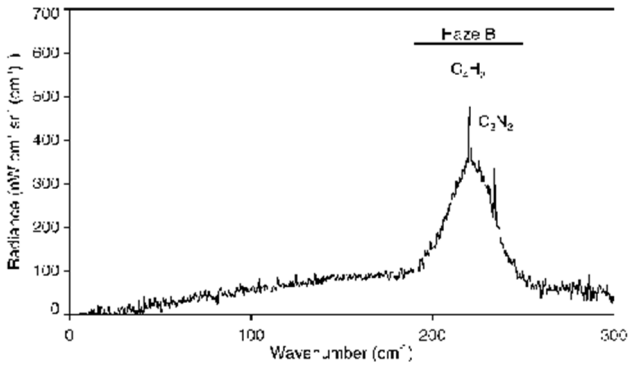

Figure CIRS-37. The average of 13 limb spectra at 85°N at 0.5 cm^{-1} resolution. The FOV centre is at 135 km and the FOV size is 135 km. This spectrum clearly shows a broad feature (Haze B) with gas emissions super-imposed on it. Figure from de Kok et al. [2007b].

A possible anti-correlation between gas and haze vertical abundances was proposed by Teanby et al. [2009a], based on joint analysis of CIRS and ISS data from 150–450 km. Periodic density enhancements were noted, with a length scale of ~50 km, and especially visible over the north pole and vortex boundary. A dynamical origin for the layering was proposed, based on cross-vortex (latitudinal) motions.

Vinatier et al. [2010a] provided the first survey of haze features in the mid-infrared regime of CIRS (600–1400 cm^{-1}), using nine limb integrations from 55° S to 80° N during the prime mission (Figure CIRS-38). Vertical profiles of haze opacity in 17 spectral bins were found, showing near-identical vertical trends, and indicating the haze composition is relatively unvarying with altitude. Distinct spectral features were found at 630 cm^{-1}, 745 cm^{-1}, and 1390 cm^{-1}. A global trend for increasing mass mixing ratio with altitude was taken as strong evidence that the haze is created at high altitudes, above the level of CIRS detection.

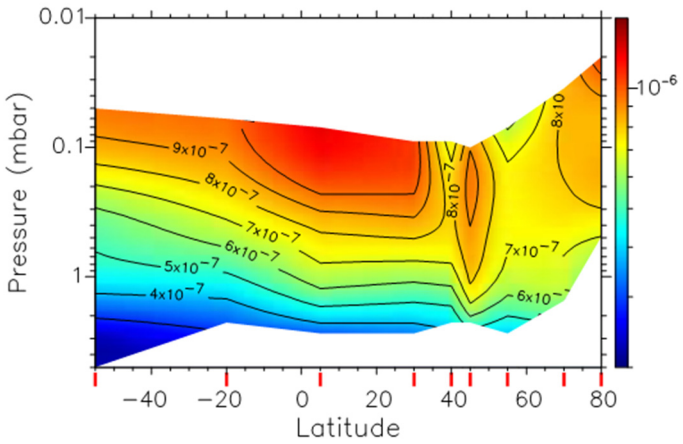

Figure CIRS-38. Latitudinal/pressure map of the haze mass mixing ratio. Latitudes of the observed spectra are displayed as red vertical bars on the latitude axis. Figure from Vinatier et al. [2010a].

A multi-instrument study of the haze banding on Titan was presented by de Kok et al. [2010b], using data from Cassini's ISS and VIMS instruments as well as CIRS. The imagery showed a prominent tropical haze band, and its orientation confirmed the tilt of the atmospheric rotation axis suggested by Achterberg et al. [2008b]. Haze profile retrievals from CIRS data at 640–670 cm^{-1} also reinforced the result.

A comprehensive follow-study by Vinatier et al. [2012] derived the optical properties of Titan's haze from the far-IR to mid-IR (70–1500 cm^{-1}), by modeling the haze particles as aggregates of ~3000 spherical monomers (0.05 micron radius) with fractal dimension n = 2. Real and imaginary refractive indices were derived across the entire range, and several distinct spectral features were found corresponding to vibrations of methyl and methylene. The same features were found across a wide array of altitudes and latitudes, indicating that Titan's haze is relatively uniform in composition.

The notorious, unidentified haze feature at 220 cm^{-1} in the CIRS far-IR was the subject of a study by Jennings et al. [2012b], who observed its seasonal change over the northern (polar) winter pole. From 2004–2012, the intensity of the feature decreased by a factor four, and the authors speculated that this could be due to either: (i) increased photolytic destruction of source chemicals, (ii) decreased condensation due to warmer temperatures, or (iii) a weakening of the subsiding branch of the seasonal circulation. In a follow-up paper [Jennings et al. 2012a] the authors reported the rapid appearance of the 220 cm^{-1} haze in the south (Figure CIRS-39), in July 2012, following non-detection in February the same year. In a 2015 paper on the same feature, it was definitively attributed to a cloud instead of a haze, as described in the following paragraph.

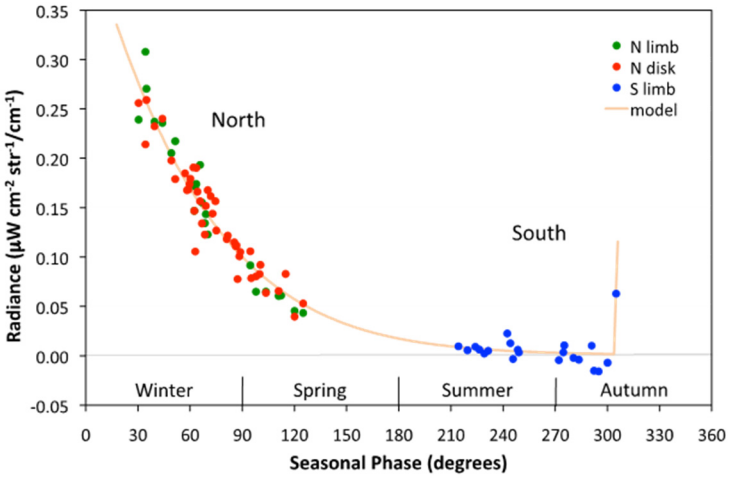

Figure CIRS-39. North and south polar radiances of the 220 cm^{-1} feature plotted on the same seasonal scale. Data from Titan's north represents winter–spring behavior and the data from the south represents summer–autumn behavior. The northern values were adapted from Jennings et al. [2012b], with the addition of a data point in the north from July 24, 2012. The southern values are from Figure CIRS-2 in this report. The seasonal phase scale begins at winter solstice and each 30° increment equals one Titan month. The model is described in the text. Figure from Jennings et al. [2012b].

CONDENSATES

Samuelson et al. [2007] provided the first update on condensates (ices) from CIRS data, comparing the spectral features seen in the far-infrared by CIRS to those seen previously by Voyager. Two definite ice/condensate features were identified in north polar (winter) spectra: the large emission feature at 220 cm^{-1}, previously seen by Voyager IRIS, and also called Haze B by de Kok the same year; and a weaker signature at 160 cm^{-1}. This latter feature was attributed to HCN ice particles of r < = 5 μm at altitudes less than 160 km, while the former was compared to pure crystalline water ice, and also ice of propionitrile (C_2H_5CN), and both candidates found to be produce insufficient spectral fits.

de Kok et al. [2008] further considered gases that might be condensing at Titan's winter (north) pole, especially the open question of C_4N_2 ice first raised by Khanna et al. [1987], and the

origin of Haze B. As with Samuelson et al. [1997], the authors found an upper limit for C_4N_2 gas based on the absence of the gas feature at 471 cm^{-1}, and therefore found the case for the ice identification to be uncertain. Likewise, an upper limit for propionitrile (C_2H_5CN) gas was found to be too low to support the large emission at 220 cm^{-1}, and an alternative explanation in terms of a mixed condensate including an HCN component was postulated instead.

A search for evidence of a tropospheric methane cloud was conducted by de Kok et al. [2010a], using CIRS far-infrared nadir and limb spectra. The authors concluded that the CIRS data were consistent with a cloud at 30 km, however this explanation was in conflict with findings from Cassini VIMS and Huygens DISR. A strong conclusion however was that the collision-induced opacity coefficients for N_2-CH_4 should be in increased by 50%, pending laboratory reevaluation.

The first confirmation for an HC_3N ice cloud on Titan was found by Anderson et al. [2010] at 62° N and 70° N, based on analysis of far-infrared spectral data (Figure CIRS-40). HC_3N ice (506 cm^{-1}) was clearly separated from HC_3N gas (499 cm^{-1}) for the first time, confirming earlier hints of its existence from Voyager IRIS [Samuelson 1985]. Cloud top altitudes were determined for HC_3N ice as 165 km (70° N) and 150 km (62° N), while upper limits for cloud abundances were measured at latitudes of 85° N, 55° N, 30° N, 10° N, and 15° S.

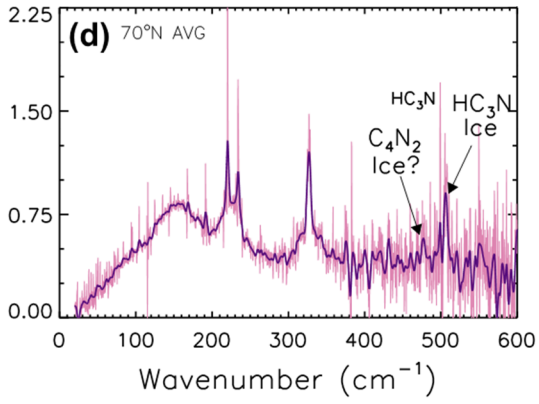

Figure CIRS-40. Weighted vertical average of both sit-and-stares at 70° N. Light pink curves are the data at the original spectral resolution (Dm) of 0.5 cm^1 and the dark purple curves represent the data smoothed by a Gaussian kernel to Dm = 3.0 cm^1. Condensed HC_3N and possibly C_4N_2 emission features are indicated by the arrows. Figure from Anderson et al. [2010].

Anderson and Samuelson [2011] derived the vertical and spectral properties of hazes and condensates at four latitudes (62° N, 15° N, 15° S, 58° S) using CIRS data at both high (0.5 cm^{-1}) and low (15 cm^{-1}) spectral resolution. While haze abundance was comparable, ices were found to be 3× more abundant at 62 °N compared to 15° S. A nitrile (HCN, HC_3N) ice cloud was inferred from a spectral signature at 160 cm^{-1}, 90 km and a second ice cloud was tentatively inferred at 80 cm^{-1}, 60 km. Aerosols were found to be uniformly mixed from the surface to the top of the stratosphere, with a broad emission feature at 140 cm^{-1} possibly due to PAHs.

In de Kok et al. [2014] looked for evidence in the CIRS data to explain the curious high-altitude (300 km) cloud seen by Cassini ISS above Titan's south polar in May 2012. The CIRS data showed

a strong cooling at this altitude (Figure CIRS-41), in contrast with previously observed warming during winter stratospheric subsidence. In addition, the saturation vapor pressure profile of HCN was found to reach 100% at this temperature minimum, providing a strong explanation for the ISS images in terms of an HCN ice cloud.

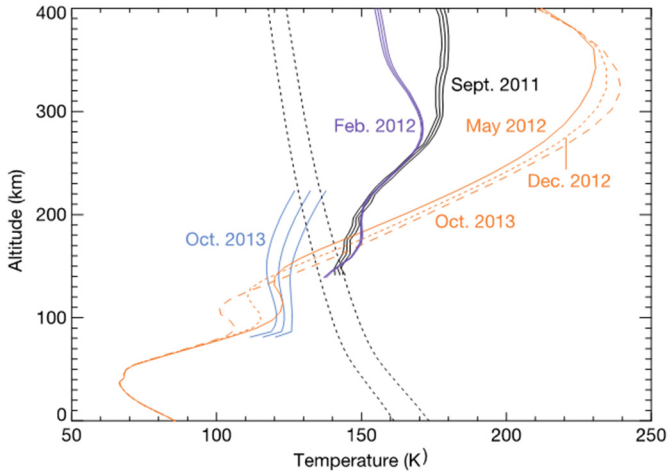

Figure CIRS-41. South-polar temperatures from models and retrievals. Retrieved temperatures and their 1 s errors at 86 u S in September 2011 (black solid line) and February 2012 (purple) from CIRS limb measurements and at 87u S in October 2013 from CIRS nadir measurements (blue). We plot only regions where the observations provide reliable temperature information. Orange lines are circulation model output for May 2012 (solid), December 2012 (dotted), and October 2013 (dashed). Black dotted lines indicate saturation temperatures for HCN volume mixing ratios of 10^{26} (*left*) and 10^{25} (*right*), which cover the measured concentrations of HCN in the south polar vortex. A cloud at 300 km would require temperatures of 125 K there [de Kok et al. 2014].

Anderson et al. [2014] proposed the existence of subsidence-induced methane clouds (SIMCs) over Titan's north pole, based on an analysis of far-infrared rotational lines of methane. By ingesting a radio science (RS) temperature profile and then deriving the vertical profile of methane, the authors showed that methane could exceed its saturation vapor pressure between 20–48 km, and that subsidence in the winter polar vortex could therefore induce condensation. A near-infrared counterpart and possible identification of this cloud was found in Cassini VIMS data.

