Phosphine. As noted earlier for Saturn, PH_3 is generally believed to be a product of rapid vertical mixing from deep atmospheric levels, and the observed abundances in the upper troposphere

represent the quenched equilibrium conditions deeper down. Irwin et al. [2004] analyzed CIRS mid-IR spectra over the ranges 600 and 700 cm^{-1} and 1000–1200 cm^{-1} to retrieve jointly the temperature profile, the deep phosphine abundance (~1 bar), the deep ammonia abundance and fractional scale height, and the total cloud (or haze) opacity. They found PH_3 to be greatest within the equatorial zone, indicating upward transport, and smaller within the north and south equatorial belts. The mid latitudes seem to be asymmetric, with PH_3 larger near 40° N at the corresponding latitude in the south. The cause of this is not understood. PH_3 was also enhanced over the Great Red Spot, consistent with upwelling there. Using a more extended spectral range and consideration of tropospheric clouds and aerosols, Fletcher et al. [2009] verified the equatorial enhancement and hemispheric asymmetry. They found Jupiter's mid-IR spectrum is best reproduced by a dual-cloud model, with a compact 10 μm NH_3 ice layer existing at the predicted condensation altitude, and a deeper source of gray opacity (possibly due to NH_4SH clouds). They also found that Jupiter's infrared aerosol opacity is elevated at the equator and within other zones.

Halides. Fouchet et al. [2004b] analyzed CIRS far-infrared spectra to place upper limits on the abundances of HF, HCl, HBr, and HI. The upper limits on the first two were sufficiently small to lie well below solar abundances and support the notion of the halogens' condensation in ammonium salts predicted by thermochemical models for the upper Jovian troposphere.

DISEQUILIBRIUM STRATOSPHERIC COMPOUNDS

Ethane and Acetylene. The thermal infrared spectrometers (IRIS) on the Voyager spacecraft provided meridional profiles of C_2H_6 and C_2H_2, but with limited sensitivity and spatial resolution. Even at a swing-by distance ~138 RJ CIRS vastly improved the latter, and had much better sensitivity. Kunde et al. [2004] found that the latitude profile of C_2H_6 was relatively flat, whereas that of C_2H_2 followed the insolation pattern. The former pattern could be explained if the meridional transport is much faster than the loss of C_2H_6 by vertical mixing (~100 years). That of C_2H_2 suggested that its distribution is mostly governed by local photochemistry with a lifetime of ~1 year. Kunde et al. [2004] concluded that the different distributions would be expected if the dynamical timescale for horizontal transport was between the lifetimes of these two gases, ~10 years.

Kunde et al. [2004] used the emission intensities of C_2H_6 and C_2H_2, relative to the adjacent continuum, as surrogates for the abundances. They corrected for airmass variations using a model of limb brightening. Nixon et al. [2007] noted that the assumption that relative abundance variations with latitude will not, in general, proportionally follow the relative variations of the line intensities, because it ignores the saturation that can occur in the stronger emission lines. As a result, the actual abundance variations are somewhat greater than the intensity analysis would suggest. Nixon et al. [2007] retrieved C_2H_6 and C_2H_2 from the CIRS mid-infrared spectra using a rigorous inversion scheme. They found that the observed spectral emission from C_2H_6 and C_2H_2 was the combination of stratospheric emission, with a peak contribution at ~5 mbar, and tropospheric absorption at 100-400 mbar. For acetylene, they found: (i) the stratospheric volume mixing ratio (VMR) at 5 mbar decreases sharply from a peak around 20° N towards both poles, by a factor ~4; (ii) the northern hemisphere stratosphere is apparently enriched compared to the southern hemisphere at the time

of observation; (iii) in the upper troposphere at 200 mbar the abundance is near constant at ~3 × 10^{-9}. For ethane, the VMR in the equatorial stratosphere at 5 mbar is around 4 × 10^{-6}, in line with previous findings; and increases by factors of ~1.75 to 70° N and ~2.0 to 70° S. The tropospheric VMR at 200 mbar shows similar increases. Nixon et al. [2010a] redid their retrievals using improved modeling of the instrument spectral resolution, and a more recent and improved line list for C_2H_6. They found little change in the meridional distribution of C_2H_2, but found observable changes in the C_2H_6, mainly attributable to the newer line list used. They then analyzed Voyager IRIS spectra from the Jupiter flyby in 1979 (northern fall equinox) and compared the resulting distributions with those from CIRS in 2000 (northern summer solstice). They found the 2-D distribution of ethane was quite similar for the two epochs, although the Cassini distribution was more symmetric than that of Voyager, where C_2H_6 was somewhat depleted in the north relative to the south. Also, the Cassini abundances were mostly higher overall, perhaps because the solar distance was smaller. Acetylene exhibited a much more dramatic change, having a uniform meridional profile at equinox, but strong depletions towards both poles at solstice. The solstice distribution seemed to match the annual-mean picture that would be predicted by a 1-D photochemical model.

HCN and CO_2. The Cassini swing-by also facilitated the mapping of HCN and CO_2 [Kunde et al. 2004]. Both species were thought to be products of the impact of the comet SL9 in 1994, near 45° S. However, observed distributions in latitude were markedly different. HCN exhibited a broad distribution with a maximum near 45° S, a steep fall-off poleward, and a smooth decrease northward to 60° N. The CO_2 profile, however, was much narrower, and its maximum lay southward of 60° S, decreasing abruptly northward of 50° S. Kunde et al. [2004] suggested that the sharp decrease in HCN could result from the inhabitation of horizontal wave-induced diffusion by the south polar vortex. The difference in the meridional distribution of CO_2, compared to that of HCN, particularly at southern latitudes, indicated that it might have other sources in addition to the SL9 impact, and the authors suggested that the precipitation of energetic oxygen ions in the southern auroral regions might be important. Another possibility is that HCN and CO_2 are located at different altitudes. The abundances of both species are so low that their emission features are optically thin; that only restricts their altitude range to be in the stratosphere. Lellouch et al. [2006] revisited the issue, considering various scenarios for transport by eddies and mean meridional circulations. They suggested that the meridional distributions were consistent with HCN and CO_2 residing at different altitudes, with the latter being at the 5-mbar level or lower, and HCN ~3 scale heights higher. However, this possibility is not exclusive, and the enigma remains.

Auroral compounds: C_4H_2 and CH_3. Two new stratospheric species were discovered on Jupiter by CIRS during the 2000-2001 flyby: methyl (CH_3) and diacetylene (C_4H_2) [Kunde et al. 2004]. Diacetylene had previously been detected on Titan, but the detection of the methyl radical marked a first for the solar system. These were detected at 606 cm^{-1} (methyl) and 628 cm^{-1} (diacetylene) on FP3 in both northern and southern hotspots using unapodized data at a resolution of 0.26 cm^{-1}. Simulations were able to replicate the spectral detections, but due to uncertainties in the non-LTE temperatures of the emissions, abundances were not determined.

Clouds and aerosols

Ammonia ice. Thermochemical models suggest that Jupiter's visible cloud deck is composed of ammonia but spectroscopic proof has been difficult to obtain. Ammonia ice can be identified by two infrared absorption features: the ν_3 absorption band (N–H stretch) at 2.96 μm (3376 cm^{-1}) and the ν_2 absorption band (N–H bend) at 9.46 μm (1057 cm_{-1}). The NH_3 ice features cannot be detected from the ground because of telluric CO_2 and H_2O absorption at 3 μm, and terrestrial ozone absorption at 10 μm. Attempts to use mid-infrared spectra from the Voyager IRIS to detect the ν_2 NH_3 ice feature were unsuccessful. Wong et al. [2004] did identify the feature in CIRS spectra, by taking the difference in brightness temperatures, T1040–T1060. They found the highest concentrations of ice at the equator and near 23° N. At the latter location, their spectral fit required at least two types of cloud particles. The NH_3 ice feature at 1060 cm^{-1} required ~1 μm particles in an extended cloud with a scale height equal to the total gas scale height, while the spectrum from 1125 to 1200 cm^{-1} can be matched by a more compact gray cloud with a scale height 20% of the gas scale height and an optical depth of 5.

A good candidate for the deeper cloud layer is NH_4SH, since it could easily form clouds at pressures lower than the predicted condensation pressure level.

Matcheva et al. [2005] used a narrow spectral window centered at 1392 cm^{-1} to map cloud opacities. At this wavenumber atmospheric absorption from ammonia gas is very weak and uncertainties in the ammonia abundance do not impact the cloud retrieval results. In the absence of clouds, the atmospheric transmission is limited by absorption of H_2 and CH_4, and the optical depth is unity near 1200 mbar. The authors found a large variation in latitude, more or less correlated with the zone-belt structure. Their results imply two distinct cloud layers: (i) an optically thick cloud layer of ammonia ice with a base pressure at about 900 mbar or larger; and (ii) a thinner cloud layer with a cloud base at about 1100 mbar that is seen through the gaps of the ammonia ice cloud layer. A good candidate for the deeper cloud layer is NH_4SH, since it could easily form clouds at pressures lower than the predicted condensation pressure level.

Gaseous NH_3. Achterberg et al. [2006] mapped the zonal-mean NH_3 gas abundance between 400 and 500 mbar as a function of latitude. They found the Equatorial Zone is rich in ammonia, with a relative humidity near unity. The North and South Equatorial Belts are depleted relative to the Equatorial Zone by an order of magnitude. The Great Red Spot shows a local maximum in the ammonia abundance. They found NH_3 abundance to be highly correlated with temperature perturbations at the same altitude. Under the assumption that anomalies in ammonia and temperature are both perturbed from equilibrium by vertical motion, they concluded that the adjustment time constant for ammonia equilibration is about one third of the radiative time constant.

Atmospheric structure and circulation

GLOBAL AND ZONAL MEAN STRUCTURE

The 138 RJ swing-by of Jupiter in December 2000–January 2001 provided the best opportunity to map the temperatures of its stratosphere and upper troposphere since the Voyager flybys in 1979. Despite the large distance, the smaller detectors in the mid-infrared focal planes enabled CIRS to achieve a spatial resolution (2.4° latitude near the equator), exceeding the global-mapping resolution obtained by IRIS on Voyager. Application of the thermal wind equation to the retrieved zonal-mean temperatures provided a meridional cross-section of the mean zonal winds [Flasar et al. 2004b]. As expected from the Voyager IRIS observations, the winds decayed with altitude above the visible clouds. However, near the equator, they began to increase with altitude above the ~20 mbar level, reaching a maximum of ~140 m/s near 4 mbar. This stratospheric jet is comparable to the winds lower in the troposphere, obtained from cloud-feature tracking. The undulating structure in altitude is reminiscent of an equatorial oscillation similar to that on Earth. Orton et al. [1991]—see also Simon-Miller et al. [2006]—had observed a temporal oscillation in equatorial brightness temperatures that was not strictly periodic, but cyclic over 4–5 years. Leovy et al. [1991] pointed out that this was reminiscent of the terrestrial quasi-biennial oscillation in the stratosphere. This is mechanically forced by the absorption of atmospheric waves, and they suggested that a similar mechanism operates on Jupiter. A similar phenomenon exists on Saturn (see the section entitled Equatorial Oscillation).

Potential vorticity (PV) has been extensively used in studies of geophysical fluid flows, because under many conditions it is approximately conserved and can serve as a tracer of motion. Moreover, it figures in several stability criteria. Read et al. [2006] used velocity measurements, obtained from tracking cloud features in Voyager and Cassini images, and thermal measurements obtained from Voyager IRIS and Cassini CIRS observations, to derive the PV associated with Jupiter's zonal-mean atmospheric flow. The profiles show some evidence for a step-like pattern suggestive of local PV homogenization, separated by strong PV gradients in association with eastward jets, though on differing scales in the northern and southern hemispheres. The northward gradient of PV is found to change sign in several places in each hemisphere, and the relationship between PV and the mean zonal flow indicate that the northern hemisphere may be closer to marginal stability with respect to Arnol'd's second stability theorem (see the section entitled Internal Rotation) than the southern hemisphere.

The zonal-mean meridional motion can be inferred from the meridional distribution of hydrocarbons discussed earlier.

Li et al. [2012] analyzed the global thermal emission from Jupiter and its meridional distribution from CIRS and VIMS observations. They found Jupiter's mean effective temperature to be 125.6° K. The hemispheric distribution of emitted power was asymmetric, with the emitted power in the north 3.0% larger than in the south. The distribution in the Voyager epoch was more symmetric. Moreover, the Cassini total power was 4% higher than that from Voyager. The authors

suggest that this difference is attributable to the warming of atmospheric layers around 200 mbar, but the cause of this is not understood.

Waves

Flasar et al. [2004b] examined the zonal structure in the 2000–2001 Jupiter swing-by data to search for planetary-scale waves in the troposphere and stratosphere. They observed structure near the equator, which conceivably could be related to the forcing of the equatorial oscillation, but they also observed a variety of thermal features well away from the equator. In the troposphere long trains of regularly spaced features were observed, and they appeared to be quasi-stationary relative to Jupiter's internal rotation. These types of waves had been observed earlier in Voyager and ground-based observations. The stratospheric thermal perturbations also exhibit regularly spaced zonal features, but they were less confined in latitude. Moreover, there was a tendency for many of the features to drift westward relative to the ambient zonal flow, consistent with Rossby waves, although an unambiguous identification could not be made. At many latitudes, the connection between the tropospheric and stratospheric disturbances was not conclusive, either in wavenumber or in zonal phase velocity.

In a later study, Li et al. [2006] compared wave structure in both the CIRS and Cassini imaging data sets. They identified a quasi-stationary wave in the north equatorial belt as a Rossby wave in both data sets that had a slow westward drift.