Jennings et al. [2015] further studied the 220 cm^{-1} feature seen in the far-infrared spectrum of CIRS, and previously referred to as a haze in papers by de Kok et al. [2007b] and Jennings et al. [2012a, 2012b]. The 2015 paper showed the evolution of the condensate cloud at both poles, which was seen to be different. The northern cloud was decreasing in intensity since the start of the mission, with a half-life of 3.8 years. The southern cloud was doubling in intensity every year from 2012, confined to a ring centered on 80° S. In contrast, south polar trace gases had a bi-modal structure with a peak abundance at 90° S, minimum at 80° S, and ring of increased emission at 70° S. The authors concluded that the condensate and gases exhibited an anti-correlation, possibly due to condensation.

Chemical changes on grains of Titan's polar ice clouds were the subject of a 2016 paper by Anderson et al. [2016]. The authors proposed that the previously observed ice signature of C_4N_2 at 478 cm^{-1} (Figure CIRS-42) could arise naturally without condensation from the vapor phase, due to the action of sunlight acting on existing HCN-HC_3N mixed condensates. This process has a counterpart in terrestrial polar stratospheric clouds, where solid state photochemistry leads to condensed nitric acid trihydrate (NAT) particles and loss of ozone.

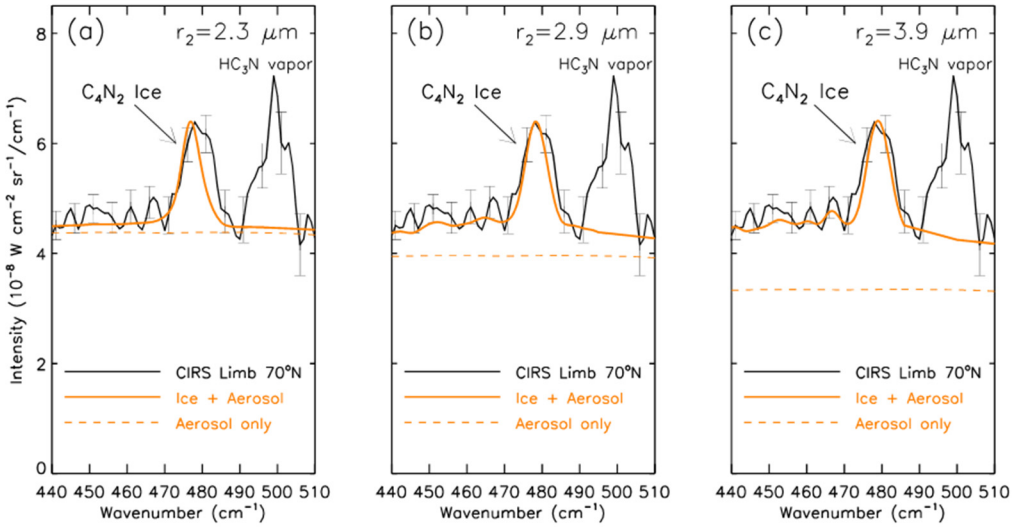

Figure CIRS-42. Radiative transfer fits (solid orange curves) to the continuum of CIRS limb-tangent spectral averages at 70° N (solid black curve). The spectral range is limited to 440–510 cm^{-1}, and the C_4N_2 ice feature at 478 cm^{-1} is included in the fits. A simplified two-stream plane-parallel model, patterned after the one by Hanel et al. [2003], is used to include effects due to anisotropic multiple scattering. Single-scattering parameters are calculated for various C_4N_2-HCN abundance ratios and mean particle radii: (a) pure C_4N_2 ice, r_2 = 2.3 μm; (b) 50:50 C_4N_2-HCN ice mixture, r_2 = 2.9 μm; and (c) 20:80 C_4N_2-HCN ice mixture, r_2 = 3.9 μm. Orange dashed curves show aerosol contributions. The 1σ error bars are spaced every 5 cm^{-1}. Figure from Anderson et al. [2016].

The south polar winter stratosphere again featured in the research of Vinatier et al. [2018], who investigated condensate signatures in the mid-infrared spectral region of CIRS. A weak feature isolated for the first time at 682 cm^{-1} was attributed to benzene ice, and a feature at 695 cm^{-1} was tentatively attributed to C_2H_3CN ice. Mass mixing ratios of both ices were determined, and it was shown that the cloud top for benzene was 300 km at the pole, decreasing to lower latitudes. An upper size limit of 1.5 micron was determined for the benzene ice particles.

Anderson et al. [2018] described their laboratory work dedicated to unraveling the spectral signatures of Titan ices, by deposition and spectroscopy of thin ice films. Pure condensates and co-condensates of HCN, HC_3N, and C_4N_2 were investigated, and the application to modeling and interpretation of CIRS spectra discussed.

Conclusions and further work

The Cassini CIRS instrument in general, and CIRS Titan science in particular, have been hugely successful relative to mission goals, as described in the section entitled CIRS Science Assessment. The original mission was projected to last for four years: in the end Cassini and CIRS returned data for 13 years, allowing an undreamt level of insight into Titan's atmospheric workings, and interactions with the surface. GCM and photochemical models that were largely speculative at the outset of the mission now have large, detailed and time-resolved datasets to use as constraints, providing fodder for study many years into the future.

In the absence of an active mission in the Saturn system, the focus will now turn to observations with ground and space-based observatories such as JWST [Nixon et al. 2016], ALMA, SOFIA, and large optical telescopes. However, given the difficulties of observing through Earth's atmosphere, significant sections of the infrared spectrum remain out reach (for all but JWST). It will be vital to continue monitoring seasonal changes in Titan's atmosphere to extend the time-base of Cassini observations, and prepare the way for the next generation of missions to visit this complex and fascinating world.

Icy Satellites

The key TM questions of Icy Satellite science that CIRS has helped address are:

Level 1

Changes on Enceladus (IC1a)

IC1a: Determine whether Enceladus exhibits any seasonal changes. Other temporal changes (e.g., mean anomaly) are also considered.

Enceladus' plume mass varies as a function time and of orbital position [Ingersoll and Ewald 2017], as shown in Figure CIRS-43. CIRS observations of Enceladus' active south polar region during Cassini's F-ring and proximal orbits (FRPO) were designed to investigate whether Enceladus' surface temperatures also vary with time. Preliminary results indicate that Enceladus' surface temperatures do vary with mean anomaly, but lag in time behind the plume change.

To determine whether the thermal emission of Enceladus varies with mean anomaly a series of observations were planned in the FRPO. A summary of the observations is given in Table CIRS-6.

Howett et al. [2017] presented analysis of this CIRS data at AGU 2017. They used focal plane 3 (FP3) observations since they offer the best compromise between spatial and spectral coverage of Enceladus' active region. The CIRS observations taken of Enceladus clearly show the active region. Figure CIRS-44 shows the original plane of sky data. The figure clearly shows the higher surface emissions from the active south polar terrain.

Table CIRS-6. Summary of the CIRS FP3 observations of Enceladus' south polar terrain. Those in bold have the best SNR, and therefore have been focused upon.

Orbit (Rev)	Date	# FP3 Observations	Mean Anomaly Range
250	**11/27/16**	**5**	**244 to 265**
251	12/4/16	9	8 to 46
254	**12/26/16**	**13**	**247 to 300**
255	1/2/17	5	1 to 18
259	**1/30/17 to 1/31/2017**	**19**	**303 to 24**
263	**2/28/2017 to 3/01/2017**	**21**	**272 to 50**
267	3/29/17	11	215 to 278
286	**8/1/17**	**17**	**280 to 252**

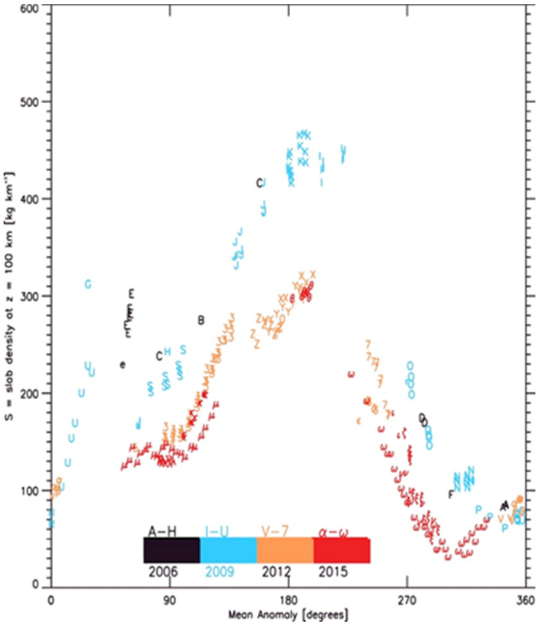

Figure CIRS-43. Enceladus' plume mass vis. Orbital position (mean anomaly). Figure from Ingersoll and Ewald [2017].

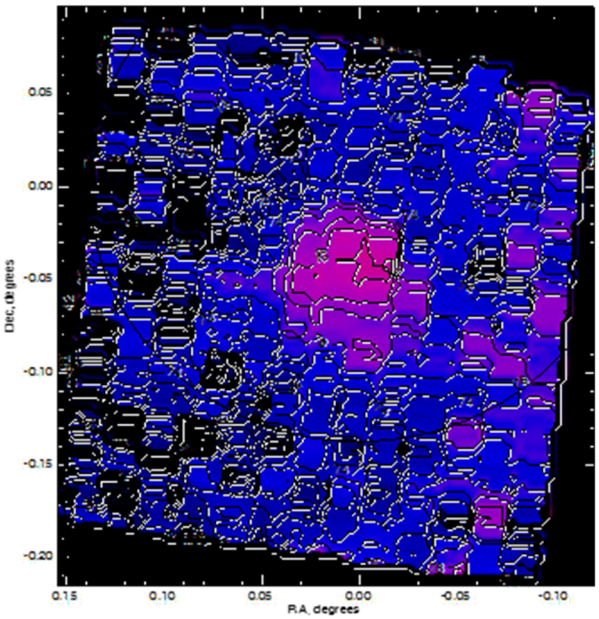

Figure CIRS-44. Typical FP3 scan shown in the plane of sky. Enceladus' active south polar terrain is clearly visible as the warmer purple region.

To properly account for the poles these data were binned into triangles, which are tessellated across the sphere. The area of each triangle is almost constant. The triangles are much smaller than the size of a single FP3 field of view, but since CIRS scans FP3 slowly across the disk subpixel resolution is achieved. Example of the resulting binned total integrated flux between 610 and 800 cm^{-1} are shown in Figure CIRS-45, at the start or end of each observation sequence.

The integrated radiances of all the high SNR observations were totaled for all bins inside of 70° S. The results are shown in Figure CIRS-46. As the figure shows only mean anomalies between ~270 and 10° are covered by these observations, but they appear to show the flux from Enceladus' surface decreasing by about a factor of two during that time.

This is smaller than the 3–5× decrease observed in the plume mass, and occurs at slightly higher mean anomalies. However, the difference is notable and tentatively implies that the temperature of Enceladus' surface in its active region does vary with its orbital location, but the change lags the plume emission change. More work is required to firm up this preliminary result, and analyze the lower signal-to-noise observations to fill in the mean anomaly coverage.

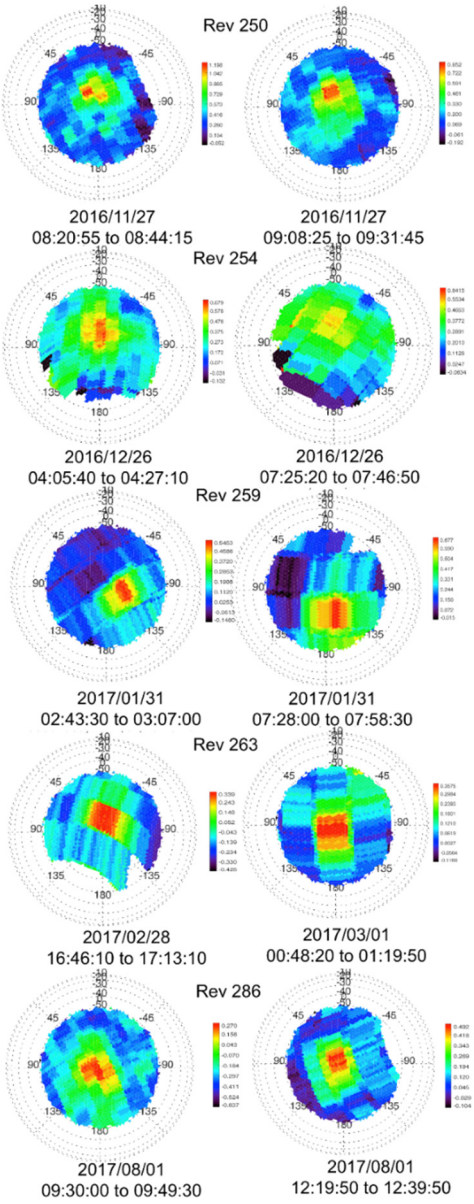

Figure CIRS-45. Binned integrated radiances (610 to 800 cm^{-1}) at the start and end of every rev considered.

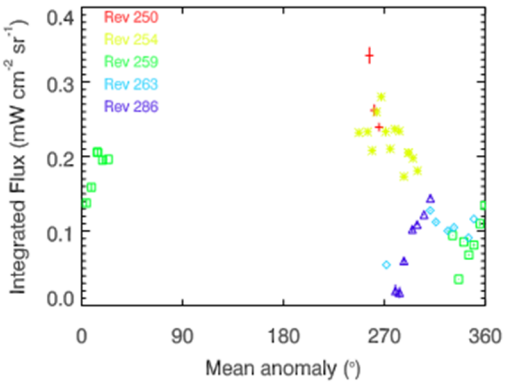

Figure CIRS-46. Total integrated flux (from 610 to 800 cm^{-1}) observed inside of 70° S for all high S/N observations.

CONCLUSIONS

Preliminary analysis indicated that Enceladus' surface emission could be varying with its orbital position, but perhaps lags behind changes in the plume emission. More work is required to firm-up this result, and increase the mean anomaly coverage.

Enceladus' interior (IN1a)

IN1a: Determine the surface temperature in active regions and constrain Enceladus' heat flow, to better constrain models of its activity.

INTRODUCTION

Much work has been done on this subject. An overview of the major results is provided chronologically.

SPENCER ET AL. [2006]

Initial analysis of mid-infrared data (600 to 1100 cm^{-1}) taken by CIRS FP3 onboard Cassini indicated that the endogenic power of Enceladus' south polar region was 5.8 ±1.9 GW [Spencer et al. 2006], much higher than the expected radiogenically produced power of 0.3 GW [Porco et al. 2006; Schubert et al. 2007]. Dissipation of tidally produced energy, most likely from the Dione and Enceladus 2:1 resonance, has been suggested as a possible production mechanism of the observed endogenic power [Spencer et al. 2006; Porco et al. 2006; Yoder 1979; Ross and Schubert 1989].

The Spencer et al. [2006] calculation of Enceladus' endogenic power found that blackbody emission at 133 ±12K over an area of 345 (−160, +320) km^2 matched the total >600 cm^{-1} CIRS FP3 spectrum of the south polar region. However, at this temperature only 10% of the blackbody spectral energy falls within the FP3 wave number range, while the remaining 90% of it falls within the 10 to 600 cm^{-1} wave number range of CIRS' FP1. The percentage of the spectral energy in the FP3 wave number range decreases further with decreasing temperature, rendering FP3 insensitive to low temperature emission, and it was noted by Spencer et al. [2006] that additional power might be radiated at lower temperatures.

HOWETT ET AL. [2011A]

Since the Spencer et al. [2006] analysis used FP3 data it was unable to quantify low-temperature endogenic emission. So another attempt was made to determine Enceladus' heat flow, this time using FP1 data [Howett et al. 2011a]. Long integrations (known as stares) were targeted at Enceladus' south polar region on March 12, 2008 (orbit or revolution, rev 61), and October 31, 2008 (rev 91). The signal to noise of each data set is increased by averaging the stares together. These stares are the only FP1 observations that will be made over the entire Cassini mission which both cover the entire south polar terrain and are sensitive to the wave number region where the bulk of

the endogenic power is radiated. Figure CIRS-47 shows the stare locations: each of the 73 integrations in rev 61 and the 48 integrations in rev 91 has comparable geometry.

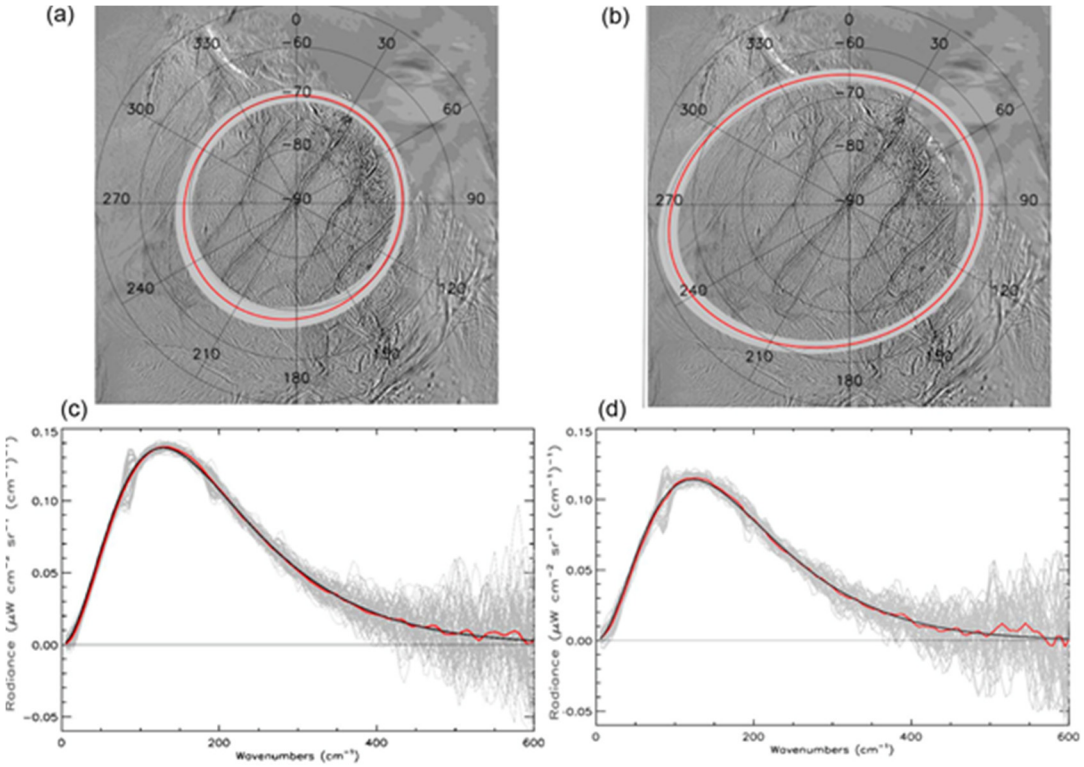

Figure CIRS-47. The range of locations of the FP1 field of view during the stare observations of rev 61 *Panel (a)*, and rev 91 *Panel (b)* over Enceladus' south pole (shown in gray). The field of view at the observation mid-time is also shown (red). The four prominent fractures within the rev 61 field of view are the active tiger stripes. The base map used is the 2006 ISS mosaic PIA 08342. In *Panel (c)* and *Panel (d)*, the spectra of each stare observation (gray), the mean spectrum (red), and the best fit two-temperature to this mean value (black) for revs 61 (*panel c*) and 91 *Panel (d)*.

FP1 is sensitive to the passive emission from the solar-heated surface, which has temperatures in the 35–80 K range [Spencer et al. 2006]. Thus, to obtain the endogenic component of the spectra this passive emission must first be removed. Passive emission is modeled for each epoch and observational geometry using a seasonal and diurnal 1-D numerical thermal model [Spencer et al. 1989]. The model determines surface temperatures by calculating conductive heat flow into and out of the subsurface through every diurnal cycle of an entire Saturnian year, accounting for insolation variations resulting from the 29° tilt of Enceladus' rotation axis relative to the sun, and the concurrent changes in heliocentric distance (9.03–10.05 AU) resulting from Saturn's orbital eccentricity. The model assumes that albedo does not vary with incidence angle, and does not initially account for the effects of heating by radiation from Saturn, or solar eclipses by Saturn, though these are discussed in the section entitled Characterize the Surfaces of Saturn's Small Satellites (IN2d) below. The thermal inertia values it uses are based on previous observations but require assumptions about the thermophysical properties at depth.

For each observation the temperatures predicted by this model are used to calculate the passive background across the FP1 field of view, assuming blackbody emission. These temperatures are weighted by the spatial sensitivity pattern of the FP1 detector, which is approximated as a 2-D Gaussian with a FWHM of 2.42 mrads [Flasar et al. 2004a]. The results from this model were validated by demonstrating the good agreement between the modeled spectrum produced, and CIRS data taken within Enceladus' south polar terrain but away from the tiger stripes themselves. For each observation, this passive thermal background is subtracted from the CIRS spectra leaving a residual, the spectrum of the endogenic emission. The residual is then weighted to correct for the assumed spatial distribution of the endogenic emissions. Three possible scenarios are considered: (i) that emission from the tiger stripes is uniform along their length, (ii) that the emission from the stripes varies in the same way as previously observed by higher spatial resolution higher wave number observations by the CIRS FP3 detector and, (iii) to set a lower limit on the endogenic power, a scenario which all emission arises from the most sensitive central 10% of the field of view is also considered. The effects these scenarios have on the endogenic emission determination are discussed further in the section entitled Tethys and the E-ring (IN2b) below. In the case of the stare observation the corrected residuals for each rev are averaged to increase the signal to noise. The final corrected residual is then fitted by a blackbody temperature curve with a filling factor, which allows the residual to be fitted by emission from only a fraction of the field of view if required. The endogenic power of that residual is then derived using the Stefan-Boltzmann law, the fitted temperature, filling factor and area of the projected FP1 field of view.

Since the response of the FP1 detector is non-uniform we also had to consider the spatial distribution of the endogenic emission. To estimate the dependence of the derived endogenic emission on its spatial distribution we evaluated three different scenarios: (i) that the tiger stripes are the sole source of the power and have uniform emission along their lengths, (ii) that the tiger stripes are the sole source of the power but that the emission intensity varies along each stripe, and (iii) finally that the emission is independent of the tiger stripes location but arises instead from an area within the most sensitive central 10% of the FP1 field of view. The last scenario is unrealistic, but is designed to determine a lower limit to the endogenic emission. The FP1 detector is most sensitive to emission from its central region and thus concentration of the emission in this region would minimize the true power required to produce the observed signal. Under the second scenario the variation in brightness along the length of the tiger stripes is assumed to be the same as that determined from high spatial resolution 600–1100 cm^{-1} FP3 observations made on rev 61 (Figure CIRS-48) from 1922:00 to 1944:00 UT. These observations had a spatial resolution of 4.1-9.6 km, sufficient to resolve the tiger stripes and the spatial distribution of emission along their lengths (Figure CIRS-48). Almost the entire tiger stripe region was covered, with the exception of the Saturn-facing end of Alexandria Sulcus, for which we have included approximate brightness values based on other CIRS observations [Spencer et al. 2006]. For the uniform case, we assigned equal brightness to all spatial bins with nonzero normalized brightness.

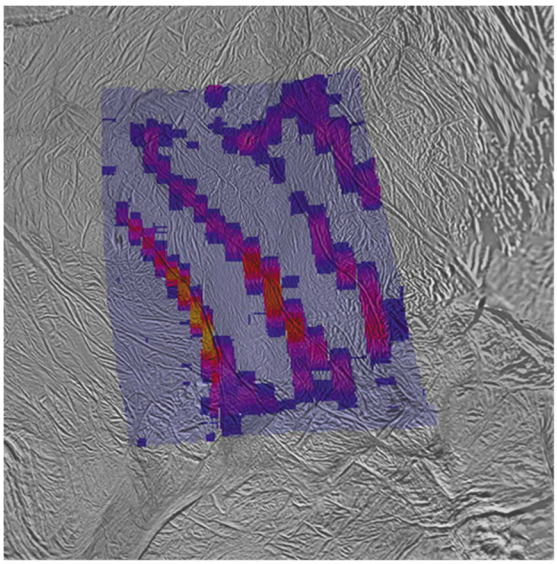

Figure CIRS-48. CIRS FP3 map of the spatial distribution of radiated 600–1100 cm^{-1} brightness along the four tiger stripes, as observed on March 12, 2008 (rev 61). Relative brightness is shown by colors ranging from blue (faintest) to yellow (brightest). The pale blue area shows regions that were mapped, but showed negligible radiated power. The data used in this scan was taken between 1922:00 and 1944:00UT on March 12, 2008.

Finally, the emission from a surface also depends on its albedo and thermal inertia. These properties are not known for Enceladus' active south polar terrain, although they are known for regions close to it [Howett et al. 2010]. By modeling FP1 observations close to, but not over the active part of Enceladus south polar terrain, it was possible to narrow down the range of albedo to ~0.80. Since constraining thermal inertia was not possible three scenarios are considered: (i) a constant thermal inertia of 27 MKS at all depths, (ii) two scenarios both of which have a thermal inertia of 27 MKS from the surface to a depth of 1 cm, but have higher thermal inertias of 100 MKS, and (iii) 1000 MKS below 1 cm. A near- surface thermal inertia of 27 MKS was derived for the latitude bin 60° S to 50° S [Howett et al. 2010], this is the closest location to the south polar terrain (SPT) for which thermal inertia has been determined. The lower deep layer thermal inertia value of 100 MKS was selected using results from 2005 Cassini CIRS observations of Enceladus' winter north pole that showed the north polar thermal inertia to be less than 100 MKS to a depth of ~1 m [Spencer et al. 2006]. The higher deep layer thermal inertia value of 1000 MKS was selected to be close to that of solid water ice [Paige et al. 1994]. The results are shown in Figure CIRS-49, and a summary of the endogenic emission predicted using these different scenarios is given in Table CIRS-7.