Aurora

Flasar et al. [2004b] detected an intense warm region at 1 mbar at high northern latitudes, centered near 65° N, 180° W. This had been extensively observed in infrared ground-based observations; however, the morphology of the spot differs from that of the Jovian aurorae described at ultraviolet, visible, and near infrared wavelengths. Because the spectra were of necessity obtained in the nadir-viewing mode (138 RJ), Flasar et al. [2004b] could not place limits on how much higher in altitude the hot spot extended. They were, however, able to place a lower limit on the altitude, because the hot spot was not visible at the 4 mbar level. From the thermal wind equation, strong anticyclonic winds would be expected to bound the hot spot, with vertical shears ~30 m/s per scale height. Kunde et al. [2004], observed enhanced emission from several hydrocarbons within the northern auroral hot spot, for example, from the Q branch of C_2H_2 at 729 cm^{-1}. They also detected enhanced emission from C_2H_2, albeit weaker, at 75°–85° S (higher latitudes were not well observed) over longitudes spanning 0° to 70° W. They estimated the excess thermal emission from the northern spot to be ~1013 W, about an order of magnitude larger than that expected from far-ultraviolet spectra from precipitating particles. They suggested that Joule heating could be a viable alternative source.

Sinclair et al. [2017] analyzed Jupiter's auroral hot spots, using spectra from IRIS on Voyager 1 and CIRS on Cassini. They attempted to separate the effects of temperature from concentration in the observed enhanced emission from C_2H_2 and C_2H_6 within the spot at mid-

infrared wavelengths. To do this, they retrieved vertical profiles of temperature for the upper troposphere and tropopause region from the 600–625 cm^{-1} and 640–665 cm^{-1} portions of the spectrum (both collision induced absorption regions associated with the S(1) line of H_2 but with the emission features of C_3H_4, C_4H_2 and C_6H_6 omitted) and stratospheric temperatures from 1230-1380 cm^{-1} (CH_4 emission) regions. This leaves a range from ~50 mbar to ~5 mbar where the information content of nadir-viewing spectra is minimal, and temperature profiles must be interpolated. However, as noted above, most of the lateral contrast associated with the aurora occurs above the 4 mbar level. The vertical profiles of C_2H_2 and C_2H_6 were retrieved from their respective emission features at 710–750 cm^{-1} and 770–890 cm^{-1}. The authors conclude that the vertical temperature profiles retrieved from CIRS spectra covering the auroral-related spots indicate the presence of two discrete vertical regions of heating, at the 1 mbar level and at pressures of 10 µbar and lower. They argued that the temperatures at 10 µbar and lower pressures were likely indicative of joule heating, ion drag, and/or electron precipitation, ion-drag and energy released from exothermic ion-chemistry. On the other hand, they concluded that the heating at the 1 mbar level is the result of either a layer of aurorally-produced haze particles, which are heated by incident sunlight and/or adiabatic heating by subsidence within the auroral hot-spot region. Retrievals of indicated that C_2H_2 is enriched but C_2H_6 is depleted in auroral regions relative to quiescent regions. They suggested that the contrast between C_2H_2 and C_2H_6 can be explained by a coupling of auroral-driven chemistry and horizontal advection. Ion-neutral and electron recombination chemistry in the auroral region enriches all C_2 hydrocarbons but in particular, the unsaturated C_2H_2 and C_2H_4 hydrocarbons. Once advected outside of the auroral region, the unsaturated C_2 hydrocarbons are converted into C_2H_6 by neutral photochemistry thereby enriching C_2H_6 in quiescent regions, which gives the impression it is depleted inside the auroral region.

Open Questions

- What is the descending pattern of Jupiter's equatorial oscillation? Is it similar to Saturn's? What are the waves driving the oscillation, compared to those identified as drivers for Earth's?
- What is the nature of the physical process causing the apparent discrepancy of stratospheric HCN and CO_2? Is ion chemistry involving exogenic H_2O important, or are the meridional circulations in the high stratosphere multi-layered?
- Why does Jupiter not exhibit the intense storms disrupting broad latitude bands that are observed on Saturn?

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AO	Announcement of Opportunity
CIA	collision-induced absorption
CIRS	Composite Infrared Spectrometer
CM	circulation model
DISR	Descent Imager/Spectral Radiometer
FOV	field of view
FRPO	F-ring and proximal orbits
FTS	Fourier Transform Spectrometer
GCM	general circulation modeling
GCMS	Gas Chromatograph Mass Spectrometer
GSFC	Goddard Space Flight Center
HCN	hydrogen cyanide
HST	Hubble Space Telescope
HWHM	half-width-half-maximum
IR	infrared
IRIS	infrared spectrometers
ISO	Infrared Space Observatory
ISS	Imaging Science Subsystem
LEMMS	Low Energy Magnetospheric Measurement System
LTE	local thermodynamic equilibrium
MIMI	Magnetospheric Imaging Instrument
MIR	mid-infrared
mrad	microradians
NAC	narrow-angle camera
NAT	nitric acid trihydrate
NSE	northern spring equinox
PPS	Power & Pyrotechnics Subsystem
PV	potential vorticity
QBO	quasi-biennial oscillation
RA/Dec	Right Ascension/Declination
RADAR	Titan Radar Mapper
RS	radio science
SAO	semi-annual oscillation
SCET	spacecraft event time
SNR	signal to noise ratio
SPT	South polar terrain
TM	Traceability Matrix

UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph
UVIS	Ultraviolet Imaging Spectrometer
VIMS	Visual and Infrared Mapping Spectrometer
VMR	volume mixing ratio
VMR	volume mixing ratio
WAC	wide-angle camera

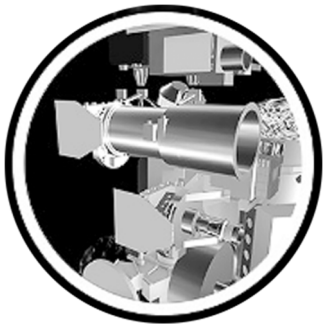
Imaging Science Subsystem



The Imaging Science Subsystem (ISS) consisted of both a wide-angle and a narrow-angle digital camera specifically designed for exploring the Saturn system. The **science objectives** included capturing lightning, investigating three-dimensional cloud structure and meteorology of Saturn's and Titan's atmospheres, imaging the surfaces of icy satellites, determining the composition and structure of Saturn's enormous ring system, and peering through the hazy Titan atmosphere to study its surface. The two cameras were able to capture beautiful images of the Saturn system as well, which inspired the public. In addition to acquiring scientific images, the cameras were also used for optical navigation to refine the knowledge of the spacecraft's trajectory and the position of the satellites.

Each camera included optics, two filter wheels, a shutter and detector head, plus their electronics. The cameras were sensitive to visible wavelengths of light and to some infrared and ultraviolet wavelengths. The filters for each camera were mounted on wheels to select the wavelengths to be sampled in each image. They were also capable of filtering for linear polarization.

EXECUTIVE SUMMARY

The Cassini Imaging Science Subsystem (ISS) was the highest resolution imaging device on the Cassini mission and was specifically designed to image the bodies in the Saturn system. In its photometric sensitivity, linearity, dynamic range, spectral range—from near-ultraviolet (UV) to near-infrared (IR)—filter complement, resolving power, and variety of data collection and compression modes, it represented a significant advance over its predecessor carried on the Voyager spacecraft to Saturn in 1980 and 1981. The ISS was also the instrument used for optical navigation of the spacecraft.

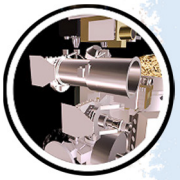
The Cassini Imaging Science Subsystem (ISS) was the highest resolution imaging device on the Cassini mission and was specifically designed to image the bodies in the Saturn system.

The range of scientific objectives addressed by the ISS, as set forth early on by the Imaging Science team, included surveys of new phenomena and new moons/moonlets, as well as deeper characterization of known phenomena and features, throughout the Saturnian system out to the orbit of Iapetus, though seminal scientific results were obtained in a late-mission study of Saturn's irregular satellites, lying well beyond Iapetus. Among the specific goals of the ISS team were: determining the life-cycle of eddies and storms, and measuring wind speeds and photometric properties, in the Saturn atmosphere; revealing the geomorphology of the surface of Titan, searching for liquid hydrocarbons on the moon's surface, and characterizing the meteorology of the moon's atmosphere and its interactions with the surface; revealing at very high-resolution the architecture and dynamics of Saturn's rings; and mapping the surfaces of Saturn's ring-region and main icy satellites at high-resolution, including a search for plumes spouting from the surface of Enceladus.

This document summarizes the results of the imaging investigations conducted at Jupiter during Cassini's flyby of that planet on the eve of the year 2001, and at Saturn between the years 2004 and 2017. A perfectly engineered Jupiter flyby and several extensions that added nine years to the prime four-year Cassini mission at Saturn, the outstanding technical skill of the mission designers and the exquisite accuracy and richness of the 13-year Saturn orbital tour they produced, the commitment of the spacecraft flight team, the excellent performance of both the ISS and the spacecraft, and the perseverance, intelligence and sheer love of exploration of the imaging science team and the operations staff that supported it, together ensured the unqualified success of the ISS investigations at Saturn and Jupiter.

ISS INSTRUMENT SUMMARY

The ISS As-Built description is documented in Porco et al. [2004]. What follows in this section are excerpts from that paper.



The Cassini ISS consists of two fixed focal length telescopes called cameras. The narrow-angle camera is 95 cm long and 40 cm × 33 cm wide (Figure ISS-1); the wide-angle camera is 55 cm long and 35 × 33 cm wide (Figure ISS-2). Both camera systems together have a mass of 57.83 kg. They sit on the remote sensing palette, fixed to the body of the Cassini orbiter, between the Visual and Infrared Mapping Spectrometer (VIMS) and the Composite Infrared Spectrometer (CIRS), and above the Ultraviolet Imaging Spectrometer (UVIS). The apertures and radiators of both telescopes are parallel to each other.

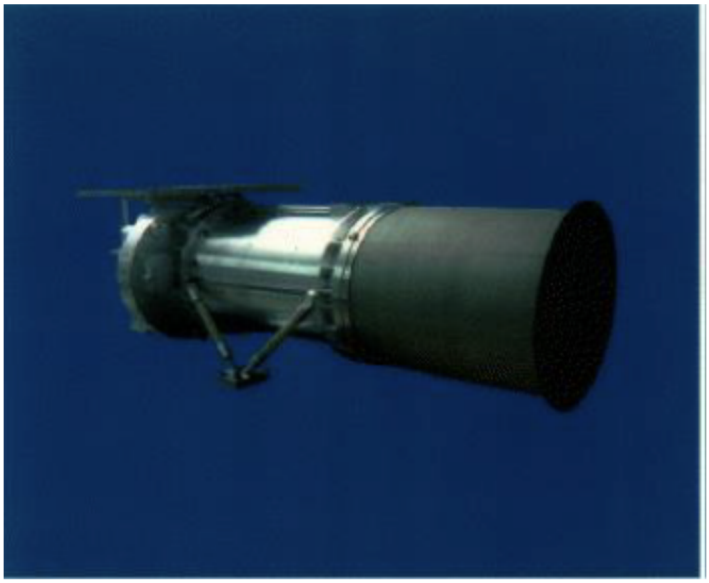


Figure ISS-1. Cassini ISS narrow-angle camera.

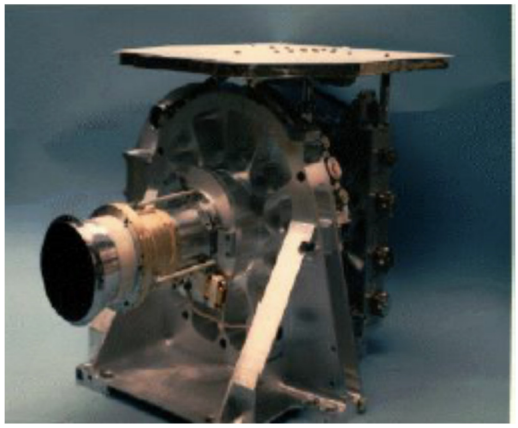

Figure ISS-2. Cassini ISS wide angle camera.

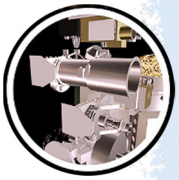
Each camera has its own set of optics, mechanical mountings, charge coupled device (CCD), shutter, filter wheel assembly, temperature sensors, heaters, various control electronics, engineering flight computer, and bus interface unit (BIU) to the central spacecraft command & data system (CDS). The electronics that control each camera consist of two parts: sensor head subassembly and the main electronics subassembly. The sensor head electronics supports the



operation of the CCD detector and the preprocessing of the pixel data. The main electronics provide the power and perform all other ISS control functions, including generating and maintaining internal timing which is synchronized to the CDS timing of 8 Hz, control of heaters, and the two hardware data compressors. The Cassini engineering flight computer (EFC) is a radiation-hardened version of IBM's standard, general purpose MIL-STD-1750A 16-bit computer and is the ISS processor that controls the timing, internal sequencing, mechanism control, engineering and status data acquisition, and data packetization.

The narrow angle camera (NAC) is an f/10.5 reflecting telescope with an image scale of ~6 µrad/pixel, a 0.35° × 0.35° field of view (FOV), and a spectral range from 200 nm–1100 nm. Its filter wheel subassembly carries 24 spectral filters: 12 filters on each of two wheels. The optical train of the wide-angle camera (WAC), a Voyager flight spare, is an f/3.5 refractor with a ~60 µrad/pixel image scale and a 3.5° × 3.5° FOV. The refractor objective lens transmission limits the lower end of the spectral range on the WAC which is 380 nm–1100 nm. The WAC filter subassembly carries 9 filters in each of two filter wheels, for a total of 18 filters. In both cameras, images are acquired through two filters, one on each wheel, allowing in-line combinations of filters for greater flexibility, i.e., polarizers in line with other spectral filters, new band-passes created by the overlap of two spectral filters, etc.

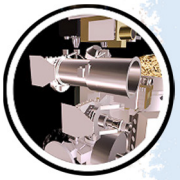
KEY OBJECTIVES FOR ISS INSTRUMENT

The Cassini ISS instrument is designed to perform multispectral imaging of Saturn, Titan, rings, and icy satellites to observe their properties. Specific science objectives are as follows:

Cassini Early Mission (2004–2010)

Saturn and Titan atmospheres

1. Motions and dynamics.
    a. Basic flow regime (Titan).
    b. Poleward flux of momentum (u′v′).
    c. Poleward flux of heat (with CIRS).
    d. Life cycles and small-scale dynamics of eddies.
    e. Radiative heating for dynamical studies.
2. Clouds and aerosols.
    a. Cloud and haze stratigraphy (strongly couples with wind studies).



b. Particle optical properties.

c. Particle physical properties.

d. Auroral processes and particle formation.

e. Haze microphysical models.