The maximum and minimum endogenic emission values given in boldface in Table CIRS-7, excluding the extreme and unlikely scenario where all emission is concentrated at the center of the FP1 field of view, are used as our estimate of the uncertainty range of the total endogenic emission. Thus, it is estimated that Enceladus' south polar endogenic emission of 14.8 ±1.9 GW for rev 61 and 16.9 ±2.4 GW for rev 91, which agree within error and give a combined value of 15.8 ±3.1 GW.

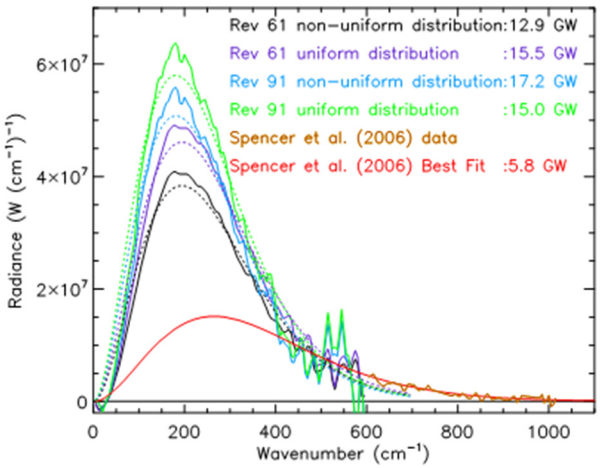

Figure CIRS-49. The mean endogenic emission of the FP1 stare observations taken during revs 61 and 91, assuming both uniform and nonuniform emission along the tiger stripes (see the section entitled Tethys and the E-ring (IN2b)). The best fitting blackbody temperature fits are given by the dotted lines, which are correspondingly colored. Temperatures of 99.1 K and 92.4 K provide the best fit to rev 61 and 91 for both of the assumed spatial distributions. However, the total surface area of the emission decreases from 2657 km^2 to 2211 km^2 for rev 61 and from 4121 km^2 to 3609 km^2 for rev 91 as the assumed spatial distribution varies from uniform to nonuniform. The 2005 FP3 endogenic emission spectrum used by Spencer et al. [2006] to determine the previous lower estimate of endogenic power is also shown, along with the extrapolation of a blackbody fit to that spectrum over the wave number range of the FP1 detector.

Table CIRS-7. Summary of the predicted endogenic emission from Enceladus under a variety of reasonable assumptions about the thermophysical properties of Enceladus' surface. See text for a full description.

SPENCER ET AL. [2012]

The previous heat flow estimates were based on observations that did not resolve the tiger stripes from their surroundings, so passive emission from the surroundings had to be modeled and subtracted to determine endogenic heat. In this work, Spencer et al. [2012] used higher spatial resolution observations to spatially separate the tiger stripe emission, which must be endogenic, from background emission, which is expected to be partly or entirely passive.

They model the surfaces radiating the endogenic emission as continuous ribbons of material of temperature T (l) and width W (l) which vary smoothly with distance l along the tiger stripes and associated warm fractures. T and W are adjusted to match the spatial and wavelength dependence

of the emission seen in specific CIRS observations, using a forward model. The most extensive FP3 map of the tiger stripes, obtained on orbit 61 in March 2008 (Figure CIRS-48 and Figure CIRS-50), can be matched with a single relatively high temperature endogenic component, denoted by subscript H , with TH (I) varying spatially between 120 and 165 K, and WH (I) varying between 60 and 330 meters. The best spatially resolved constraint on lower-wavenumber emission, an FP1 scan across the tiger stripes Damascus, Baghdad, and Cairo from orbit 136 in August 2010 (Figure CIRS-50) shows that an additional lower temperature component is also needed (Figure CIRS-51). However the limited spatial coverage of this and other FP1 scans does not allow unique constraints on the spatial distribution of the low temperature component. To estimate the contribution of this component (denoted by subscript L), we constrain TL and WL from the wavelength-dependent FP1signature where the rev 136 scan crosses the tiger stripes (Figure CIRS-51), and extrapolate to the rest of the system by assuming that both TL and WL /WH are independent of location. We then re-fit all parameters using these assumptions.

The resulting total heat flow is 2.7 GW and 1.5 GW from the high and low temperature components respectively, for a total of 4.2 GW. Enceladus' power output also includes the latent heat of the escaping plume (~0.5 GW [Ingersoll and Pankine 2010]), giving a total output of ~4.7 GW. There may be additional endogenic heat from the regions between the tiger stripes, included in previous estimates but excluded here, which may account for some of the discrepancy with earlier estimates. It is also possible that previous models under-estimated the passive contribution to the integrated south polar emission (e.g., due to spatial variability of thermophysical properties), and thus, over-estimated of the endogenic component.

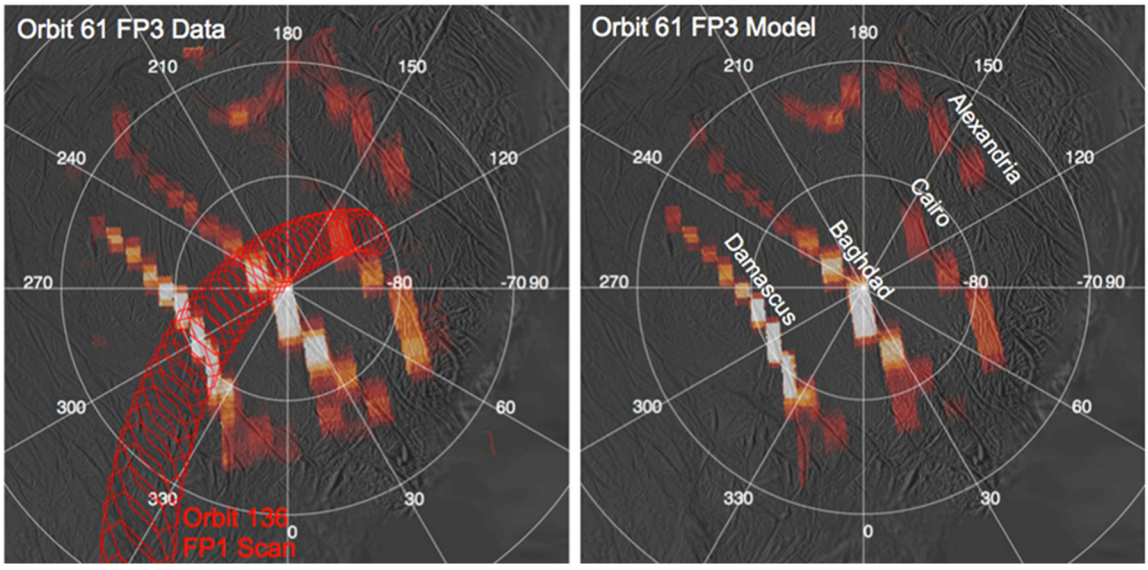

Figure CIRS-50. Constraining the tiger stripe emission distribution model using the orbit 61 CIRS FP3 scan of the tiger stripe system. *Left*: shows observed 600–850 cm^{-1} radiance. *Right*: shows the simulated observation derived from the best-fit model. *Left*: also shows (red) the location of the orbit 136 FP1 scan used to constrain the longer wavelength emission from the tiger stripes (Figure CIRS-51).

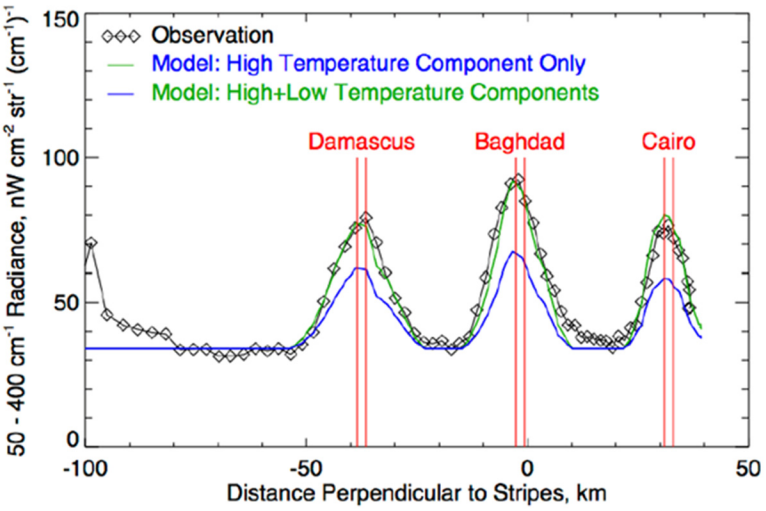

Figure CIRS-51. Profile of low-wavenumber FP1 radiation across three of the tiger stripes (Figure CIRS-50) from orbit 136, compared to predictions from our best-fit model of tiger stripe temperatures, with and without the inclusion of a low-temperature component. The model also includes a constant background radiance, assumed here to be passive re-radiated sunlight. This FP1 scan reveals that the high-temperature component fitted to the FP3 observations (Figure CIRS-50) does not account for all the radiated power at low wavenumbers, and an additional low temperature component is need to match the data.

The inconsistency of heat flows derived from different techniques highlights the difficulty of these measurements, indicating that all heat flow estimates should be treated with caution. However, all estimates are much larger than the expected maximum steady-state tidal heating of 1.1 GW [Meyer and Wisdom 2007].

CURRENT WORK

To minimize the effect of passive emission observations of Enceladus were made with FP1 late in the Cassini mission, when Enceladus' active south pole was in winter. During such time, the effect of low-temperature passive emission is minimized (Figure CIRS-52). Observations taken during rev 250 by FP1 offer one of the best opportunities for determining Enceladus' heat flow. In this rev, a scan of Enceladus entire south polar terrain was made by FP1. Preliminary analysis has been performed using two methods and provides similar results.

The first method was to look at individual spectra taken over Enceladus' active region, remove the (small) expected passive emission, and assume the remaining emission is endogenic (Figure CIRS-52). The resulting endogenic emission is ~9 GW.

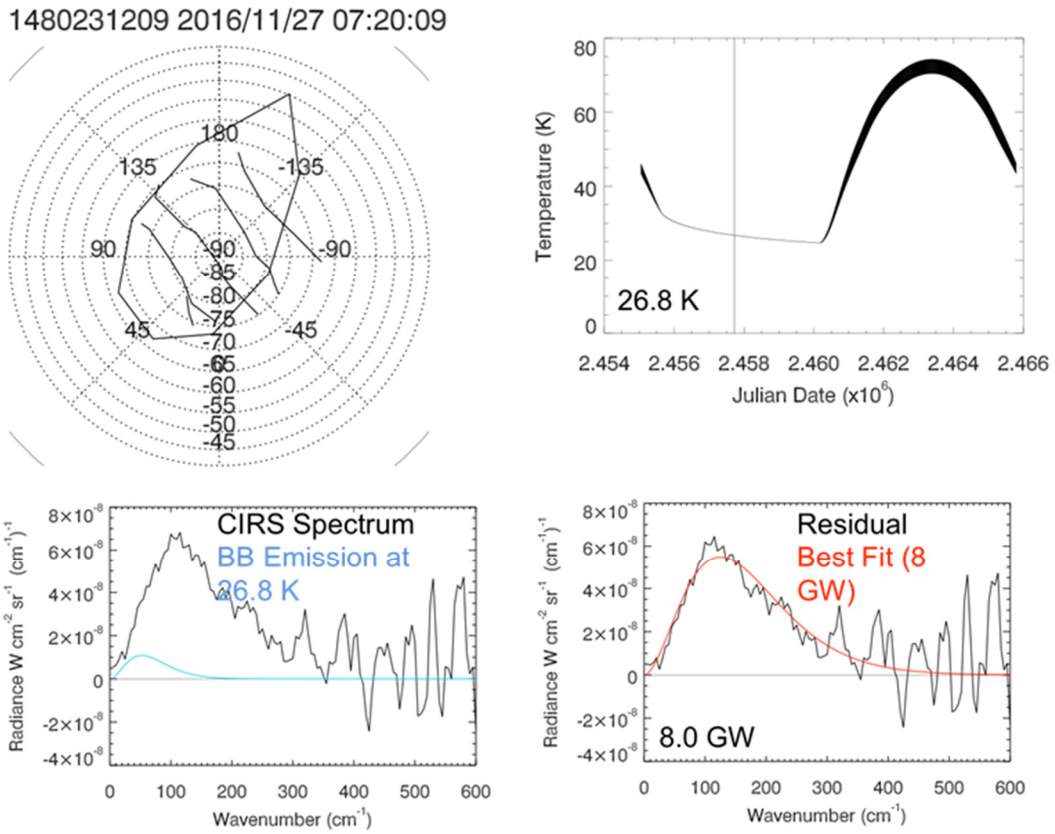

Figure CIRS-52. Individual spectra taken over Enceladus' active region. *Top left*: location of the observation analyzed, spacecraft event time (SCET) relative to Earth time, it was taken. The position of the tiger stripes is indicated. *Top right*: Seasonal model for a surface with an albedo of 0.80 and a constant thermal inertia with depth of 27 MKS. The temperature this model predicts for Enceladus' passive emission at the time the observation was taken is 26.8 K. *Bottom left*: calibrated CIRS FP1 spectrum taken, compared to the predicted passive emission. *Bottom right*: residual CIRS spectrum and the best fit.

The second technique is to use observations close to the tiger stripe but away from the activity as a proxy for the expected passive emission (see Figure CIRS-53). These results imply that the total south polar power (in one FP1 FOV) is ~6–8 GW. However, further work is required to determine to what extent power spills into multiple field of views.

Conclusions

Determining the heat flow of Enceladus' active region is a particularly difficult thing to do, since in order to determine the low-temperature heat flow Enceladus passive emission must be removed (particularly early on in Cassini's mission when the south pole was not in winter). This modeling effort is hampered by a somewhat chicken-and-egg problem: in order to model the passive emission the thermophysical properties of Enceladus' surface are needed to be accurately known, but it is difficult to determine these properties because of the activity.

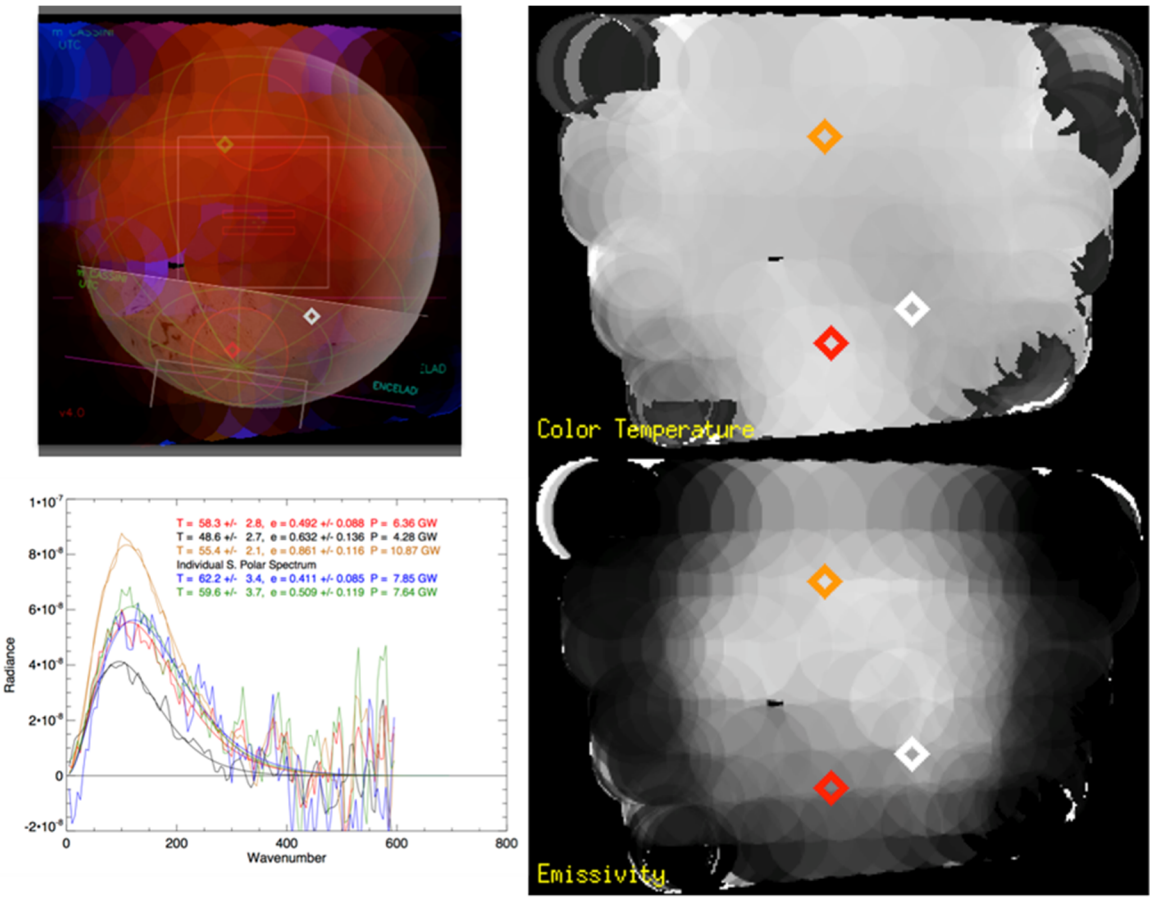

Figure CIRS-53. Observations close to the tiger stripe but away from the activity as a proxy for the expected passive emission. *Top Left*: Temperature map of Enceladus, with geometry overlaid. The position of three reference points are indicated: one away from the tiger stripes (orange), another close but not in the active south polar terrain (white) and another in the heart of the active region (red). *Bottom Left*: calibrated CIRS FP1 spectra and their best fits at the reference points. *Top/Bottom Right*: The radiance map plotted as a function of color temperature and emissivity variations. The plots show the temperature highest over the south polar terrain, which also displays the lowest emissivity.

Early attempts set a limit based on the high-temperature endogenic emission: 5.8 ±1.9 GW [Spencer et al. 2006]. Later attempts characterized both the high- and low-temperature emission: 15.8 ±3.1 GW [Howett et al. 2011a]. Continued modeling of the high- and low-temperature emission from only the stripes themselves pointed to a lower value of ~4.7 GW [Spencer et al. 2018]. New and ongoing work trying to characterize Enceladus' heat flow while the southern polar region is in winter (i.e., has a reduced passive emission) provides an estimate between 6 and 8 GW, but more work is required to fully characterize this emission.

So, more work is required! And even then, there will always be some ambiguity over this number—particularly if it is varying, as preliminary results from Howett et al. [2017] suggest. However, what is certain is that Enceladus' activity is continuing and impressive.

Compare Saturn's mid-sized satellites (IN1b)

IN1b: Compare the surface characteristics of Saturn's mid-sized satellites, including the thermally anomalous Pac-Man regions.

INTRODUCTION

Observations returned by CIRS and ISS showed a thermal and color anomaly at low latitudes on Mimas and Tethys' leading hemisphere (see Figure CIRS-54). This anomaly, dubbed Pac-Man (because its shape mimics that of the 1980s' video icon), displays warmer nighttime and cooler daytime temperatures than its surroundings and appears darker in IR/UV color ratio maps [Howett et al. 2011b, 2012; Schenk et al. 2011]. The color and thermal anomalies are believed to be the result of surface alteration by high-energy electrons, which preferentially bombard this region, altering its surface and increasing its thermal inertia. These high-energy electrons, in Saturn's magnetosphere, drift in a retrograde direction relative to corotation. Recent modeling efforts, supported by the Low Energy Magnetospheric Measurement System (LEMMS) on Cassini's Magnetospheric Imaging Instrument (MIMI), have shown that these electrons preferentially bombard low latitudes on Mimas, Tethys, and Dione's leading hemisphere [Paranicas et al. 2012, 2014; Howett et al. 2011b; Schenk et al. 2011].

COMPARISON OF THE SURFACE PROPERTIES OF THE SATELLITES, HOWETT ET AL. [2010]

We measure surface temperatures by determining the temperature that best match the observed thermal radiation, on the assumption of blackbody radiation. Nighttime temperatures provide the strongest constraints on thermal inertia, and of the icy satellites only Phoebe (due to its low ABB and rapid rotation) has nighttime temperatures warm enough to be detectable by FP3 Flasar et al. [2005a]. The higher wavenumbers detected by FP4 are insensitive to all of the Saturnian icy satellite's passive daytime and nighttime temperatures. This investigation therefore solely uses FP1 data, which is sensitive to both daytime and nighttime radiation from Saturn's icy moons. The

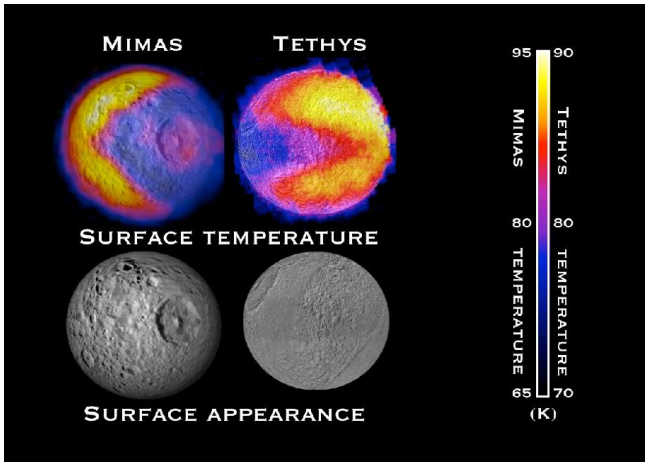

Figure CIRS-54. Summary of the two Pac-Man.

consistency of temperatures derived from FP1 and FP3 observations were spot-checked using selected daytime observations of Rhea and Dione that included near-simultaneous measurements with both detectors. Derived temperature were consistent to within 2–3 K.

The best fitting values for each of Saturn's icy moons is summarized in Table CIRS-8. For Enceladus, the local time coverage of each 10° latitude bin was good enough to constrain the thermal inertia and albedo as a function of latitude between latitude 60° S and 70° N.

Table CIRS-8. Summary of the CIRS derived thermal inertia and albedo for icy satellites in the Saturn system. Table data from Howett et al. [2010].

Accurate determination of the endogenic south polar heat flow from Enceladus [Spencer et al. 2006] requires subtraction of the passive component from the total thermal emission, making knowledge of the thermophysical properties of Enceladus, and their latitudinal variation, particularly important. The CIRS observations previously used to determine the global surface properties between 60° S and 70° N were separated into 10° latitude bins and the same analysis techniques as previously described were applied to each bin. The number of high resolution spectra available between 50° N and 60° N and north of 70° were not high enough to allow the albedo and thermal inertia to be adequately constrained.

However, the bolometric Bond albedos and thermal inertias of Mimas, Enceladus, Tethys, Dione, the leading and trailing hemisphere of Rhea, and the trailing hemisphere of Iapetus have been determined. The diurnal curves derived using these values provide good fits to the calculated black body temperatures fits to the CIRS spectra. The bolometric Bond albedo of the leading side of Iapetus is too low to accurately determine a value; however, an upper limit is found and the local time coverage is adequate to determine its thermal inertia. The thermal inertia of all of Saturn's icy satellites is shown to be less than half that of the Galilean satellites, implying less consolidated and more porous surfaces, perhaps partially due to the limited mobility of water ice on the Saturnian satellites due to their low temperatures compared with the Galilean satellites, or to a surface coating of E-ring particles. The latitudinal variation in the thermal inertia of Enceladus implies the surface becomes more consolidated towards the southern pole, whereas the higher albedo in the southern hemisphere implies a cleaner surface, perhaps due to plume fallout. Further work investigating the hemispheric bolometric Bond albedo asymmetries of Dione would be valuable, as although the globally averaged values derived here provide a good fit to the CIRS data, observations of viable wavelength have observed notable differences between the leading and trailing hemispheres [Buratti and Veverka 1984].

MIMAS, HOWETT ET AL. [2011B]

CIRS day- and nighttime observations of Mimas taken in rev 126 and 139 are shown in Figure CIRS-55. Both the orbit 126 and 139 maps show a V-shaped boundary, sharp at CIRS resolution, separating warmer and cooler temperatures. The apex of the V is at 0° N and 180° W, and the boundary extends in a northeasterly and southeasterly direction, during orbit 144 indicates the eastern edge of the thermal anomaly is near 0_ longitude. The region east of the boundary, on Mimas' leading hemisphere, is colder than its surroundings in the orbit 126 daytime observations, but is warmer than its surroundings in the orbit 139 nighttime and early morning data. This region thus displays much smaller-amplitude diurnal temperature variations than regions to the west, north, and south, which show thermal behavior more typical of other Mimas longitudes and most of the surfaces of Mimas' neighboring satellites, Tethys, Dione, and Rhea [Howett et al. 2010]. Thus, we refer to the region east of the boundary, on the anti-Saturn hemisphere, as the thermally-anomalous region.

Overlaid on Figure CIRS-55 are new estimates of the energy flux of MeV electrons bombarding Mimas, updating those given in Schenk et al. [2011]. Because energetic electrons in Saturn's magnetosphere drift in a retrograde direction relative to corotation they preferentially

bombard Mimas' leading hemisphere. Notable improvements in the new model include the use of additional data from the LEMMS on Cassini's MIMI (several-year averages were used) and the introduction of data from the channel E7 on LEMMS. The E7 channel is the highest energy electron channel on LEMMS and adding these data modifies the spectral slope at high energies, which turns out to be very important for the behavior of the contours particularly away from the equator. Further details on the mission averaged electron data are given in Paranicas et al. [2012, 2014].

The thermal anomaly is closely correlated spatially with an IR/UV (0.930/0.338 lm) color ratio anomaly previously observed in global maps of Mimas using Cassini ISS data. An updated version of the global IR/UV map of Mimas, originally given in Schenk et al. [2011], is shown in Figure CIRS-55. Though there are some inconsistencies in the latitudes and longitudes of features on the two maps, the location of the thermal and color anomalies can be compared by reference to craters near the anomaly boundaries appearing on both maps (red circles, Figure CIRS-55).

Figure CIRS-55 boundaries of the thermal and color anomalies appear to be nearly identical, although the apex of the thermal anomaly appears sharper. In the absence of endogenic emission, surface temperatures are controlled by surface bolometric Bond albedo and thermal inertia. A surface's thermal inertia describes how well it is able to store and release thermal energy. To investigate the cause of the anomalous temperatures seen by CIRS we determine albedo and thermal inertia for two representative regions, one outside and another inside the anomaly (shown by the boxes in Figure CIRS-55). The surface temperature for each of the two regions in orbits 126 and 139 was determined by fitting a single blackbody curve to the mean CIRS FP3 spectra of all the observations taken of that region. Following the example of Spencer et al. [2006], the spectral noise was estimated using the difference between a blackbody emission spectra. These two steps are repeated numerous times and the temperature error estimate is given by the standard deviation of the temperatures whose best able to fit the created spectra.