3. Lightning (related to water clouds on Saturn, unknown for Titan).

4. Auroras (H and H_2 emissions on Saturn, N and N_2 emissions on Titan).

Titan surface

a. Map the surface of Titan in haze-penetrating spectral regions.

b. Search for bodies of liquid hydrocarbons (morphology, glints, etc.).

c. Determine surface/atmospheric interactions.

Rings

a. Ring architecture/evolution—azimuthal, radial, temporal variations across tour.

b. New satellites—orbits, masses/densities, effects on rings; complete inventory of Saturn's ring-region moons.

c. Search and characterize material potentially hazardous to Cassini—diffuse rings, arcs, Hill's sphere material, etc.

d. Orbit refinement of known satellites; temporal variations; resonant effects.

e. Particle/disk properties—vertical disk structure; particle physical properties and size distribution; variations across disk.

f. Spokes—formation timescales/process; periodic variations.

g. Diffuse rings (E-ring, G-ring)—structure, characterize particle properties.

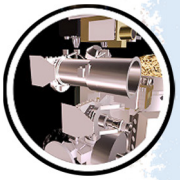
Icy satellite objectives

a. Determine the general characteristics and geological histories of the satellites.

b. Define the mechanisms of crustal and surface modifications, both external and internal.

c. Investigate the compositions and distributions of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles.

d. Constrain models of the satellites' bulk compositions and internal structures.



e. Investigate interactions with the magnetosphere and ring systems and possible gas and particle injections into the magnetosphere.

f. Search for plumes erupting from the surface of Enceladus.

Cassini Solstice Mission (2010–2017)

The ISS objectives for Cassini's late mission, or Solstice Mission, have been captured, by discipline, in a series of matrices outlined in the section entitled Science Objectives and Traceability Matrices.

ISS Science Assessment

The ISS Science Assessment describes if and how well ISS observations met the objectives listed in the sections entitled Key Objectives for ISS Instrument and Science Objectives and Traceability Matrices. Evaluation of the objectives are highlighted below. The Cassini Solstice Mission evaluation is given in the section entitled Science Objectives and Traceability Matrices.

Saturn and Titan Atmospheres

1. Motions and dynamics.

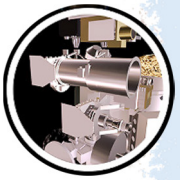
   a. Basic flow regime (Saturn and Titan). This goal was met on Saturn and Titan (see Porco et al. [2005a, 2005b] and subsequent ISS papers on Saturn's dynamics). ISS images confirm the discovery by the CIRS team that Titan's zonal flow has a pole location that is offset by a few degrees from Titan's solid body rotation pole [Roman et al. 2009; West et al. 2016].

   b. Poleward flux of momentum ($u'v'$). This goal was met for Saturn [Del Genio et al. 2007].

   c. Poleward flux of heat (with CIRS). This goal has not yet been met for Titan or Saturn. The appropriate ISS data were obtained but the analysis is not complete. However, there have been new global circulation models for Titan constrained by Cassini data [Lora et al. 2015].

   d. Life cycles and small-scale dynamics of eddies. This goal was partially met for Saturn (see Porco et al. [2005a]; Antuñano et al. [2018] and parts of other ISS papers on Saturn's clouds and dynamics).

   e. Radiative heating for dynamical studies. This goal was met [Li et al. 2011, 2013, 2015; Li et al. 2018].



2. Clouds and aerosols.

    a. Cloud and haze stratigraphy (strongly couples with wind studies). This goal was partially met [West et al. 2009, 2016].

    b. Particle optical properties. This goal was met for a restricted latitude band on Saturn [Pérez-Hoyos et al. 2016]. Appropriate data were obtained for other latitudes but the analysis is not complete.

    c. Particle physical properties. This goal has not yet been met. The appropriate data were obtained but the analysis is not complete.

    d. Auroral processes and particle formation. The goal was met for Saturn [Dyudina et al. 2010, 2015].

    e. Haze microphysical models. This goal has not yet been met. The appropriate data were obtained but the analysis is not complete.

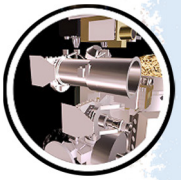
3. Lightning (related to water clouds on Saturn, did not know what to expect for Titan). Lighting on Saturn was detected and studied. It was found correlated with Saturn Electrostatic Discharges (see Porco et al. [2005a] and subsequent ISS papers). No lightning was detected for Titan.

4. Auroras (H and H_2 emissions on Saturn, N and N_2 emissions on Titan). Auroras on Saturn were studied [Dyudina et al. 2010, 2015]. Airglow on Titan was discovered [West et al. 2012; Lavvas et al. 2014].

Titan Surface

a. Map the surface of Titan in haze-penetrating spectral regions. The goal was met, providing a global albedo map of Titan [McEwen et al. 2005a, 2005b; Turtle et al. 2009, 2011a, 2011b, 2011c, 2013, 2018a; Perry et al. 2005, 2007; Stephan et al. 2009]. Reprocessing using the complete ISS dataset for much improved signal/noise is underway [Karkoschka et al. 2017a, 2017b].

b. Search for bodies of liquid hydrocarbons (morphology, glints, etc.). The goal was met, with the ISS discovery of the largest lakes and seas in both the south and northern polar regions, from morphology [http://ciclops.org/view.php?id=1161; http://ciclops.org/view.php?id=1194; http://ciclops.org/view.php?id=2607; http://ciclops.org/view.php?id=2631] and temporal changes [Turtle et al. 2009; Turtle et al. 2011b, 2011c, 2018a] and by searching for glints [Fussner et al. 2005], although no glints were found at ISS wavelengths.



c. Determine surface/atmospheric interactions. The goal was met [Porco et al. 2005b], especially via co-analysis of ISS with other datasets [Turtle et al. 2009, 2011a, 2011b, 2011c, 2018a, 2018b; Barnes et al. 2013; Birch et al. 2017].

Rings

a. Ring architecture/evolution—azimuthal, radial, temporal variations across tour. This goal was met, with substantial discoveries about the azimuthal, radial, and temporal characteristics of the rings [Porco et al. 2005c]. See reviews by Cuzzi et al. [2018]; Murray and French [2018]; Nicholson et al. [2018].

b. New satellites: orbits, masses/densities, effects on rings; complete inventory of Saturn's inner moons. This goal was met. See Porco et al. [2005c] and subsequent papers reporting discovery of Daphnis, Aegaeon, Methone, Pallene, Anthe, Polydeuces; and a survey that verified the non-existence of shepherd moons in most of the gaps within the main rings [Spitale 2017].

c. Search and characterize material potentially hazardous to Cassini—diffuse rings, arcs, Hill's sphere material, etc. This goal was met, with substantial discoveries about current resonant characteristics and long-term evolution of satellite orbits [Porco et al. 2005c; Jacobson et al. 2006a, 2006b, 2008; Lainey et al. 2017], as well as an unexpected sudden change in the orbit of Daphnis [Jacobson 2014].

d. Orbit refinement of known satellites; temporal variations; resonant effects. This goal was met, with substantial discoveries about current resonant characteristics and long-term evolution of satellite orbits [Porco et al. 2005c; Jacobson et al. 2006a, 2006b, 2008; Lainey et al. 2017], as well as an unexpected sudden change in the orbit of Daphnis [Jacobson 2014].

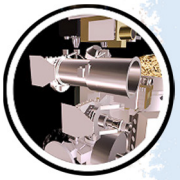
e. Particle/disk properties—vertical disk structure; particle physical properties and size distribution; variations across disk. This goal was met, with substantial discoveries about particle and disk properties [Porco et al. 2005c]. See reviews by Cuzzi et al. [2018]; Estrada et al. [2018]; Murray and French [2018]; Spahn et al. [2018]; Spilker et al. [2018].

f. Spokes—formation timescales/process; periodic variations. This goal was met, with detailed studies of the workings of spokes [Mitchell et al. 2006, 2013].

g. Diffuse rings (E-ring, G-ring): structure, characterize particle properties. This goal was met, with substantial discoveries about the structure and particle properties of diffuse rings [Porco et al. 2005c]. See review by Hedman et al. [2018].

Icy Satellites

a. Determine the general characteristics and geological histories of the satellites. These goals were met [Porco et al. 2005d; Porco et al. 2006]. See comprehensive reviews



and references therein: Patterson et al. [2018]; Schenk et al. [2018]; Verbiscer et al. [2018]; Postberg et al. [2018]; Kirchoff et al. [2018]; Goldstein et al. [2018]; Thomas et al. [2018]; Spencer et al. [2009]; Matson et al. [2009]; Jaumann et al. [2009a]; Roatsch et al. [2009a]; Dones et al. [2009].

b. Define the mechanisms of crustal and surface modifications, both external and internal. This goal was partially met [Porco et al. 2005d; Porco et al. 2006; Patterson et al. 2018; Schenk et al. 2018; Thomas et al. 2018; Kirchoff et al. 2018; Postberg et al. 2018; Wagner et al. 2006, 2007, 2009, 2010; Matson et al. 2009; Dones et al. 2009].

c. Investigate the compositions and distributions of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles. This goal was partially met [Porco et al. 2005d]. See comprehensive reviews and references therein: Verbiscer et al. [2018]; Schenk et al. [2018]; Thomas et al. [2018].

d. Constrain models of the satellites' bulk compositions and internal structures. This goal was met [Porco et al. 2006; Thomas et al. 2007a, 2016, 2018; Thomas 2010; Castillo-Rogez et al. 2018].

e. Investigate interactions with the magnetosphere and ring systems and possible gas and particle injections into the magnetosphere. This goal was partially met [Thomas et al. 2018; Verbiscer et al. 2014; Annex et al. 2013; Verbiscer et al. 2018; Schenk et al. 2017; Spencer and Denk 2010].

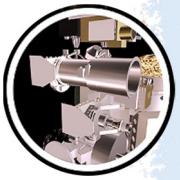
f. Search for plumes emerging from the surface of Enceladus. This goal was met [Porco et al. 2006; Porco et al. 2014].

ISS Saturn System Science Results

Titan

Imaging of Titan's surface, with global mapping at 4 km or better resolution, shows the distribution and wide variety of surface features, including first sighting of a hydrocarbon lake in the south polar region (Ontario Lacus) [http://ciclops.org/view.php?id=1161; http://ciclops.org/view.php?id=1194], the first sighting of Titan’s largest sea in the north polar region (Kraken Mare) [http://ciclops.org/view.php?id=2607; http://ciclops.org/view.php?id=2631], both confirmed as liquid-filled later by other Cassini instruments and Titan's largest impact crater (Menrva). Analysis of the entire equatorial dataset acquired over the duration of the mission indicates surface albedos range from 0.25 in the dunes to 0.9 at Hotei Arcus [Porco et al. 2005b; Perry et al. 2005, 2007; McEwen et al. 2005a, 2005b; Turtle et al. 2009; Stephan et al. 2009; Karkoschka et al. 2017a, 2017b].

Strategies have been developed for effective imaging of Titan's atmosphere and surface as well as image processing techniques to achieve as high signal-to-noise ratio from the surface as



possible. [Porco et al. 2005b; Perry et al. 2005, 2007; Fussner et al. 2005; McEwen et al. 2005a, 2005b; Turtle et al. 2009, supplementary material; Karkoschka et al. 2017a, 2017b].

Features ISS has identified and mapped on the surface include:

- Equatorial dune fields and Xanadu, impact craters, polar lakes and seas, and undifferentiated mid-latitude plains [Porco et al. 2005b; McEwen et al. 2005a, 2005b; Turtle et al. 2009; Lopes et al. 2016].
- Possible shoreline changes at Titan lakes [Turtle et al. 2009, 2011c].
- Identification of a bright surface deposit at Titan's North Pole [Turtle et al. 2013].
- Joint analyses of surface processes and features, including Hotei Arcus; Tui Regio; surface modification associated with seasonal rainfall; and polar lakes, seas, and implications for Titan hydrology [Barnes et al. 2005, 2006; Turtle et al. 2009, 2011b, 2011c; Hayes et al. 2011; Jaumann et al. 2009b].

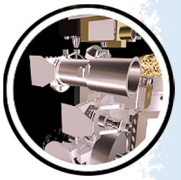
Surface darkening was observed from Titan rainstorms at Arrakis Planitia in 2004-2005 [Turtle et al. 2009] and at ~30° south latitude, including Concordia Regio, Adiri, in 2010–2011 [Turtle et al. 2011b, 2011c] as well as subsequent isolated brightening [Turtle et al. 2011b; Barnes et al. 2013].

Titan's main haze is almost featureless but shows hemispheric contrast that changes with season. This was known from Voyager images. Work with Cassini images [Roman et al. 2009] showed that the pole of rotational symmetry determined by the shape of the contrast boundary is displaced from Titan's solid body rotational pole by a few degrees, and corroborates the finding of pole displacement by Achterberg et al. [2008]. This finding opens up a new mystery about Titan's atmospheric dynamics.

The behavior of the detached haze provides new information to test and improve Titan dynamical models of the mesosphere and upper stratosphere.

Titan's detached haze, first seen in Voyager images, was again seen in Cassini images, but at altitudes that depend on season [Porco et al. 2005b; West et al. 2011, 2018]. West et al. [2011] showed that the detached haze underwent rapid descent centered around the northern spring equinox in 2009. It reached the same altitude as seen in Voyager images (near 350 km) one Titan year after the Voyager images were obtained. From about mid-2012 to early 2016 the detached haze was not seen in ISS images. It emerged in early 2016 but was weak, and showed irregular variations in latitude and time. The behavior of the detached haze provides new information to test and improve Titan dynamical models of the mesosphere and upper stratosphere.

In 2012, a distinct cloud was observed at an altitude of 300 km near Titan's south pole [West et al. 2016]. Spectral measurements by the VIMS instrument indicate an HCN ice composition [de Kok et al. 2014]. ISS measured altitude, morphology, texture, and motions of the cloud and showed that the atmospheric rotation at 300 km altitude is around a pole that is offset from Titan's solid



body rotational pole. Texture suggests that the cloud is undergoing open-cell convection, an unusual configuration for high-altitude clouds initiated by downwelling.

ISS documented the distribution, morphology, speeds, and seasonal behavior of Titan's tropospheric clouds starting on approach in April 2004 (late southern summer on Titan) through September 2017 (after the northern summer solstice in May 2017), as well as implications for atmospheric general circulation models and Titan's methane cycle including sub-surface reservoirs. During Titan's late southern summer, extensive convective cloud systems were common over Titan's south pole, and in the case of a large cloud in October 2004 led to substantial precipitation. Starting in 2007 as the Sun rose in Titan's north, clouds began to appear at northern latitudes >55° N and were relatively common until the equinox when northern cloud activity dropped off precipitously. The expectation from atmospheric models had been that cloud activity would increase at high northern latitudes as northern summer approached. However, only small isolated cells were seen near Titan's north pole, leaving the mystery of when/if north polar cloud systems form during northern summer. [Porco et al. 2005b; Turtle et al. 2009, 2011a, 2018a, 2018b; Mitchell et al. 2011].

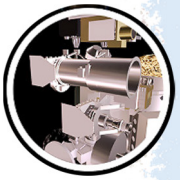
In addition to polar clouds, Titan exhibited a preference for mid-latitude clouds, at ~40° S early in the mission during late southern summer, and gradually drifting poleward to ~60° S by equinox and beyond [Porco et al. 2005b; Turtle et al. 2009, 2011a]. After equinox, similar mid-latitude clouds were expected in the northern hemisphere but were not observed with any regularity until early 2016 (first at ~50° N and drifting poleward to 60° N). These cloud bands imply a seasonal Hadley circulation with rising motion at these latitudes, a feature that can only be predicted by models that include methane moist convection. However, the timing of the transition from the southern summer to the northern summer configuration is observed to be several Earth years later than predicted by the models [Turtle et al. 2018b]. Similar clouds appeared with lower frequency near ~15° S earlier in the mission and ~30° N late in the mission.

Spectral dependence of detection of some north-polar cloud features was observed starting in 2016, with VIMS detecting features at 2.1 μm that are not seen by ISS at 938 nm [Turtle et al. 2016, 2018a, 2018b] or by VIMS at wavelengths both shorter and longer than 2.1 μm.

Atmospheric airglow observations were made while Titan was in Saturn's shadow. [West et al. 2012; Lavvas et al. 2014].

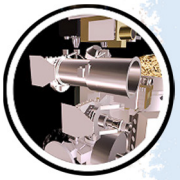
Enceladus

Early ISS observations of Enceladus and its plume yielded many new discoveries, all refined in subsequent papers. Only the major highlights from these papers are presented next.



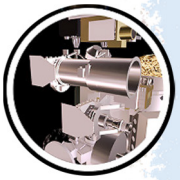
Plume

- A plume of fine, icy particles was discovered erupting from the south polar region of Enceladus in images taken in January and February 2005 [Porco et al. 2006]. In November 2005 the plume was resolved into discrete jets, or geysers, that eject the particles that eventually supply Saturn's E-ring, carried aloft by water vapor in the jets.
- The first argument is presented that the jetting activity at the South Pole is the result of venting from subsurface reservoirs of liquid water [Porco et al. 2006].
- Cassini's revised estimates of the bulk density of Enceladus and the inferred rock mass fraction suggest that radiogenic heating is not the dominant source of heat within the moon, compared with estimates of tidal heating via the Dione:Enceladus 2:1 resonance [Porco et al. 2006].
- In a multi-year high-resolution imaging survey of the south polar terrain (SPT), ~100 discrete geysers were found erupting from the four main fractures crossing the SPT [Porco et al. 2014]. A later claim—that the majority of the jet detections were not real and rather the result of observational bias [Spitale et al. 2015]—was refuted [Porco et al. 2015].
- Anomalously hot regions observed by CIRS at low resolution were found to be coincident with the SPT fractures [Porco et al. 2006; Spitale and Porco 2007]. At very high-resolution, very small scale (~10 m) hot spots reported by VIMS were found coincident with the surface locations of individual discrete geysers [Porco et al. 2014]. This correlation, along with the small size estimates of the hot spots derived from the observations of other instruments, strongly suggests that the source of the surface warmth is not shear heating but latent heat from the condensation of vapor onto the near-surface walls of the vents [Porco et al. 2014], allowing for a deep source of the venting materials.
- The plume that is formed from the geysers varies diurnally due to the varying extensional tidal stresses across the surface, with a phase lag of ~45° (or ~4.5 hours) compared to simple tidal models that assume an elastic ice shell [Nimmo et al. 2014]. The origin of the phase lag is not yet clear. Notable is the observation that the plume never goes to zero strength. Behounkova et al. [2015] showed the variation is best described by the cyclical variation in the normal stresses across the fractures, averaged over the SPT, and simulated the viscoelastic tidal response of Enceladus with a full 3-D numerical model. The delay in eruption activity may be a natural consequence of the viscosity structure in the south-polar region and the size of the putative subsurface ocean.
- Individual geysers were observed to be time variable, turning on and/or off on timescales that were not comparable to the diurnal cycling of stresses [Porco et al. 2014]. This was taken as an indication that condensation of ice in the vents leads to the stochastic clogging of the vents and consequently the shutoff of geysers, but



averaged across the SPT, the plume is continuous in time while variable in strength. The estimated timescale for the clogging process is months to a couple of years [Porco et al. 2006].

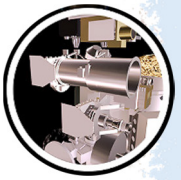
- Models of vapor arising by sublimation from the walls of the cracks and then condensing to make ice particles [Ingersoll and Pankine 2010] yield ice mass fractions no greater than 1.3%, confirming an earlier argument [Porco et al. 2006] that ice/vapor ratios of order unity favor a liquid source rather than sublimating ice.
- Observations by ISS of plume brightness at scattering angles ranging from 2.25° to 5.30°, which are only possible when the spacecraft is in Saturn's shadow, yield estimates of the particle size distribution in the plumes [Ingersoll and Ewald 2011]. The best-fitting distributions have a median mass-weighted radius r0 = 3.6 μm and differential power laws of r1 and r-3 for r << r0 and r >> r0, respectively. If the particles were solid ice spheres, the ice/vapor ratio is in the range 0.35–0.70, which would favor a liquid source.
- The ISS observations at scattering angles of 2.25–5.30° yield estimates of 51 ±18 kg s^{-1} for the mass leaving the vents and 9% for the fraction that escapes into the E-ring [Ingersoll and Ewald 2011]. The implied lifetime of particles in the E-ring is then ~8 years, but this assumes the particles are solid ice spheres. The estimate would be longer if the particles were fluffy aggregates rather than solid ice.
- Modeling the particles as irregular aggregates of spherical monomers yields ice/vapor ratios of 0.07 ±0.01 for the plume [Gao et al. 2016]. Therefore, a vapor-based origin for the plume particles cannot be ruled out if plume brightness is the only criterion.
- Comparison of ISS measurements of plume particle number density with those taken by other Cassini instruments has significantly reduced initial differences among them (factors of 10–20) by accounting for the temporal variability of the plume and the differing times and geometries of the different observations [Porco et al. 2017]. These results remove the need to assume low-density particle aggregates [Gao et al. 2016] to bring about agreement among all Cassini measurements. The preferred exponent in a differential size distribution was q = 3 at an altitude of 50 km.
- During the early years of the Cassini mission, 2006–2010, the computed diurnally averaged ice mass production rate that reproduces ISS observations of plume mass at 50 km altitude was 29 ±7 kg/s [Porco et al. 2017]. This new value is likely a lower limit as it does not account for heavier ice particles that don’t make it up to 50 km altitude. Because of the time-varying behavior of the plume, comparison of quantities of interest must be made at the same time and geometries, or nearly so. Utilizing a diurnally averaged estimate from other Cassini instruments of vapor production rate for the same time period, a solid to vapor ratio > 0.06 was computed. At 50 km altitude, the plume’s peak optical depth during the same time period was ~10^{-3}; by 2015, it was ~10^{-4}.



- Analysis of ISS observations from 2005–2015 reveals a decrease of plume brightness by roughly a factor of two [Ingersoll and Ewald 2017]; suggested explanations included a long-period tide (the decreasing phase of an 11-year cycle in orbital eccentricity), clogging of vents over time, or seasonal thermal effects. (The observations are from 47 individual days, usually with many observations per day, and document in great detail the four-fold to five-fold variation with orbital phase.)
- Thousands of ISS observations of the plume extending over the entire Cassini mission, through late 2017 [Porco et al. 2018], showed, after a multi-year decline in plume brightness, a resurgence to a brightness level exceeding that earlier in the mission. The analysis of this result confirmed previous suggestions [Nimmo et al. 2016] that the plume is varying on three time periods associated with the Dione/Enceladus 2:1 orbital resonance (diurnal, ~4 years and ~11 years) and that secular clogging and seasonal effects can be dismissed. The brightness of the secondary peak at MA ≈55°, near mission's end, declined substantially from its early-mission and mid-mission levels.
- A model of flow of vapor in vertical cracks yields estimates of crack width in the range 0.05–0.075 m [Nakajima and Ingersoll 2016]. A wider crack would yield an unacceptably high ratio of escaping vapor compared to that condensing on the walls as inferred from the observed radiated power.
- A model of the liquid-filled cracks introduces the concept of controlled boiling, in which backpressure limits the rate of evaporation [Ingersoll and Nakajima 2016]. The backpressure arises from frictional stress of the walls on the upward-flowing vapor, and leads to a steady state in which the evaporation rate is proportional to the width of the crack divided by its depth.
- The average geothermal flux into the sea beneath Enceladus' SPT was estimated to be comparable to that of the average Atlantic, of order 0.1 W/m^2 [Porco et al. 2017]. Based on this value, microbes could be present on Enceladus and concentrations at its seafloor hydrothermal vents could be comparable to those on Earth, ~10^5 cells/mL. Bubble-scrubbing, a process well-known to marine microbiologists, could enhance microbial concentrations over native ocean values by up to factors of 1000's in the Enceladus' plume. Estimates of microbial concentrations that might be collected in future missions of various designs were given.

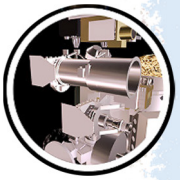
Body and surface

- Fracturing and tectonic modification of Enceladus' surface is much more pervasive than predicted from Voyager imaging—tectonic resurfacing has likely played a major role in shaping youthful appearance of Enceladus. Intensely modified expanses are regionally divided by diverse styles of tectonic features among which are deep rifts, horst-and-graben terrains, folded ridges, braided or vermicular



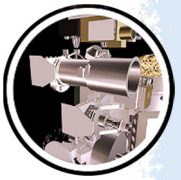
networks of grooves, and curvilinear ridges and fractures [Helfenstein et al. 2005a; Rathbun et al. 2005; Porco et al. 2006].

- An ubiquitous spidery network of sub-parallel, curvilinear, high-angle cracks appear to dissect topographic structures into vertical slabs. Numerous impact craters have been modified by cracks, the orientations of which appear to have a radial component, indicating that the extensional stress field that caused the fractures was influenced by stresses due to the craters themselves [Helfenstein et al. 2005a; Rathbun et al. 2005].
- A network of kilometer-scale ridges (now called Dorsa) and linear arrays of rounded domes are present on the trailing hemisphere of Enceladus and they appear to have extruded through preexisting surface fractures. Some wrinkled, flow-like features with lobate margins are found near the ridge and dome features. New details of viscously-relaxed craters, first seen by Voyager, include central dome features with structurally breached summits [Helfenstein et al. 2005a].
- A geologically active province at the south pole of Saturn's moon Enceladus is circumscribed by south-facing scarps and a chain of folded ridges and troughs at ~55° S latitude. The terrain southward of this boundary is distinguished by its albedo and color contrasts, elevated temperatures, extreme geologic youth, and narrow tectonic rifts that exhibit coarse-grained ice and coincide with the hottest temperatures measured in the region [Porco et al. 2006].
- The placement, morphology, and orientations of the SPT boundary is consistent with its interpretation as a convergent tectonic boundary arising from global deformation due to axial shortening along Enceladus' spin axis. Youthful systems of N-S tending fractures extending from Y-shaped discontinuities (i.e., a Y-shaped tectonic pattern of scarps and confined arcuate ridges that interrupt the SPT boundary) are also consistent with this deformation mechanism [Porco et al. 2006; Helfenstein et al. 2006; Helfenstein 2014].
- Flexural uplift along the ~3.5 Ga aged Harran Sulci rift zone in the tectonically resurfaced trailing hemisphere of Enceladus indicates that, at the time of formation, the mechanical lithospheric thickness was 2.5 km with heat fluxes comparable to average values measured in the active south polar region [Giese et al. 2008b].
- Tiger stripe fractures fall into a family of gradational morphological types. Smooth Flank formations coincide with volcanically active sections. The highest-resolution images (<10 m/pixel) show ice blocks up to tens of meters in size that are widely but non-uniformly distributed over a variety of terrain units. The upraised flanks and valley walls are mantled in places by smooth fluffy-looking deposits, most likely accumulations of coarse-grained plume fallout. Peculiar narrow lenticular ridges (now called shark fins), perhaps emplaced by extrusion or as icy pyroclastic deposits, rise from tens to hundreds of meters along the medial fissures of some tiger stripes. The Smooth Flank formations grade into Platy Flank formations near the ends of the tiger stripes. Platy Flank formations are notably less covered by



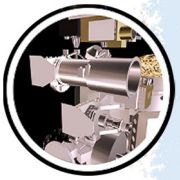
smooth materials giving a somewhat armored surface that reveals small surface cracks. Relict tiger stripe materials exist at the segmented, distal ends of tiger stripes and in at least one large system of parallel ridges and medial troughs eastward of Damascus Sulcus that are superficially similar in appearance and scale to the tiger stripes, but with smooth, strongly muted topography [Helfenstein et al. 2008; Spencer et al. 2009].