The ranges of bolometric Bond albedos capable of fitting the data outside and inside of the anomaly overlap: 0.49–0.70 and 0.56–0.62 respectively. This is consistent with the lack of a noticeable albedo boundary in visible-wavelength images. These albedos are comparable in value with those observed on Tethys, Dione and Rhea. As expected, it is the thermal inertias that vary significantly: <16 J m^2 K^{-1} $s^{-1/2}$ outside the anomaly (these units henceforth referred to as MKS) and 66 ±23 MKS within it. The low thermal inertias outside of the anomaly are similar to those observed on Tethys, Dione and Rhea [Howett et al. 2010], whilst those inside the anomaly are greater than but more comparable with values observed on the icy Galilean satellites. The higher thermal inertias inside the anomalous region indicate that the surface there is less porous and/or has a higher thermal conductivity.

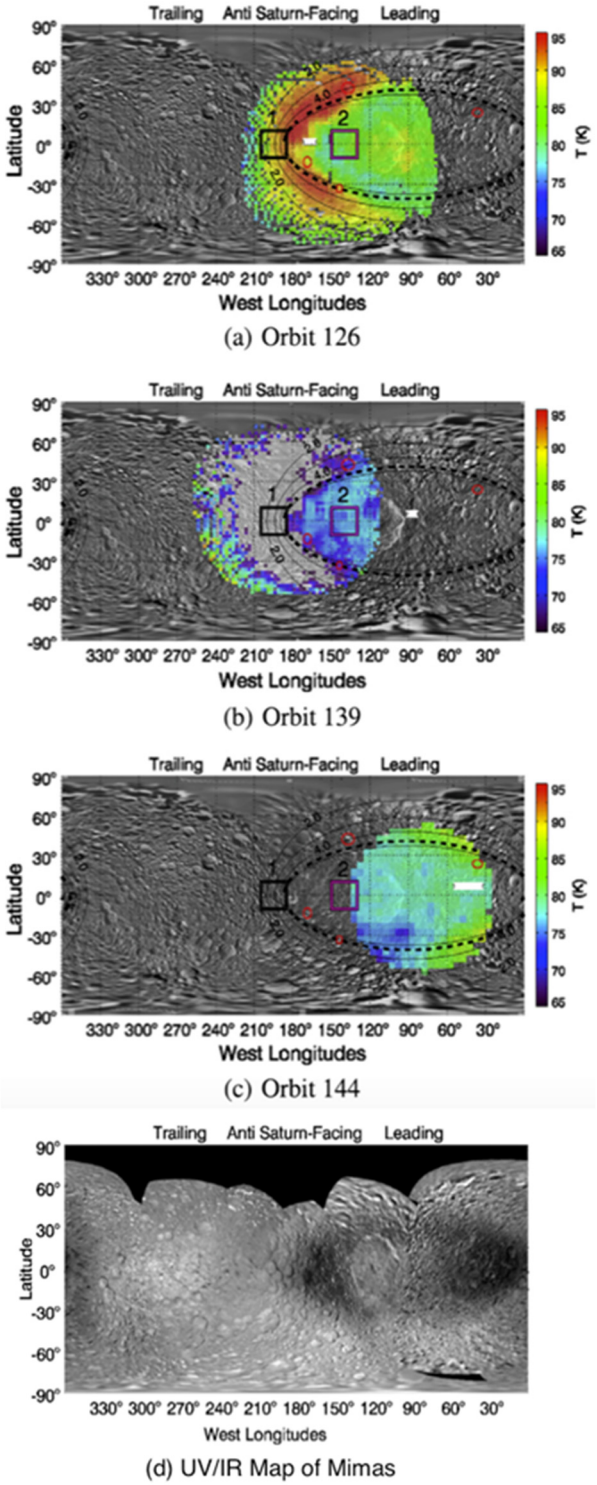

Figure CIRS-55. CIRS day- and nighttime observations of Mimas. *Panel (a)*: Orbit 126 daytime surface temperatures. *Panel (b)*: Orbit 139 nighttime surface temperatures of Mimas. *Panel (c)*: Orbit 144 daytime surface temperatures. *Panel (d)*: IR/UV (0.930/0.338 lm) color ratio map of Mimas' surface determine from Cassini ISS data.

The close spatial correlation of the thermal and IR/UV color ratio anomalies suggests a common origin. It has been proposed that high-energy (MeV) electron bombardment of Mimas' surface is responsible for the observed IR/UV color ratio variation [Schenk et al. 2011]. Plasma corotates with the planet and thus flows around Saturn in a prograde sense, overtaking Mimas in its orbit and impacting its trailing hemisphere. However, electrons with energies above about 1 MeV flow retrograde with respect to Mimas. Their north–south motion is much faster than their longitudinal motion and these electrons therefore bombard the moon close to its leading equator. The impact patterns are represented by lens-shaped contours of energy deposition very similar in shape to the color and thermal boundary (Figure CIRS-55). The color boundary at Mimas corresponds to an electron energy deposition rate contour of about 5.6×10^4 MeV cm^2 s^{-1} [Schenk et al. 2011]. The contour corresponding to the boundary of the thermal anomaly is harder to determine due to its poorer spatial correlation, however it appears to be similar to that of the color anomaly.

TETHYS, HOWETT ET AL. [2012]

In September 2011 (during Cassini's orbit 153) CIRS obtained a daytime medium-spatial resolution observation (the average resolution was 84 km/pixel) of Tethys' leading hemisphere. FP3 was used for these observations since it provides the best compromise between sensitivity to thermal radiation and spatial resolution for daytime observations of icy satellites. These observations were at a significantly better spatial resolution than the previous best thermal map of this hemisphere, a nighttime map obtained in June 2007 (Cassini's orbit 47; 150 km/pixel) using FP1. The lower spatial resolution FP1 is the only CIRS detector sensitive to the cool nighttime surface emission of Saturn's icy satellites; therefore, spatial resolution differences in the night-day-time coverage with CIRS are common. Combination of the orbit 47 and orbit 153 observations provides sufficient local time coverage to constrain surface albedo and thermal inertia.

The results, given in Figure CIRS-56, clearly show a thermally anomalous region exists on Tethys' leading hemisphere at low latitudes in both the daytime and nighttime temperatures. The region appears to be ~10 K cooler during the day and ~10 K warmer at night than its surroundings, quite unlike the pattern expected if surface properties were spatially uniform (also shown in Figure CIRS-56), with largest thermal contrast occurring at the northern anomaly boundary, particularly towards the east. The thermally anomalous region is lens-shaped with apexes at 0° W and 180° W, and is widest in the center of the leading hemisphere (90° W) reaching latitude ±20°. This anomalous region spatially coincides with a dark (low) albedo region at low latitudes on Tethys' leading hemisphere was first observed in Voyager data [Stooke 1989, 2002]. Photometry applied to Cassini ISS images showed the band to be 2–3% brighter in the NAC CL1-UV3 filter (338 nm) and 8% darker in the NAC CL1-IR3 (930 nm) filter [Elder et al. 2007].

The best-fit bolometric Bond albedo for all three of these regions is remarkably constant: 0.67 ±0.02, whilst the best-fit thermal inertia increases from 5 ±1 MKS outside the anomaly, to 11 ±1 MKS at the western boundary and 25 ±3 MKS inside the anomaly. The values outside the thermal anomaly are comparable to those seen on other Saturnian satellites [Howett et al. 2010]. The derived albedo is also consistent with previous estimates.

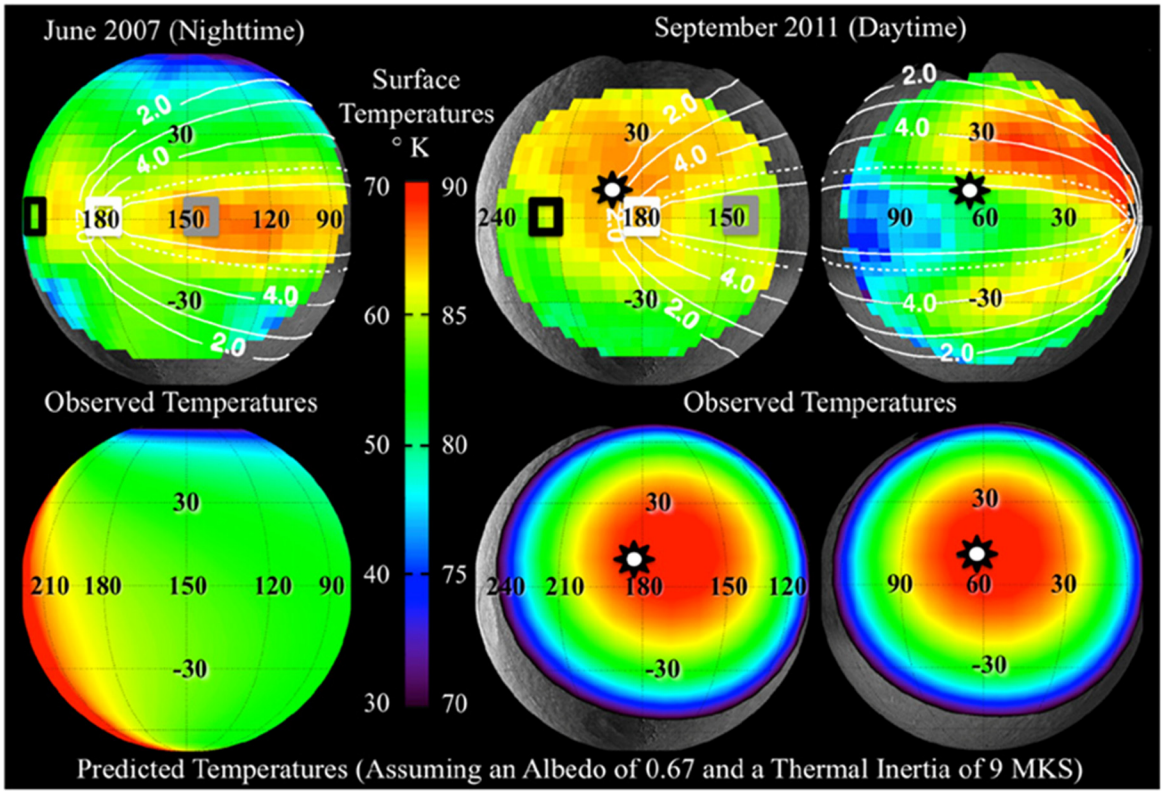

Figure CIRS-56. Tethys' thermal anomaly can be seen by comparing the observed and predicted surface temperatures of Tethys at night (June 2007) and during the day (September 2011). Contours overlaid on the observed temperatures show the predicted electron energy flux onto Tethys' surface, in units of log10(MeV cm^{-2} s^{-1}), with the white dashed line contour representing the best fit electron energy flux contour to the observed surface color alteration (18 GeV cm^{-2} s^{-1}) [Schenk et al. 2011]. The black stars-shapes with the white centers indicate the location of the subsolar point.

The maximum electron energy flux bombarding Tethys is nearly six times lower than that on Mimas and is constrained to a smaller latitudinal extent, consistent with the relative amplitude and shape of the thermal anomaly on the two bodies [Paranicas et al. 2012; Schenk et al. 2011]. The discovery of Tethys' thermal anomaly, which as Figure CIRS-56 shows has a boundary corresponding to an 18 GeV cm^{-2} s^{-1} electron flux (compared to 56 GeV cm^{-2} s^{-1} on Mimas), greatly strengthens the case that energetic electrons are able to significantly alter an icy satellite surface, and also proves that the threshold electron energy flux able to do so is lower than previously thought. A lower energy flux threshold increases the probability that such alteration occurs on other satellite surfaces. Why high-energy electron bombardment would decrease the IR/UV surface color ratio and why the thermal anomalous region appears darker in visible light images of Tethys, but not on Mimas, remains a mystery.

DIONE, HOWETT ET AL. [2014]

Maps of variations in albedo and thermal inertia were derived for Dione, using eight separate CIRS observations taken from 2005 until 2012, which provided both day and nighttime coverage. Figure CIRS-57 shows the thermally-derived bolometric Bond albedo variation across Dione. The map shows that the bolometric Bond albedo of Dione's trailing hemisphere (0.39 ±0.13) is much darker than its leading hemisphere (0.49 ±0.11). The disk-integrated value (0.44 ±0.13) is consistent (to within error) of previously determined values: 0.52 ±0.08 Pitman et al. [2010] and 0.63 ±0.15 Howett et al. [2010]. The trailing/leading hemisphere albedo trend has been previously observed on Dione from visible-wavelength observations (e.g., in the geometric albedo map by Blackburn et al. [2012]) and, as noted in the introduction, is thought to be due to the preferential bombardment of Dione's leading hemisphere by E-ring particles [Hamilton and Burns 1994], which plausibly cause surface brightening [Verbiscer et al. 2007].