- The active Tiger Stripe rifts are separated by a system rounded, platy-textured, elongate hills and a conspicuous system of quasi-parallel ropy ridges and grooves that have spacings and dimensions comparable to the tiger stripe flanks themselves (now called funiscular terrain) [Porco et al. 2006; Helfenstein et al. 2008; Spencer et al. 2009].
- Enceladus' shape deviates slightly from a nominal equilibrium ellipsoid and has a south polar basin with a depth of ~0.4 km [Porco et al. 2006; Thomas et al. 2007a; Thomas 2010; Nimmo et al. 2011].
- The leading hemisphere of Enceladus has distinct geological provinces that exhibit diverse tectonic styles and different cratering histories. The highly tectonized terrains are bounded by a prominent broad annulus of grooved and striated terrains that ranges from about 60 km to over 140 km in width. It surrounds a complex arrangement of tectonic structures, including a conspicuous province near 30° N, 90° W of curvilinear massifs and roughly orthogonal-trending ridged-troughs that define a crudely radial and concentric pattern relative to a point near 25° N, 125° W. This angular sector, about 65° in width, may be the partial remains of an ancient impact basin with a diameter of about 180 km. It could also be the surface expression of an ancient, large diapir. Peculiar quasi-radial ridged-troughs superficially resemble extinct, topographically degraded examples of tiger stripes seen elsewhere on Enceladus. While these features may have a different fracture origin from tiger stripes, their comparable morphology suggests that long ago they may have expressed a similar style of fissure volcanism. Among our other significant findings is a region near 10° S, 60° W of rounded, rope-like sub-parallel ridges similar to ropy (funiscular) plains materials previously found only in the SPT region near active tiger stripes [Helfenstein 2010].
- The topography of a ~1 km high, 250 km wide bulge on the leading side of Enceladus has undergone strong resurfacing and has distinct boundaries to surrounding lower lying cratered terrains; it is consistent with the presence of convection-related warm ice at depth in isostatic equilibrium with surrounding non-convecting cooler ice. [Giese et al. 2010b].
- Tectonic deformation is a major source of blocky-ice features in the SPT. Impact cratering as well as mass wasting, perhaps triggered by seismic events, cannot account for a majority of ice-block features within the inner SPT [Martens et al. 2015; Giese et al. 2010a].



- Geologically young cycloidal fracture segments are found over a variety of different locations on the surface of Enceladus, including the SPT. These features likely have initiated as tension cracks with their form being controlled by diurnal variation of tides, as suggested for Europa. Such a mechanism requires that the ice be mechanically weak and, to allow for sufficient tidal amplitude, there must be a fluid layer below the icy surface. Thus, rather than being confined to just southern latitudes, our observations hint at the presence of fluid layers beneath other areas on Enceladus, potentially at a global sub-surface ocean in recent times [Giese et al. 2011a].
- Geysers emplaced along the three most active tiger stripe fractures (Damascus Sulcus, Baghdad Sulcus, and Cairo Sulcus) occur in local groupings with relatively uniform nearest-neighbor separation distances (~5 km). Their placement may be controlled by uniformly spaced *en echelon* Riedel-type shear cracks originating from left-lateral strike-slip fault motion inferred to occur along tiger stripes. The spacing would imply a lithosphere thickness of ~5 km in the vicinity of the tiger stripes [Helfenstein and Porco 2015].
- The orientations of tilted geyser jets are not randomly distributed; rather their azimuths correlate with the directions either of tiger stripes, cross-cutting fractures, or else fine-scale local tectonic fabrics. Periodic changes of plume activity may be significantly affected by crosscutting fractures that open and close at different times than the tiger stripes that they intersect [Helfenstein and Porco 2015].
- Geyser jets and their associated local hot-spots have the capacity to alter the morphology of surrounding icy geological features, possibly through ablation and sublimation-aided erosion, but also through condensation (which is the source of the heat) and the creation of vent plugs. Plausible morphological examples of ablation and sublimation-erosion include formations of pinnacles along the ridge crests surrounding active areas on and near tiger stripes fractures, possible scour marks or dust trails surrounding active vents, and the excavation of circular pit-like enlargements of active fracture troughs [Helfenstein and Porco 2015].
- Enceladus has a global subsurface ocean which was detected by multi-year imaging observations of forced librations in Enceladus' rotation [Thomas et al. 2016].

Geyser jets and their associated local hot-spots have the capacity to alter the morphology of surrounding icy geological features, possibly through ablation and sublimation-aided erosion, but also through condensation … and the creation of vent plugs.

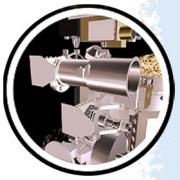


- An exceptionally high-standing (1750 m), 100 km long sawtooth-shaped ridge in the Samarkand Sulci fault band likely initiated by rift flank-uplift caused by extension followed by sinistral shear and compression 3.7 ±0.7 Ga ago, emplacing small-scale fragments sticking out of the surface and creating a (previously enigmatic) pattern of black spots on the sun-facing side of the ridge [Helfenstein et al. 2005a]. The estimated effective elastic lithospheric thickness is ~0.36 km at the time of formation compared to a present-day lower limit of 1.5 km obtained from lithospheric loading modelling [Giese et al. 2017; Wagner et al. 2017; Roatsch et al. 2016].
- A global chain of topographic depressions on Enceladus indicate that this synchronously locked moon has likely undergone True Polar Wander by ~55° about the tidal axis, from an early orientation in which the present terrain near (77° W, 40° N) would have been located at the paleo north pole [Tajeddine et al. 2017a].
- The large collection of high-resolution Cassini ISS images of Enceladus has provided a complete global photomosaic Enceladus base map at 100 m/pixel resolution [Roatsch et al. 2008a; Becker et al. 2016].

Main Icy Satellites (except Enceladus)

Mid-sized icy moons overview

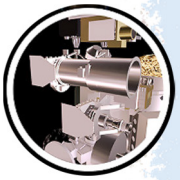
- Accurate values for fundamental whole-body physical properties of the moons were obtained. These include mean radii, densities, shapes, etc., for example, Thomas [2010]; Thomas et al. [2018]; Castillo-Rogez et al. [2018], and also photometric quantities like geometric albedo, the phase integral, or Hapke photometric model parameters [Verbiscer et al. 2018].
- The sizes and shapes of the six mid-sized icy satellites were measured from ISS data. Mimas, Enceladus, Tethys, Dione and Rhea are well described by triaxial ellipsoids; Iapetus is best represented by an oblate spheroid [Thomas et al. 2007a].
- Global photomosaic base maps (ISS CL1:CL2 filter) were completed at better than ~400 m/pxl over the surfaces (Mimas to Rhea; ~800 m/pxl for wide parts of Iapetus) [Roatsch et al. 2009a; Roatsch et al. 2006, 2008a, 2008b, 2009b, 2012, 2013; Schenk et al. 2011; Schenk et al. 2018].
- Images of selected or serendipitous targets at very high-resolution (up to ~3 m/pxl) included bright-ray crater Inktomi (Rhea), fracture networks on Tethys, Dione, and Rhea, equatorial spots on Rhea, parts of Iapetus's ridge (Toledo Montes), etc.
- Almost complete stereo imaging was acquired for all mid-sized icy satellites from Mimas to Rhea (and > 50% for Iapetus), and global topographic maps are now essentially complete for each of the five moons [Schenk et al. 2018].



- Impact craters dominate the surfaces and provide the primary means of estimating terrain ages as well as many other properties of the surfaces [Dones et al. 2009; Kirchoff and Schenk 2010; Schenk et al. 2018; Kirchoff et al. 2018].
- However, crater saturation (crater density has reached a point where the formation of new craters erases the same area of older craters, and crater density has reached an equilibrium) is found on probably most, if not all, heavily cratered terrains on the mid-sized icy moons [Dones et al. 2009; Kirchoff et al. 2018].
- A predicted apex-antapex asymmetry in crater density is not observed at all on the Saturnian moons. Non-synchronous rotation is considered unlikely as the cause [Kirchoff et al. 2018].
- Secondary craters have been identified [Schmedemann et al. 2017; Schenk et al. 2018].
- None of the unusual crater landforms (like multi-ring basins or shallow distorted craters on the Galilean moons) seen on icy worlds that have confirmed internal oceans are seen on the mid-sized moons. However, this does not preclude possible oceans [Schenk et al. 2018].
- Global mapping has revealed geologically complex worlds. All (except perhaps Iapetus) have been tectonically deformed to different degrees. Almost all tectonic landforms are interpreted as extensional structures [Schenk et al. 2018].
- The trailing sides of Tethys and Dione and to a lesser degree of Rhea are darker than the respective leading sides. This is due to E-ring material infalling preferentially on the leading sides and has originally been discovered in Voyager data. The colors of the trailing sides are also redder than the leading sides of these moons.
- Potential endogenic processes acting on Saturn's mid-sized moons are cryovolcanism, tectonism, and viscous relaxation, see Kirchoff et al. [2018] and numerous references therein.
- Smooth plains were observed on Tethys and Dione by Voyager, and Cassini mapping confirmed that these are the only moons with such plains [Jaumann et al. 2009b].
- Wispy terrains, discovered on the trailing hemispheres of Dione and Rhea by Voyager, are rather recent and relatively pristine fracture networks. Their morphology and distribution are similar on these two moons [Schenk et al. 2018].
- The orbits and masses of the mid-sized moons have been largely improved.

Mimas

- Mimas was globally mapped at 216 m/pxl [Roatsch et al. 2013].



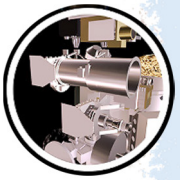
- It is a heavily cratered object with little evidence of endogenic resurfacing [Schmedemann et al. 2015].
- There was no targeted Mimas flyby of Cassini. Closest approach occurred on February 13, 2010 during rev 126, and the best images obtained at this flyby have a spatial resolution of ~93 m/pxl.
- There is morphologic evidence for a highly degraded impact basin of ~153 km diameter northeast of crater Herschel [Schmedemann and Neukum 2011].

Tethys

- Tethys was globally mapped at 292 m/pxl [Roatsch et al. 2009b].
- The highest definition view of Tethys' surface has a spatial resolution of 18 m/pxl and was obtained during the targeted flyby in rev 15 on September 24, 2005.
- Rugged topography of overlapping craters is typical for wide parts of Tethys [Schenk et al. 2018].
- Large 425 km-wide impact basin Odysseus is one of the largest well-preserved basins in the Saturnian system. Flat-floor deposits (as commonly found in large craters on the Moon and Mercury) are lacking, suggesting that impact melt ponding did not occur in large quantities. This lack of large melt sheets is characteristic of all craters in the Saturn system [Schenk et al. 2018].
- Tectonic structures on Tethys are all extensional [Schenk et al. 2018].
- Ithaca Chasma is the dominant tectonic feature. It is a giant rift zone already identified by Voyager, 1,800 km in length and subtending at least 270° of arc, between 70 km and 110 km in width, and 2–5 km deep. It predates the Odysseus basin and thus should not have been formed by this impact feature [Giese et al. 2007].
- Red streaks were only found on Tethys and are very enigmatic. They show an enhanced color signature in the near-IR which is a very unusual color for features on Saturn's icy satellites. No associated surface deformation is visible even at image resolutions of 60 m/pxl [Schenk et al. 2015].

Red streaks were only found on Tethys and are very enigmatic.

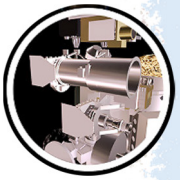
- Tethys's equatorial albedo band, first seen in Voyager images, was analyzed in several ISS NAC wavelengths. The band is symmetric 15° on either side of the equator and extends from 0° to 160° W that is, almost centered on the leading edge of Tethys. There is no evidence that the band is topographically-based; margins are gradational and there is no visible difference in underlying geology [Elder et al. 2007].



- ISS NAC polarization images found no evidence for surface textural variations on size-scales comparable to individual geological features, like crater walls and floors—on these size scales, the surface texture of Tethys appears to be uniform. However, a banded pattern on the surface was found and that likely originates in the subtle albedo variations tied to Tethys equatorial band [Elder et al. 2007] and thermally anomalous terrain [Helfenstein et al. 2005b].

Dione

- Dione was globally mapped at 153 m/pxl [Roatsch et al. 2013].
- Some Dione images taken from very close range are formally better than 6 m/pxl (rev 129 on April 7, 2010 and rev 220 on August 17, 2015), but these are somewhat smeared because of the large speed of the spacecraft.
- Dione is the geologically most-complex of the mid-sized moons except Enceladus.
- Although the Magnetometer (MAG) instrument detected a small mass loading from Dione toward space, ISS did not detect plumes or jets like those on Enceladus.
- The 345 km-wide Evander basin, discovered in Cassini images (this area was not covered by Voyager) features a prominent central peak ~4 km high, surrounded by a nearly complete peak ring. Unlike Odysseus on Tethys, Evander is strongly relaxed, with the floor nearly elevated up to the ground level. Despite this, relief of up to 4 km is preserved within the basin. Outside the rim, low topographic lobes radiate out from Evander ~1 crater radius from the rim [Schenk et al. 2018].
- Dione's most dramatic tectonic features are a distributed network of linear walled depressions interpreted as normal-fault-bound graben and half graben, for example, Wagner et al. [2006, 2009]. The so-called wispy terrain (associated directly with these extensional tectonic structures) might reflect exposures of clean water ice along normal fault scarps [Stephan et al. 2010; Beddingfield et al. 2016].
- There are only few positive-relief tectonic landforms on Dione. The most obvious is Janiculum Dorsa, a single ridge ~900 km long that trends approximately north-south in the moon’s leading hemisphere. Most other positive-relief landforms are related to impact craters, for example, Wagner et al. [2006].
- At the center of the smooth plains on the leading side of Dione is a pair of oblong craters (named Murranus and Metiscus). They are 45 to 70 km across, but only ~1 km deep. Their irregular shapes and the central mounds do not resemble the circular conical relaxed craters elsewhere on Dione [White et al. 2017]. It is suggested that Murranus and Metiscus might be volcanic craters. If so, these irregular craters were the only evidence for explosive or collapse-forming volcanism on Saturn's icy moons [Schenk et al. 2018].