Dione displays a different trend in its thermal inertia, which is highest at low latitudes on its leading hemisphere. Between 30° S and 30° N, 180° W and 360° W, the mean thermal inertia is 8 MKS, while between the same latitudes and 30°–150° W, the mean thermal inertia is 11 MKS.

As noted above, Mimas and Tethys display similar anomalies [Howett et al. 2011b, 2012]. However, on Dione the magnitude of the thermal inertia increase is too subtle for its effect to be easily observed in maps of the surface temperature (unlike on Mimas and Tethys). Nonetheless, the inference of high thermal inertia in these regions becomes clear when diurnal temperature curves are compared with Dione's observed surface temperatures; the lower thermal inertia value (8 MKS) is unable to fit Dione's leading hemisphere's higher nighttime temperatures. Diurnal temperatures probe thermophysical properties over a range given by the thermal skin depth, which for these thermal inertias is 0.4–0.6 cm (assumptions as in Howett et al. [2010]). The location of Dione's higher thermal inertia region is spatially correlated with the region preferentially bombarded by high energy electrons. This is the same trend that is observed on Mimas and Tethys. On Mimas E-ring grain particles bombard opposite hemispheres, while on Tethys (and Dione) they both bombard the leading hemisphere. The similarity between Mimas' and Tethys' thermal anomalies (their location on the leading hemisphere and strong spatial correlation to the region preferentially bombarded by high-energy electrons) provides a compelling argument for them having the same formation mechanism, which on Mimas cannot be E-ring grain bombardment. Thus, it is concluded that surface alteration by high-energy electrons is the dominant process on Tethys, and by extension, the same is likely on Dione.

The magnitude of the thermal inertia difference between the background and inside the thermal anomaly is greatest on Mimas and then decreases from Tethys to Dione. However, on Dione the thermal anomalous region does not appear to be spatially correlated with a decrease in the IR/UV albedo ratio as it is on Mimas and Tethys, which suggests either that the surface alteration on Dione is below the threshold for UV darkening to occur or that the color change is too subtle to be detected. No such anomaly is observed on Enceladus, presumably due to its high resurfacing rates.

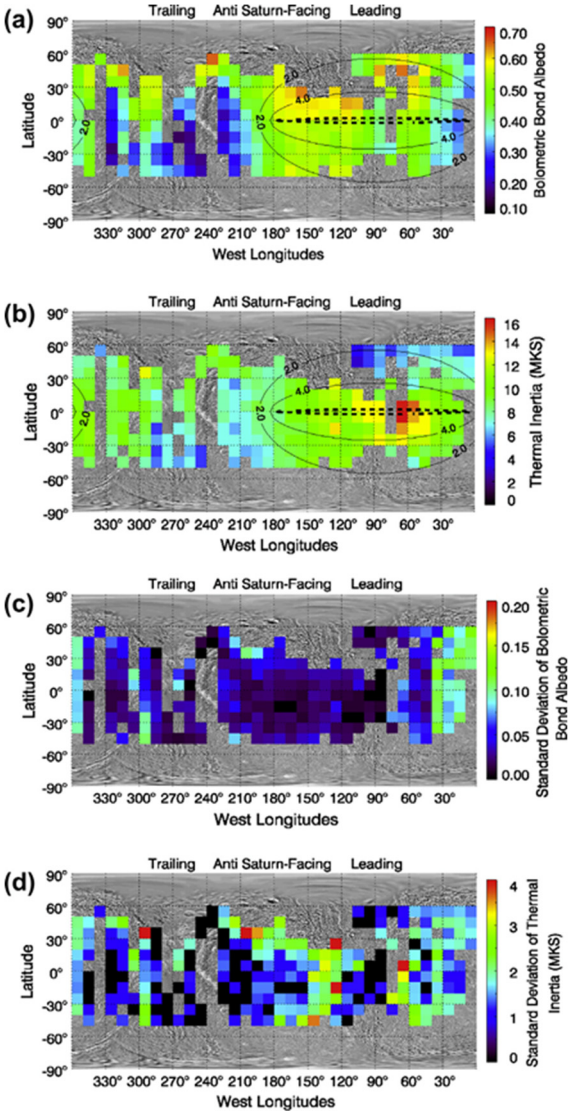

Figure CIRS-57. Maps of derived thermophysical properties for Dione. *Panel (a)*: Bolometric Bond albedo map of Dione. Overlaid are contours of energetic electron power deposited into the surface per unit area (log10 MeV cm^2 s_1). *Panel (b)*: Thermal inertia map of Dione. Overlaid are contours of high-energy electron flux, see the description in *Panel (a)* for details. *Panel (c)*: The standard deviation of the bolometric Bond albedo values given in *Panel (a)*. *Panel (d)*: The standard deviation of the thermal inertia values given in *Panel (b)*.

RHEA, HOWETT ET AL. [2014]

Maps of variations in albedo and thermal inertia were derived for Rhea, using eight separate CIRS observations taken from 2005 until 2012, which provided both day and nighttime coverage. The bolometric Bond albedo and thermal inertia maps of Rhea are given in Figure CIRS-58. Two trends are obvious in the maps: the trailing hemisphere of Rhea is somewhat darker and there is a region of high thermal inertia centered on 110° W, 20° S. Rhea's hemispherical albedo pattern has been previously observed directly at visible wavelengths—for example, Verbiscer and Veverka [1989] and via thermal observations [Howett et al. 2010]. The bolometric Bond albedo maps give a disk-integrated value of 0.58 ±0.12, and leading and trailing hemisphere value of 0.59 ±0.11 and 0.56 ±0.13, respectively. Within error these results agree with the literature values: 0.48 ±0.09 disk-integrated Pitman et al. [2010]; 0:63 (+0.11, −0.12) leading hemisphere Howett et al. [2010]; 0:57 (+0:20, −0:26) trailing hemisphere Howett et al. [2010].

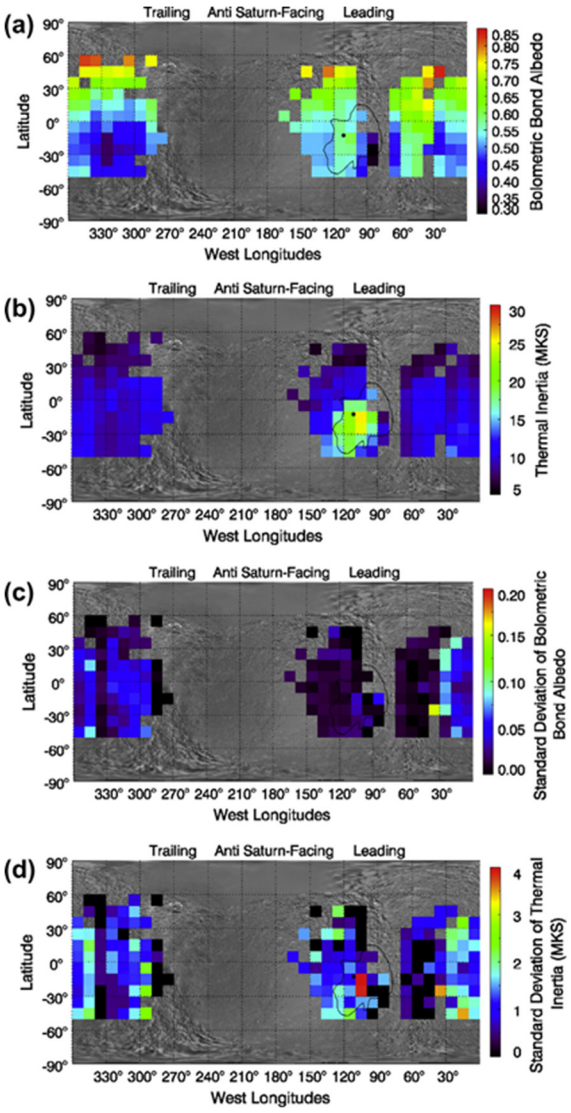

Figure CIRS-58. Maps of derived thermophysical properties for Rhea. The black solid contour shows the approximate edge of the Inktomi ejecta blanket, while the dark circle at 14.1° S and 112.1° W shows the location of the Inktomi crater. *Panel (a)*: Bolometric Bond albedo map of Rhea. *Panel (b)*: Thermal inertia map of Rhea. *Panel (c)*: The standard deviation of the albedo values given in *Panel (a)*. *Panel (d)*: The standard deviation of the thermal inertia values given in *Panel (b)*.

The high thermal inertia region in the southern hemisphere of Rhea's leading hemisphere is a new discovery. The anomalous region does not bear the characteristics of the high thermal inertia regions observed on Mimas, Tethys, and Dione (described in Howett et al. [2011b, 2012, 2014] for Mimas, Tethys and Dione respectively), and Rhea does not display a darkening on this hemisphere in the IR/UV associated with Mimas and Tethys' thermally anomalous region. Rather the thermally anomalous region on Rhea appears to be spatially correlated with the ejecta blanket of Rhea's bright ray crater, Inktomi. Here the thermal inertia increase is more dramatic than on Dione: the background value (the mean value from 30° to 60° W and 10° to 30° S) is 10 MKS, whilst the value on the Inktomi crater ejecta blanket (the mean value between 100° and 120° W, and 10° and 30° S) is 19 MKS. Craters floors with a high thermal inertia compared to the background value have been observed on Mars—for example, Edwards et al. [2013], and the Moon [Bauch et al. 2011], but this is the first time such change in thermal inertia has been observed over a crater on an icy saturnian satellite. This range of thermal inertias corresponds to a thermal skin depth of 0.7–1.3 cm.

Activity on Dione (IN1c), Howett et al. [2018]

IN1c: Determine whether Dione is currently active, or has been so on recent geological timescales.

There are hints that maybe activity does occur on Dione: Dione has smooth plains (indicative of recent resurfacing). Plasma was detected flowing from Dione, which could have been caused by recent geological activity [Burch et al. 2007], although this can also be explained without activity.

FP1 Cassini CIRS data to make nighttime temperature maps of Dione's surface, and model temperature maps were produced by modeling Dione's seasonal temperature change (using previously published thermal inertia and albedo values from Howett et al. [2014]): thermal inertia: 5, 11, and 29 MKS, and albedo values: 0.48, 0.63, and 0.78. Then observed versus modeled temperatures were compared, and temperatures outside of the expected range were looked for. The results are shown in Figure CIRS-59, which shows that for this preliminary example no temperatures are observed outside of those predicted by a passive emission model. When this is repeated for all nighttime CIRS FP1 and FP3 observations of Dione no evidence for activity was found. Therefore, we conclude that there is no evidence in CIRS observations of Dione for activity, and upper-limits of undetected activity have been placed. These results were published in Howett et al. [2018].

The maximum temperature of a 50, 100 and 200 km^2 hot spot is then derived using the highest resolution observation at a given location. The results are shown in Figure CIRS-60.

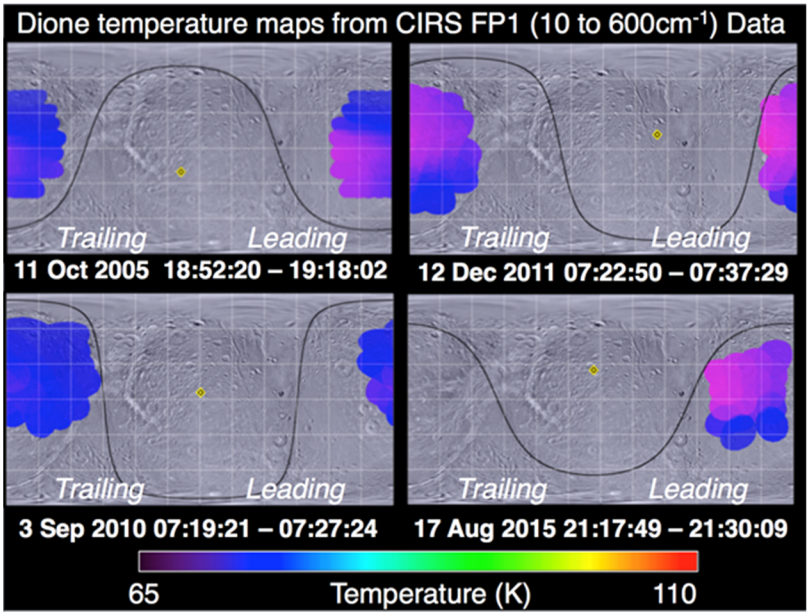

Figure CIRS-59. Comparison of surface temperatures derived from Cassini CIRS FP1 observations to those predicted by a passive emission model.