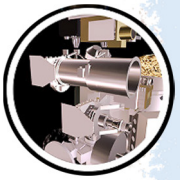


Rhea

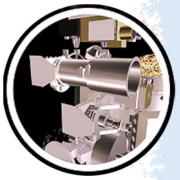
- Rhea was globally mapped at 416 m/pxl [Roatsch et al. 2012].
- The best-resolved images of Rhea were acquired from rev 143 (January 11, 2011) and show details as small as ~5 m in size.
- The largest of the bright ray craters found in the Saturn system, the 49 km diameter Inktomi, is a flat-floored crater with a ray system radiating several hundred kilometers from the crater rim. It was imaged by ISS in August 2007 in 3 colors at resolutions up to 32 m/pxl and in stereo. The images are the best for a pristine crater in the Saturnian system and reveal a rugged landscape. Most of the ejecta and floor is essentially free of small craters [Wagner et al. 2011; Schenk et al. 2018].
- Many of the tectonic lineaments are normal faults and graben, for example, Wagner et al. [2007, 2010]. Most of this is concentrated in the trailing hemisphere as two major rift zones (Galunlati and Yasmi Chasmata) that trend roughly northeast–southwest and that are up to 3 km deep. These rifts are morphologically similar to those on Dione.
- The blue pearls (bluish spots; discovered with ISS) are a series of near-IR-dark irregular patches located at the crests of the highest ridges or massifs located along the equator of Rhea. Their origin is speculated to be related to infalling or collapse of a former orbiting debris ring [Schenk et al. 2011]. A dedicated search with ISS showed that present Rhea has no ring system [Tiscareno et al. 2010a].
- The blue pearls are not associated with any tectonic feature along its length or in near proximity. Instead, they appear to be associated with steep slopes (e.g., crater rims). The lack of any constructional artifacts associated with these color patterns on Rhea implies that they are due to regolith disruption [Schenk et al. 2011].

Iapetus

- About 75% of the surface of Iapetus was mapped at better than ~500 m/pxl [Schenk et al. 2018]. The scale of the global map from Roatsch et al. [2009b] is 802 m/pxl.
- Iapetus's unusual shape is best represented by an oblate spheroid; it supports a fossil bulge of ~34 km [Thomas et al. 2007a; Castillo-Rogez et al. 2007].
- A total of 10 basins larger than 300 km have been identified on Iapetus (despite the lack of resolved imaging in some locations), but only four on Rhea. Dione, Tethys, and Mimas are similarly depleted [Schenk et al. 2018].
- These three points show that there must be something fundamentally different between Iapetus and the inner mid-sized moons.
- Global and regional topography is much less smooth than for the other mid-sized icy moons [Thomas et al. 2007a].



- The close targeted flyby in September 2007 revealed many properties of the anti-Saturn and the trailing hemisphere at high spatial resolution. The best-resolved images have resolutions of 10 m/pxl and show parts of the equatorial ridge within the dark terrain on the anti-Saturn side near 165° W longitude [Denk et al. 2008].
- ISS data show numerous impact craters down to the resolution limit [Denk et al. 2010].
- Iapetus's global albedo dichotomy, first described by the spacecraft's eponym Jean-Dominique Cassini in 1677 and unexplained since then, has been solved through Cassini CIRS and ISS data [Spencer and Denk 2010].
- Dust from Phoebe or possibly from other retrogradely-orbiting irregular moons has likely been painting the surface of Iapetus, forming the newly-detected global color dichotomy of Iapetus [Denk et al. 2010], which triggered the evolution of low-latitude and mid-latitude parts of the leading side into the stark bright and dark patterns we see today as the global albedo dichotomy [Spencer and Denk 2010].
- The global color dichotomy is identified as a fuzzy margin located approximately at the boundary between the leading and the trailing hemisphere; it is consistent with infalling material from Phoebe or the other irregular moons, while the boundary of the global albedo dichotomy is sharp, abrupt, irregular, and somewhat lens-shaped with equatorial parts extending from the leading to the trailing side and completely avoiding the polar areas. The global albedo dichotomy is not consistent with infalling material, but with thermal migration of water ice [Denk et al. 2010].
- A major property of the global color dichotomy is that dark material on the leading side is redder than dark material on the trailing side, and that bright material on the leading side (mainly at high latitudes) is also redder than bright material on the trailing side [Denk et al. 2010].
- Observations of small, bright-ray craters within the dark terrain indicate that the dark material corresponds to a blanket of a few meters or less in thickness [Denk et al. 2010], a finding also supported by Titan Radar Mapper (RADAR) data and consistent with the thermal migration model of Spencer and Denk [2010]. Bright ice, excavated through an impact, presumably sublimates away quickly; fading down to about twice the brightness of the dark surroundings happens within some ~107 years [Denk et al. 2008, 2010].
- While the global albedo dichotomy was known for centuries, Cassini ISS data showed that the stark dark-bright contrast is also a local phenomenon. The surface is either bright or dark, but almost never gray, even in the transition zone between the dark Cassini Regio and the bright Roncevaux Terra and Saragossa Terra [Denk et al. 2008].
- At mid-latitudes on the leading side and also low-latitudes on the trailing side, most of the equator-facing crater walls are covered by dark material, while



poleward-facing walls are mostly bright. Thermal segregation of water ice is again the explanation [Denk et al. 2008].

- The crater size-frequency distribution of Iapetus could be measured over almost four orders of magnitude (from > 60 m to ~600 km) [Denk et al. 2010].
- Iapetus's equatorial ridge—a huge and enigmatic ridge located exactly at the equator was discovered in ISS images [Porco et al. 2005d; Denk et al. 2005a, 2005b]. In places, this ridge is up to 20 km high and 70 km across, and it spans almost 75% of the moon's circumference [Porco et al. 2005d; Denk et al. 2008; Giese et al. 2008a; Singer and McKinnon 2011].
- While the ridge is mainly continuous on the leading side (Toledo Montes), it separates into the isolated mountains of the Carcassone Montes which were already discovered in Voyager data (and thus sometimes dubbed Voyager mountains) [Denk et al. 2000]. In general, it shows a wide range of cross-sections and heights at different longitudes [Denk et al. 2008; Singer et al. 2012]. Singer and McKinnon [2011] did not find potential hints for tectonic or volcanic origin.
- Defying any obvious explanation, numerous endogenic and exogenic formation mechanisms were proposed—for example, see short review of them by Damptz et al. [2018]. None of them can be favored over the others at this point.
- ISS NAC CL1:GRN-filter polarization images of Iapetus's highly contrasting terrains demonstrate that the degree linear polarization correlates almost linearly with the terrain albedo, thus verifying that Umov's Law broadly holds for all terrains visible in our Iapetus images even though there are stark albedo contrasts across the boundary of Cassini Regio and adjacent high-albedo regions. Thus, at sub-centimeter size scales, Iapetus's regolith most likely has a fairly uniform surface texture [Burleigh et al. 2010].

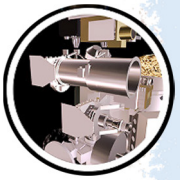
Satellite Orbits (including OpNav) and Orbital Evolution

Determination of gravitational mass (GM) for Mimas using an analysis of its resonant motion with Tethys and its effect on Methone [Jacobson et al. 2006a].

Pioneering use of systematic ISS astrometric observations (including OpNav images), including the use of mutual events, to improve the orbits of the Saturnian satellites [Spitale et al. 2006; Jacobson et al. 2008; Tajeddine et al. 2013; Cooper et al. 2014; Tajeddine et al. 2015].

The discovery and orbital dynamics of Polydeuces, establishing that it is an L5 co-orbital of Dione [Murray et al. 2005a].

The discovery and orbital dynamics of Anthe, establishing that Anthe is librating in the 11:10 resonance with Mimas: the first known example of a planetary satellite in a coupled inner Lindblad



resonance (ILR) / co-rotation-eccentricity resonance (CER), leading to a new determination of the GM of Mimas [Cooper et al. 2008].

Association of Anthe's libration with the structure of its newly-discovered ring arc, in accordance with theory [Hedman et al. 2009b].

The discovery and orbital dynamics of Aegaeon in the G-ring, establishing that Aegaeon is also librating in a coupled first-order ILR/CER, in common with Anthe and Methone [Hedman et al. 2010b].

Improved orbits of the inner satellites and demonstration that the motion of Atlas is chaotic and can be modelled using the CoraLin theory applied to the 54:53 Lindblad and co-rotation resonances with Prometheus [Cooper et al. 2015; Renner et al. 2016].

The first determination of Saturn's tidal parameters incorporating Cassini astrometric data, including the tidal dissipation number Q and the Love number k_2, with confirmation that Q has previously been overestimated by a factor of 10. Important consequences for tidal heating of Enceladus [Lainey et al. 2017].

Small Satellites

Six new moons were discovered in Cassini images …

Six new moons were discovered in Cassini images: Daphnis, Aegaeon, Anthe, Pallene, Methone, and Polydeuces [Murray et al. 2005a; Cooper et al. 2008; Hedman et al. 2009b; Hedman et al. 2010b].

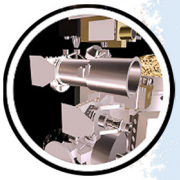
Cassini showed small satellites in the rings had a two-step origin. The innermost ones—Daphnis, Pan, Atlas, even Prometheus and Pandora—are likely not homogenous bodies and must have formed through aggregation of material around a denser core [Porco et al. 2007]. Pan and Atlas later developed equatorial ridges from late-stage accretion from the rings [Charnoz et al. 2007].

The inner small satellites of Saturn have distinctive physical properties and surface morphologies in each of several dynamical niches [Thomas et al. 2013].

Cassini image monitoring of Janus and Epimetheus revealed forced libration for Epimetheus which placed limits on any inhomogeneous mass distribution [Tiscareno et al. 2009].

Cassini showed that small (< 5 km) solid bodies can assume hydrostatic equilibrium ellipsoid shapes [Thomas et al. 2013].

The chaotically rotating satellite Hyperion has unique sponge-like topography that may reflect sublimation of species more volatile than water ice [Thomas et al. 2007b].



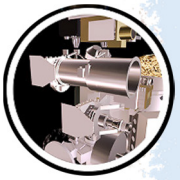
The chaotic rotation of Hyperion was analyzed using data from three flybys. The Lyapunov timescale was found to be approximately 100 days [Harbison et al. 2011].

Cassini images showed some small satellites had surface grooves, and the morphology and patterns of some of these were consistent with tidal effects [Morrison et al. 2009].

Phoebe and the Irregular Satellites

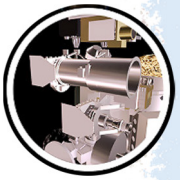
Phoebe

- June 11, 2004—only close flyby of Cassini-Huygens at Phoebe.
- ISS obtained images at better than 2 km pxl^{-1} over slightly more than three Phoebe rotations. The highest resolution ISS images have a pixel scale of 12.3 m.
- A global map was produced and delivered to the United States Geological Survey (USGS). Scale: 1:1,000,000; resolution: 8 pxl deg^{-1} or 233 m pxl^{-1} [Roatsch et al. 2006].
- Phoebe's global shape is close to an oblate spheroid, with a = b to within the uncertainties of the data [Thomas 2010; Castillo-Rogez et al. 2012; Thomas 2010].
- Mean radius: 106.4 ±0.4 km; Ellipsoidal radii (a × b × c):
  109.3 ±0.9 km × 108.4 ±0.4 km × 101.8 ±0.2 km [Thomas et al. 2018].
- Mean density: 1.642 ±0.018 g cm^{-3} [Thomas 2010].
- Even if the porosity of Phoebe were zero, its density would be 1σ above that of the regular icy Saturnian satellites. Therefore, Phoebe appears to be compositionally different from the mid-sized regular satellites of Saturn, ultimately supporting the evidence that it is a captured body [Johnson and Lunine 2005].
- Numerous impact craters are visible on the surface; they range in diameter from the lower limit imposed by the ISS image resolution up to ≈100 km [Porco et al. 2005d].
- Phoebe's topography, relative to an equipotential surface, is within the range of other small objects and is much higher than that for clearly relaxed objects [Thomas 2010].
- Digital terrain model (DTM) and orthoimage of the surface were produced from ISS data [Giese et al. 2006].
- J2000 spin-axis was found at Dec = 78.0° ±0.1°; RA = 356.6° ±0.3°, substantially different from the former Voyager solution [Giese et al. 2006].
- Two ISS observations from remote were designed to obtain light-curves at low and high phase angles [Denk et al. 2018].
- The Phoebe dust ring, discovered from Earth, has also been observed with the ISS WAC [Tamayo et al. 2014].



Other irregular satellites

- The irregular-moon observation campaign with ISS was the first use of an interplanetary spacecraft for a systematic photometric survey of a relatively large group of solar-system objects. They were not part of the original science goals of Cassini ISS.
- With 38 known members, the outer or irregular moons constitute the largest group of satellites in the Saturnian system. Except Phoebe, all were discovered between 2000 and 2007 from Earth (Cassini itself did not discover an irregular moon).
- Due to the large distance to the Cassini orbiter and the small sizes of the objects, the irregulars except Phoebe were always smaller than the size of a NAC pixel. The goal of the observations was thus to obtain light curves. The information for this sub-section stems from the summary chapter on irregular moons from Denk et al. [2018].
- All 9 known prograde plus 16 of the known 29 retrograde irregular moons were successfully observed with ISS, mainly with the NAC. Rotational periods could be derived for most of them (from light curve phasing), and also minimum ratios of the equatorial axes (from light curve amplitudes).
- Due to the position of the spacecraft inside the orbits of the moons, a large range of phase angles was available (and used) for the ISS observations.
- Most measured light curves show either four or six extrema (2-maxima/2-minima or 3-maxima/3-minima patterns), indicative that the objects have quite different shapes.
- All but Phoebe's light curves are primarily shape-driven, as expected for such small bodies.
- Average rotational period of 22 objects is 11.4 ±0.1 h (spin rate 2.10 ±0.02 d^{-1}). This is quite slow compared to main-belt asteroids of similar size range (~4 to ~45 km), but maybe not much different from the Jupiter Trojans, Hildas, or objects beyond Saturn's orbit.
- The fastest measured period is 5.45 h (Hati). This is the fastest reliably known rotational period of all moons in the solar system.
- However, the Hati period is much slower than the fastest rotations of asteroids, indicating that the outer moons may have rather low densities, possibly as low as comets.
- The slowest measured period is slightly longer than three days (Tarqeq).
- All light curves of moon Kiviuq show large amplitudes and are relatively symmetric. This makes Kiviuq a potential candidate for a binary or contact-binary object.
- The spin of Tarqeq is only ~0.5% off the 1:5 orbit resonance of Titan.