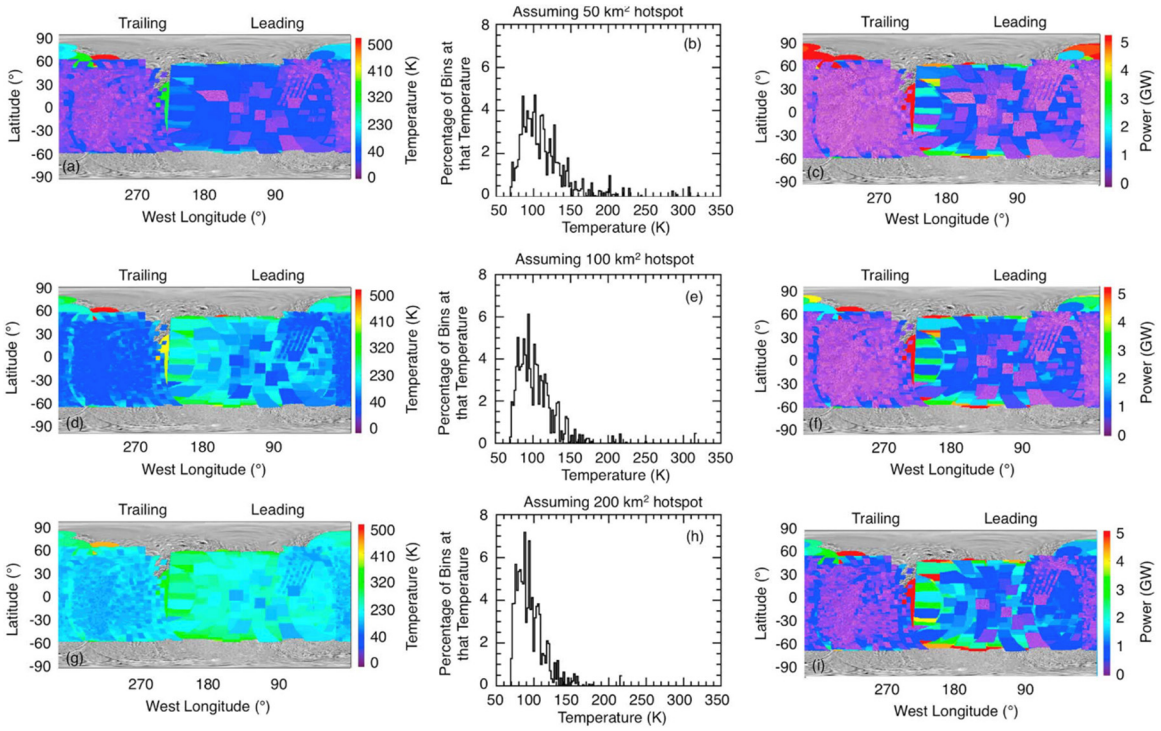

Figure CIRS-60. Details of the upper limits for a 50, 100, and 200 km2 hot spot that could exist on Dione and not be detected in this work. *Panels (a), (d), (g)*: The maximum temperature of a hot spot that could exist on Dione and have remained undetected in this work. *Panels (b), (e), (h)*: The maximum power of a hot spot that could exist on Dione and have remained undetected in this work. *Panels (c), (f), (i)*: Histograms of the maximum temperature a hot spot could have and remain undetected in this study.

Level 2

Rhea's ring (IN2a)

IN2a: Determine if there is a ring (or debris disk) around Rhea, and if so, characterize the spatial and particle size distribution.

ALTERATION OF RHEA'S SURFACE BY INFALL FROM AN ANCIENT RING

Schenk et al. [2011] found blue patches along Rhea's equator, which they believe are evidence for infall from a ring around Rhea. This is because the patches are not associated with any obvious, endogenic tectonic process, as no linear or other tectonic fabric is apparent. Furthermore, a thin ring (or halo) around Rhea was tentatively discovered by Jones et al. [2008] (although this has not been upheld by further observations) [Pitman et al. 2008; Tiscareno et al. 2010].

These patches are small (<1 km), and often well-below the spatial resolution of CIRS thus making them hard to detect. The best estimate of how the surface properties of Rhea vary was

given by Howett et al. [2014], and is shown in Figure CIRS-58. As the figure shows, no obvious change in albedo or thermal inertia is observed along Rhea's equator. We conclude CIRS is unable to contribute to whether infall from an ancient ring around Rhea has altered its surface.

Tethys and the E-ring (IN2b)

IN2b: Determine whether Tethys is geologically active, and thus could be contributing to the E-ring.

Nighttime observations of Tethys have been investigated—see Howett et al. [2012] and this section—and show no evidence for high temperatures expected from activity. Further work is required to set explicit limits on such activity.

Characterize the surfaces of Saturn's small satellites (IN2d)

IN2d: Derive the surface thermophysical properties of Saturn's small satellites, including (but not limited to) Epimethys, Janus, Methone, and Promethus.

CIRS made positive detections of two moons: Epimetheus and Atlas. These results have been submitted as part of a multi-instrument paper [Buratti et al. 2018].

Detections of both Epimetheus and Atlas were made using dedicated CIRS scans bracketed by ISS observations. Epimetheus was detected on January 30, 2017, during a scan that occurred between 19:54:20 to 20:05:50 UTC, at a distance that decreased from 80,179 to 67,237 km. During this time, the sub-spacecraft position changed from 345.0° W / 73.5° N to 346.5° W / 73.7° N, the local time at the sub-spacecraft point increased from 271° to 276° and the phase increased slightly from 68.0° to 68.5°.

Atlas was detected a few months later on April 12, 2017, during a scan that ran from 13:16:39 to 13:24:40 UTC, at a distance that decreased from 33,572 km to 24,580 km. During that time, the phase at the sub-spacecraft point decreased from 51.2° to 47.2°, the sub-spacecraft position changed from 141.9° W / 60.1° N to 149.8° W / 52.1° N, and the local time at the sub-spacecraft point decreased from 226° to 221°.

In both detections, CIRS used its focal plane 3 (FP3, which covers 570–1125 cm^{-1}) to scan the target and background sky. The results are given in Figure CIRS-61, which shows the temperature that has a blackbody emission curve best able to fit the observed radiance over all wavelengths. Both Epimetheus and Atlas are clearly visible above the background dark sky. The mean surface temperature observed on Epimetheus is 90.1 ±2.7 K, and 82.4 ±4.7 K on Atlas.

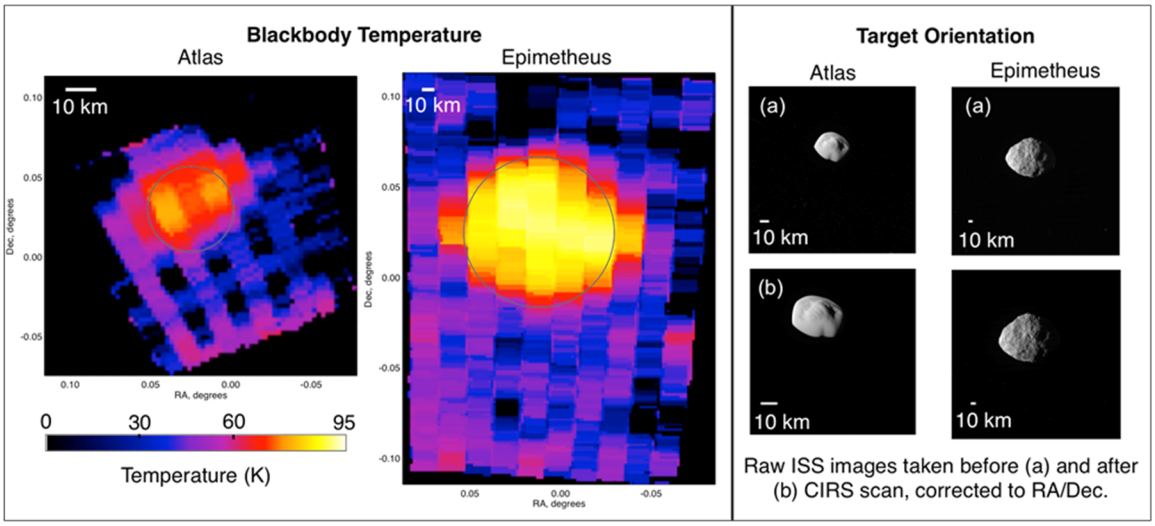

Figure CIRS-61. CIRS and ISS observations of Atlas and Epimetheus. *Left*: The blackbody temperature of the two targets, as determined by fitting a blackbody curve to the full CIRS radiance spectrum at each location. The results are shown in Right Ascension/Declination (RA/Dec) space, which has been corrected so the center of the target lies at 0°/0°. *Right*: Raw ISS observations of both targets taken before and after the CIRS scan, the images have been rotated so they are also in RA/Dec coordinates. However, the scale of the CIRS data and the ISS images is notably different, as indicated by the 10 km scale bar given in every image. Images of Atlas *Panel (a)*: ISS image N00279648 taken using CL1 and CL2 filters on April 12, 2017, at 1:15 UT; *Panel (b)*: ISS image N00279649 taken using CL1 and CL2 filters on April 12, 2017, 1:27 UT. Images of Epimetheus *Panel (a)*: ISS image N00275708 taken using CL1 and CL2 filters on January 30, 2017, 7:53 UT; *Panel (b)*: ISS mage N00275709 taken using CL1 and UV3 filters on January 30, 2017, 8:07 UT.

Open Questions

Saturn

- Exactly how does tropospheric eruption of the great storms perturb the stratosphere so strongly? Presumably by waves generated near the tropopause, but what is the nature of these nonlinear waves?
- What are the waves driving the equatorial oscillation, compared to those identified as drivers for Earth's equatorial oscillations?
- What are the systematic errors affecting the different estimates of the helium abundance from remote sensing techniques (thermal infrared spectra, thermal infrared and radio occultations, thermal infrared and ultraviolet stellar occultations)?
- How important is interannual variability?
- Geophysical systems are complex, nonlinear, and their behavior can be difficult to understand or predict. Cassini, given its proximity and duration, provided us a unique 4-dimensional slice of Saturn. When can we go back?

Rings

Some key open questions on rings are listed below. Other CIRS-specific questions are discussed in the Conclusions and Future Work.

- Why is the ring thermal inertia so low?
- What is the internal structure of ring particles?
- How does the thermal inertia vary with radial distance from Saturn?
- What will even higher spatial resolution data tell us about radial and azimuthal thermal variations in Saturn's rings?
- At higher spatial resolution, which ring regions exhibit a thermal surge and which do not?
- Are there spectral signatures of compounds other than water ice in infrared spectra?
- What are the thermal properties of the faint rings (D-ring, E-ring, G-ring, Phoebe ring) and ringlets (A-ring/Encke gap, F-ring)?
- Do the thermal properties of rings with clumps (A-ring/Encke gap, F-ring, G-ring, E-ring) vary with time?

Titan

- What is the nature of the 220 cm^{-1} absorber?
- How high in altitude does the stratospheric/mesospheric circulation extend?
- Does Titan have a well-defined mesopause?
- Are the nitriles CH_3CN, C_2H_3CN and C_2H_5CN, already seen at sub-mm wavelengths, detectable in the infrared with sufficiently high resolution?
- What functional groups are causing the aerosol absorption features in the mid-IR?
- What is mechanism driving the tilted stratospheric pole?
- How is stratospheric super-rotation generated and maintained?
- What is the link between gas chemistry and aerosol production, and are the abundances anti-correlated?
- Are there condensate clouds of homogenous composition, or are all clouds co-condensates?
- Can we make inferences about Titan's methane history from isotopic ratios?
- Why is the $^{15}N/^{14}N$ much higher in HCN than in N_2?

- Do the abundances of H_2 and CH_4 vary with latitude?
- Are there oxygen bearing molecules beyond CO, CO_2 and H_2O?

Icy satellites

Mimas

- Is there evidence on Mimas' trailing hemisphere for surface alteration due to (low) energy electron bombardment?

Enceladus

- Does the thermal emission of Enceladus' tiger stripes increase over the jet positions predicted by Helfenstein and Porco [2015]?
- Does the thermal emission of Enceladus' tiger stripes show any temporal variability, both in the short-term (with mean anomaly) and long-term (decadal)?
- Are there any more small-scale hot spots?
- Is there any evidence for a thermal anomaly in the location of the radar ones—for example, Le Gall [2017]; Ries et al. [2015]?
- Is there any evidence for a change in thermophysical properties in plume fallout regions?

Tethys

- How does the thermophysical properties vary across Tethys' trailing hemisphere?

Dione

- What is the lower limit of activity on Dione?
- Does the Creusa on Dione show a lower thermal inertia than its surroundings (like Inktomi on Rhea)?
- How do the thermophysical properties of Dione's surface change across its wispy terrain?

Rhea

- What are the thermophysical properties of Rhea's anti-Saturn hemisphere?

Iapetus

- How does the thermal inertia of Iapetus' dark and light terrain vary?

Other Questions

- Can we say anything useful about the surface properties of Saturn's other icy moons?
- What can we learn by combining data sets?
- Is there other evidence of emissivity signatures in the CIRS data?

N^{15}/N^{14}

Fouchet et al. [2004a] used large averages of mid-infrared CIRS spectra at the highest apodized resolution (0.5 cm^{-1}) to isolate the weak $^{15}NH_3$ lines from the forest of strong $^{14}NH_3$ lines. The averages were segregated into latitude bins. They found no measurable variation with latitude. The mean global value ($(2.22 \pm 0.52) \times 10^{-3}$) agreed with previous measurements obtained from the Infrared Space Observatory and from the Galileo Probe Mass Spectrometer. They interpreted these values as representative of the proto-solar value. The terrestrial value is a factor nearly 1.7 larger, which they interpreted as originating in a reservoir isolated from the main reservoir of the proto-solar nebula. Abbas et al. [2004] independently analyzed comparable data sets and obtained essentially the identical result for the global average.