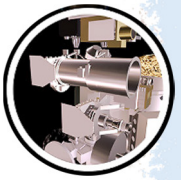
- Siarnaq and Ymir show very distinct 3-maxima/3-minima light curves. Convex-shape models of these moons resemble triangular prisms.
- Siarnaq and Ymir light curves from color filters do not show measurable deviations from the clear-filter light curves, indicating that their surfaces are not colorful at regional scales.
- Siarnaq's pole axis points to low ecliptic latitudes, indicating that this moon experiences strong seasons similar to the regular Uranian moons.
- Contrary to this, the pole axes of Phoebe and Ymir point close to one of the ecliptic poles.
- Most rotational periods of the prograde moons were found to be longer than those of the retrograde moons.
- Most rotational periods of the moons on higher tilted orbits were found to be longer than those on lower tilted orbits.
- Most rotational periods of the moons closer to Saturn were found to be longer than those of the moons farther away.
- Most rotational periods of the larger moons were found to be longer than those of the smaller moons.

Saturn

Cloud top zonal winds in Saturn's equatorial region were documented to be ~100 m s^{-1} weaker than those measured by Voyager, while winds outside the equatorial region were shown to be stable over this same time interval [Porco et al. 2005a; Pérez-Hoyos and Sánchez-Lavega 2006; Sánchez-Lavega et al. 2007; Li et al. 2013]. Stratospheric winds appear to vary over the Cassini mission, perhaps affecting the semi-annual equatorial oscillation [Li et al. 2011; Sánchez-Lavega et al. 2016].

The first direct measurements of vertical wind shear on Saturn showed that the equatorial zonal wind decreases sharply with increasing altitude, suggesting that the observed decrease in cloud top winds since Voyager may be a combination of time variation in the wind itself and time variation in the altitude of the equatorial cloud top [Porco et al. 2005a; Sayanagi and Showman 2007; Garcia-Melendo et al. 2010].

A giant long-lived dragon storm at 35° S appeared in 2004 and was found to be correlated with repeatable Saturn electrostatic discharges (SEDs), implying that the cloud feature is indeed an organized convective disturbance and that the origin of the SEDs is lightning discharges [Porco et al. 2005a; Dyudina et al. 2007; Fischer et al. 2007]. This in turn implies that Saturn's water abundance at depth must not be substantially less than Earth's.



An even larger and longer-lasting giant storm was discovered by ISS at 33° N in 2010. This storm eventually encircled the entire latitude band, was also accompanied by SEDs, and created the largest tropospheric vortex ever seen on Saturn. The storm originated from the string of pearls feature previously discovered by VIMS. The string of pearls was found to be accompanied by a chain of dark cyclonic spots [Fischer et al. 2011, 2014; Sánchez-Lavega et al. 2011; Garcia-Melendo et al. 2013; Sayanagi et al. 2014]. The giant storm has a non-negligible effect on Saturn's global reflected sunlight and emitted thermal radiation [Li et al. 2015].

The first direct detection of lightning flashes on Saturn was made by ISS at the dragon storm latitude in the southern hemisphere [Dyudina et al. 2010]. This was followed by a similar direct lightning detection at the latitude of the giant northern hemisphere storm [Dyudina et al. 2013]. The lightning originates at a depth 125–250 km below the cloud tops, consistent with it being generated by water convective cloud systems.

The quasi-periodic occurrence of giant storms on Saturn on time scales of decades may be explained as the result of suppression of moist convection by the relatively high molecular weight of water in a hydrogen-helium atmosphere [Li and Ingersoll 2015].

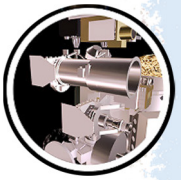
Vortices occur preferentially in latitude bands containing westward jets, preferentially on the anticyclonic side of the jet maximum but sometimes on the cyclonic side. Most vortices last for less than a year, but the largest one observed has lasted for at least four years. The southern hemisphere has more vortices than the northern hemisphere [Vasavada et al. 2006; del Rio-Gaztelurrutia et al. 2010; Trammell et al. 2014, 2016].

Horizontal eddy momentum fluxes are directed into eastward jet cores and away from westward jet cores, converting eddy kinetic energy to zonal kinetic energy [Del Genio et al. 2007; Del Genio and Barbara 2012], as on Jupiter. Deep convective clouds exist at all latitudes but preferentially at cyclonic latitudes, as on Jupiter. This behavior is consistent with the idea that the rising branch of the mean meridional circulation occurs at cyclonic shear latitudes and the sinking branch at anticyclonic shear latitudes, implying that the jets are maintained by eddies due to instabilities of the large-scale flow [Del Genio et al. 2009].

Zonal winds weaken with increasing altitude in the cores of eastward jets [Garcia-Melendo et al. 2009, 2011a] and strengthen on either side of the jet core, implying that the jets broaden with increasing altitude [Del Genio and Barbara, 2012]. Eddy momentum fluxes weaken with altitude on the flanks of the jets, consistent with the broadening with altitude and suggesting that the eddy source is near or below cloud level [Del Genio and Barbara 2012].

Inferences about meridional circulation and convective storms from ISS images were found to be consistent with some of the spatial variations in ammonia abundance derived from Cassini RADAR radiometer [Laraia et al. 2013].

Objective analysis of cloud types in ISS continuum and methane band images suggests that dynamically, there are three distinct types of latitude bands on Saturn: 1) deep convectively



disturbed cyclonic shear regions poleward of the eastward jets; 2) convectively suppressed regions near and surrounding the westward jets; and 3) baroclinically unstable regions near eastward jet cores and in anti-cyclonic regions equatorward of them. These are roughly analogous to Earth's tropics, subtropics, and mid-latitudes [Del Genio and Barbara 2016].

Saturn has distinct vortices at both poles, with cyclonic winds, a warm core and cloud clearing near the pole, and high eyewall clouds surrounding the core. This feature resembles polar vortices found on several other planets [Dyudina et al. 2008, 2009; Sánchez-Lavega et al. 2006; Sayanagi et al. 2017].

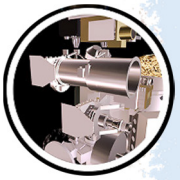
The Saturn ribbon feature embedded in the 47° N eastward jet has properties in common with meandering western boundary currents in Earth's oceans such as the Gulf Stream and may be explained by a nonlinearly saturated shear instability [Sayanagi et al. 2010].

The ~78° N polar hexagon first seen by Voyager has persisted through the Cassini era [Sánchez-Lavega et al. 2014; Antuñano et al. 2015, 2018]. Simulations suggest that stable meandering polygonal structures resembling the hexagon can emerge without forcing when dynamical instabilities in a shallow eastward jet nonlinearly equilibrate. The wavenumber of the feature and its phase speed depend on the wind speed both at the cloud level and at the base of the flow [Morales-Juberías et al. 2011, 2015].

Stratospheric haze in Saturn's atmosphere produces photometric and polarimetric signatures that are most apparent in the short (near-UV and blue) wavelengths, in methane absorption bands at 619, 727, and 889 nm, and in polarization at visible and near-IR wavelengths. When Cassini arrived at Saturn in 2004, and earlier during the cruise phase, the northern high latitudes were blue, indicating an atmosphere with little haze content, emerging from a long period of little or no photochemical activity. During the course of the mission the northern high latitudes became exposed to sunlight, leading to photochemical haze formation and a trend toward redder colors [Fletcher et al. 2018]. Hemispheric differences in cloud feature contrast and decreases in contrast in the northern hemisphere over the course of the Cassini mission occur as a result [Del Genio et al. 2009; Del Genio and Barbara 2016].

Most latitudes on Saturn show little polarization, a consequence of reflection from an optically thick layer of large (relative to the observation wavelength), nonspherical ammonia ice or ammonia ice crystals mixed with an unknown component (since the near-infrared spectral feature of ammonia ice is rarely observed for Saturn). Cassini polarization images show enhanced polarization, enhanced forward scattering and darker particles in the region contained within the north polar hexagon [West et al. 2015; Pérez-Hoyos et al. 2016; Sayanagi et al. 2018]. These features indicate that, like Jupiter's poles, auroral input to the high atmosphere leads to the breakup of methane molecules and the subsequent

ISS made the first detection of Saturn's aurora at visible wavelengths in both hemispheres.



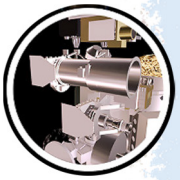
formation of heavier hydrocarbons leading to formation of a UV-dark haze of aggregate particles [Sayanagi et al. 2018].

ISS made the first detection of Saturn's aurora at visible wavelengths in both hemispheres. The color of the aurora varies with altitude and contains a distinct H-alpha line. The auroras form as bright arcs that sometimes spiral around the poles and sometimes form double arcs. The period of the north aurora is close to that of the Saturn Kilometric Radiation [Dyudina et al. 2015].

Rings

Discovery of many new ring phenomena, and more detailed observations of known phenomena, occurred very early in the Cassini mission in ISS observations [Porco 2005], all refined or extended in subsequent papers:

- Moonlets in the F-ring.
- New moons, Methone, Pallene and Polydeuces, among the mid-sized satellites, and estimates of their orbital elements,
- Refined orbits and sizes of ring region satellites Janus, Epimetheus, Prometheus, Pandora, Atlas, and Pan.
- High-resolution images of the edge of the Encke gap revealing in clear detail the edge waves created by Pan.
- Wakes created by Pan seen at large distances from the moon and the inference of low damping, and importance of self-gravity and collective effects, in the rings.
- Many previously undetected spiral waves, Atlas 5:4, 9:8, and 10:9, and Pan 7:6, producing estimates of ring and satellite properties in some cases.
- A wave in the middle of the narrow eccentric Maxwell ringlet.
- A wave in the Huygens ringlet.
- Very fine scale (~0.1 to 1 km) in high optical depth regions in the inner and outer B-ring, attributed to pulsation instabilities (or overstabilities).
- Mottled, ropy, and straw-like structure in the rings at fine scales (few km), indicative of particle clumping.
- New diffuse but relatively narrow tenuous rings between the A-ring edge and the F-ring, and within gaps (Encke, Huygens and Maxwell) in the main rings.
- Spikes and wisps, sharp and broad structures, that extend into the Keeler gap from its outer edge, predicting the presence of an embedded moon (which was discovered later to be Daphnis).
- Spectrophotometric results on the rings.



Discovery of characteristic gravitational signature of Prometheus in the F-ring core [Porco 2005].

Discovery of mirroring of F-ring core structure at opposite ansae confirming the effect of eccentricity/periapse perturbations [Porco 2005].

Discovery that the apparent multiple strands of the F-ring are kinematic spirals due to Keplerian shear following collisions [Charnoz et al. 2005].

Detailed understanding of how the gravitational perturbations from Prometheus combined with Keplerian shear produce the characteristic streamer and channel structures visible in the F-ring core [Murray et al. 2005b].

First observation of spokes with Cassini, confirming (with theoretical explanation) that they are a seasonal phenomenon [Mitchell et al. 2006].

Discovery of small moons embedded in the mid A-ring via the propeller-shaped disturbance they create in the ring [Tiscareno et al. 2006a].

First understanding of the complex morphology of spiral density waves due to the co-orbital moons Janus and Epimetheus, tracing their history as recorded in the rings and deriving ring surface mass density values for wave locations [Tiscareno et al. 2006b].

Discovery that the D-ring has undergone substantial changes in the 25 years between Voyager and Cassini [Hedman et al. 2007a].

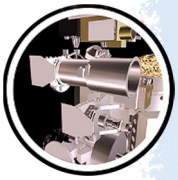
Discovery of a vertical corrugation in the D-ring with a wavelength that decreases with time, interpreted as a winding spiral due to differential nodal regression after the ring was initially very slightly tilted in the early 1980s [Hedman et al. 2007a].

Discovery of a denser arc within the G-ring, confirming initial indications from Cassini Magnetospheric Imaging Instrument (MIMI). The ISS images are dominated by dust, but the MIMI absorptions must be due to a population of meter-sized objects [Hedman et al. 2007b].

Discovery that the G-ring arc material is trapped in a 7:6 corotation eccentricity resonance with Mimas [Hedman et al. 2007b].

Detailed understanding of spiral density waves and other radial structure from Cassini images taken during Saturn orbit insertion (SOI), deriving surface mass density and ring viscosity values for many locations within the rings with much higher fidelity than pre-Cassini measurements [Tiscareno et al. 2007].

New upper limit on the vertical thickness of the ring, 3–5 meters in the Cassini Division, 10-15 meters in the inner A-ring [Tiscareno et al. 2007].



Detailed understanding of propellers in the Propeller Belts of the mid A-ring from analysis of ~150 objects seen in Cassini images [Tiscareno et al. 2008].

Discovery of moonlets embedded in the F-ring core and that the combined gravitational and collisional effects of Prometheus and small satellites produces the F-ring's unusual morphology [Murray et al. 2008].

In studies of the azimuthal asymmetry in Saturn's A-ring, the coefficient of restitution of the particles was found to be ~3.5 times lower than previously assumed, suggesting that particle collisions in the A-ring are more lossy than previously expected, possibly due to particle surface roughness, a regolith, and/or a large degree of porosity [Porco et al. 2008].

Discovery of the time variability of the outer edge of the A-ring due to the 7:6 inner Lindblad resonance with Janus and the effect of the Janus-Epimetheus orbital swap in January 2006 [Spitale and Porco 2009].

Detailed understanding of the relationship between the mass of a moon in a gap and the amplitude of the wavy edges of that gap, with more accurate measurements of the masses of Pan and Daphnis [Weiss et al. 2009].

Measurement of the inclination of Daphnis' orbit, via measurement of shadow lengths of scalloped gap edges and understanding of how those two quantities are related [Weiss et al. 2009].

Discovery of resonance-sculpted patterns within three dusty ring regions (the G-ring, the D-ring, and the Roche Division) with the latter two linked to periodicities within Saturn [Hedman et al. 2009a].

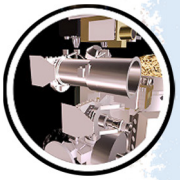
Discovery of three dusty ring structures at the orbits of three small Cassini-discovered moons (Methone, Anthe, and Pallene) confirming, in the case of Pallene, initial indications from Cassini MIMI. The Methone and Anthe ring structures are arcs centered on their moon and are associated with Mimas resonances, while the Pallene ring is circumferential and does not appear to be associated with any strong resonance [Hedman et al. 2009b].

Discovery of the mechanism by which perturbations from Prometheus produce gravitational instabilities in the F-ring core leading to moonlet formation and evolution [Beurle et al. 2010].

Discovery of unforced 1-lobed, 2-lobed, and 3-lobed self-excited patterns in the outer edge of the B-ring, in addition to the previously known 2-lobed pattern forced by Mimas, which implies the importance of viscous overstability in sculpting this region of the rings [Spitale and Porco 2010].

Discovery of localized structures, up to 3.5 km in vertical height, near the outer edge of the B-ring, implying the presence of embedded massive bodies [Spitale and Porco 2010].

Discovery of a single compact object or structure near the outer edge of the B-ring, designated S/2009 S1, casting a shadow implying a size of ~0.3 km [Spitale and Porco 2010].



Detailed understanding of the Charming Ringlet, a dusty structure within the Laplace gap of the Cassini Division, as a heliotropic ring whose apoapse always points towards the Sun due to radiation pressure [Hedman et al. 2010a].

Discovery of Aegaeon, a 1 km moon embedded in the G-ring at the heart of the arc in that ring. Determination that Aegaeon is trapped in a strong resonance with Mimas, like Methone and Anthe [Hedman et al. 2010b].

Careful examination of the region around Rhea at both high and low phase angles, with the conclusion that there is no system of rings around that moon, contradicting an earlier report [Tiscareno et al. 2010a].

Discovery of giant propellers and long-term tracking of their orbits [Tiscareno et al. 2010b]. These constitute the first objects in the history of astronomy to have their orbits tracked while they are embedded in a disk, rather than orbiting in free space.

Measurement of shadow lengths for giant propellers during equinox, inferring sizes up to 1-2 km [Tiscareno et al. 2010b].

Discovery of corrugations in the C-ring, like those previously identified in the D-ring, consistent with being caused by an event that occurred in 1983. The identification of such a pattern in the more massive C-ring points to a massive but dispersed cloud of interplanetary debris as the cause [Hedman et al. 2011].

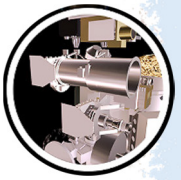
Detailed understanding of the three-dimensional structure of the E-ring, including a radial profile with a local minimum at the location of Enceladus, and variations that correlate with the orientation relative to the Sun [Hedman et al. 2012].

More detailed understanding of the shadow-casting compact object near the B-ring outer edge, S/2009 S1, indicating that it is an unresolved propeller structure and not an isolated embedded moon [Spitale and Tiscareno 2012].

Discovery that, compared to the Voyager epoch, the F-ring core was brighter by a factor two, was three times wider, and had a higher optical depth [French et al. 2012].

The use of geometrical fits of the F-ring core to show the extent of local variability in the orbital elements even though the average values are consistent with those determined from stellar occultations [Cooper et al. 2013]. Discovery of an empirical commensurability between the precession rates of Prometheus and the F-ring.

Discovery and detailed understanding of dusty ringlets in the Encke Gap, one sharing the orbit of Pan and two others on either side, with determination that the radial structure of these ringlets indicates heliotropic behavior as previously described for the Charming Ringlet, while the azimuthal structure constitutes many clumps that are moving with respect to Pan and corotation [Hedman et al. 2013].



Detailed understanding of the spokes in the B-ring, following their growth and decline as seen in ISS images. Discovery that spokes undergo an active phase during which they grow in size and optical depth, with one edge apparently governed by Lorentz forces and the other edge apparently governed by Keplerian motion. Discovery via light-scattering behavior that spoke particles are irregularly shaped, not spherical. Discovery that spoke activity on both sides of the rings occurs with a period commensurate with the period of northern Saturn kilometric radiation (SKR) emission, though a period commensurate with the southern SKR also seems to be present. Discovery that peak spoke activity is near 200 degrees SLS4, which is divergent from the Voyager value (Mitchell et al. 2013)

Use of the Iapetus—1:0 spiral bending wave to derive a continuous mass density profile for the outer Cassini division and the inner A-ring, in particular finding that the sharp change in optical depth that defines the inner edge of the A-ring does not in fact correspond to any sharp change in surface mass density [Tiscareno et al. 2013a].

Discovery of impact ejecta clouds rising above the rings, and use of those clouds to infer the population of decimeter-to-meter-sized objects in heliocentric orbits near Saturn [Tiscareno et al. 2013b].

Discovery that the exceptionally bright, extended clumps which were common during the Voyager epoch were much rarer in the Cassini era with only two having been seen [French et al. 2014].

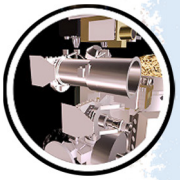
Detection and explanation of mini-jets in the F-ring as collisional products due to low velocity impacts with nearby objects [Attree et al. 2012; Attree et al. 2014].

Discovery of an object (Peggy) at the edge of the A-ring. Subsequent tracking of radial discontinuity (probably due to gravitational effect of embedded object) suggests stochastic behavior possibly due to encounters with smaller, nearby objects [Murray et al. 2014].

Discovery of an anti-resonance mechanism which can provide a stabilizing effect to reduce the effect of chaotic evolution of ring particle orbits at the F-ring's location.

Discovery of an anti-resonance mechanism which can provide a stabilizing effect to reduce the effect of chaotic evolution of ring particle orbits at the F-ring's location. The core may be located at a unique location where an anti-resonance and a co-rotation resonance with Prometheus are coincident [Cuzzi et al. 2014].

Detailed understanding of D68, a ringlet in the D-ring, with explication of patterns whose evolution may place important constraints on the ringlet's local dynamical environment and/or the planet's gravitational field [Hedman et al. 2014].



First observation of the Phoebe Ring in visible light, by Cassini images tracing Saturn's shadow as it recedes through that ring, placing new constraints on the properties of Phoebe Ring particles [Tamayo et al. 2014].

Detailed understanding of the tendrils of the E-ring surrounding Enceladus, and the mechanisms by which the E-ring is fed by the Enceladus geysers [Mitchell et al. 2015].

More detailed understanding of corrugations in the D-ring, including a time-variable periodic modulation that likely indicates organized eccentric motions of ring particles, suggesting that the 1983 event that started the spiral had an in-plane component as well as a vertical component, with the vertical component some 2.3 times larger. Mismatch between wavelengths in the D-ring and C-ring may indicate a two-stage initiating event [Hedman et al. 2015].

Detailed understanding of the wide range of viewing geometries available for Cassini ISS photometric measurements of the D-ring and G-ring, and application of the derived functions to understanding similar debris disks around other stars [Hedman and Stark 2015].

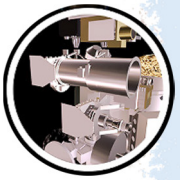
Discovery that the Janus-Epimetheus orbital swap in 2010 led to the disappearance of the characteristic 7-lobed pattern as the Janus resonance moved away from the ring edge. Other signatures in the edge pattern could be due to inhomogeneities in Saturn's gravity field [El Moutamid et al. 2016].

Discovery of a new evolving pattern in the D-ring, apparently created by an event that occurred in 2011, possibly debris striking the rings or a disturbance in the planet's electromagnetic environment, with explanation of similar patterns seen by Voyager having possibly resulted from an event that occurred in 1979 [Hedman and Showalter 2015].

Further observations of the Phoebe Ring, yielding a radial profile from 80 to 260 Saturn radii. Evidence of a change in behavior around 110 Saturn radii that may be due to interactions between the dust grains and Iapetus, or to other orbital instabilities. Evidence of material beyond the orbit of Phoebe, which may be due to other moons that contribute material to the ring. Evidence that the Phoebe ring is unusually rich in particles smaller than 20 μm, compared to particles larger than that size, which may be due to a steep size distribution of ejecta or to a subsequent process that preferentially breaks up larger grains [Tamayo et al. 2016].

Detailed understanding of the Huygens ringlet in the C-ring, with each edge modelled separately, finding one 2-lobed pattern forced by a resonance with Mimas as well as a self-excited 2-lobed pattern, and substantial additional structure that is not easily explained [Spitale and Hahn 2016].

Discovery of signs of embedded massive bodies within the Huygens ringlet, especially at two particular co-rotating longitudes [Spitale and Hahn 2016].



Detailed understanding of the inner edge of the Keeler Gap from ISS images, finding not only strong evidence for a 32-lobed pattern generated by Prometheus, but also 18-lobed and 20-lobed normal modes rising from within the ring. Also, discovery of multiple localized features on eccentric orbits that appear to move at the local Keplerian rate and persist for only a few months. Hypothetical explanations may include differences in how ring particles respond to resonances, and/or unseen embedded objects [Tajeddine et al. 2017b].

Detailed understanding of spiral density waves and their role in holding the ring system in place, using Cassini results for surface mass density and viscosity combined with improved theoretical understanding, demonstration that the A-ring is held in place by many resonances involving at least seven moons [Tajeddine et al. 2017c].

Detailed understanding of spiral density waves and their role in holding the ring system in place, … .

Discovery of a dusty ring that shares the orbit of Prometheus but precesses at a rate characteristic of the F-ring [Hedman and Carter 2017].

Discovery of previously unseen structures in the D-ring and the Roche Division, as well as novel fine-scaled structures in the core of the E-ring, in high-resolution high-phase images obtained during the Ring Grazing Orbits and Grand Finale [Hedman et al. 2017].

Determination that many of the gaps in the C-ring and the Cassini division are not held open by shepherd moons, based on non-detection during intensive Cassini searches for such moons [Spitale 2017].

Discovery of radial variations in the degree of visible clumpiness in the ring, in high-resolution images obtained during the Ring Grazing Orbits and Grand Finale [Tiscareno 2017].

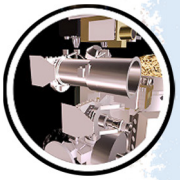
Measurement of the particle-size distribution for small propellers in the Propeller Belts of the mid A-ring, in high-resolution images obtained during the Ring Grazing Orbits and Grand Finale [Tiscareno 2017].

Detailed images of the fine structure of giant propellers, obtained during the Ring Grazing Orbits and Grand Finale [Tiscareno 2017].

Detailed images of impact ejecta clouds in the A-ring and C-ring, with unprecedented color and frequency information, obtained during the Ring Grazing Orbits and Grand Finale [Tiscareno 2017].

Corrected and more complete profile of spiral density in the A-ring [Tiscareno and Harris 2018].

Measurement via spiral density and bending waves of surprisingly low surface density, 25 g/cm^2, in the inner B-ring [Tiscareno and Harris 2018].



Creation of an atlas of resonant features in Saturn's rings [Tiscareno and Harris, 2018].

Systematic identification of resonant features with moons that drive each wave, and of apparently resonant features with no known driving source [Tiscareno and Harris 2018].

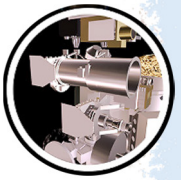
Open Questions for Saturn System Science

Titan (summarized in Nixon et al. [2018])

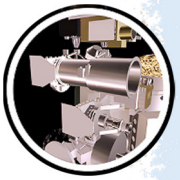
- What is the timing of the onset of north-polar summer storms?
- Is the weather Cassini observed typical for these seasons on Titan? If so, why does the implied seasonal transition in the mean meridional circulation lag that predicted by models by several Earth years?
- What explains the spectral behavior of some north-polar cloud features visible to VIMS at 2.1 μm but not to ISS at 938 nm or VIMS at other wavelengths (shorter and longer than 2.1 μm)?
- Over what timescale do changes occur in north-polar lakes and seas? And are liquid reservoirs exchanged between the north and south poles, and if so, over what timescale?
- What is the nature of exchange between surface organics and subsurface water? Is there cryovolcanism? Do tectonics facilitate exchange combined with icy mantle convection?
- What are the implications of seasonal behavior of haze for production processes?

Enceladus

- What mechanism(s) produce the phase lag between the maximum normal tidal stresses across the fractures and the maximum plume brightness (and hence mass) over the course of an Enceladus day? Is this phase lag also present in the response of the plume to the 4-year and 11-year periodic variations in tidal stresses across the SPT?
- What processes are occurring in the conduits leading from the ocean to the surface, and how do they change the contents of the plume? How wide are the conduits?
- Does liquid water ever reach the surface?
- How does the magnitude of the flux of curtain-style venting products compare with those of discrete geysers?
- How did the SPT form and how has it evolved with time?

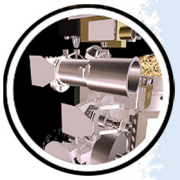


- Was the region of anomalous high thermal flux, presently under the SPT, much more extensive in the past? Did it extend to the equatorial regions on the leading-hemisphere and trailing-hemisphere, where there is widespread evidence for a strongly elevated thermal flux in the past, or where these regions affected by separate hot spots that have diminished over time? Has the activity been constant over time, or does it periodically diminish and return due to tectonic overturn? [Helfenstein 2010].
- To what extent might true polar wander (TPW) have resulted in the formation of tectonic features that are visible today? Are there regions of Enceladus outside the SPT that show evidence of elevated thermal flux due to the lithosphere passing over one or more regional hot spots?
- What does ancient terrain tell us about the early history of Enceladus?
- Are there unique, specific types of local geological structures that discrete geysers deposit or sculp which are diagnostic of their presence, activity, and persistence?
- Can extinct or relict tiger stripe structures be reliably identified outside of the SPT region?
- Are there examples of possibly relict structures other than tiger stripes on Enceladus that have been shaped by some form of ancient venting or cryovolcanism?
- Are the fine, gossamer cracks that slice though terrains throughout the SPT region part of the pervasive system of fine cracks that exist outside of the SPT region? What is their origin and what does it indicate about the mechanical structure of the surface and the nature of stresses that produced them?
- How does the thickness of the icy crust, and its thickness relative to the underlying ocean, vary with location on Enceladus? How has it changed over time?
- What role have tidal interactions played in controlling the evolution of Enceladus' global ocean, lithosphere, tectonism, and water eruptions? [cf. Thomas et al. 2016; Giese et al. 2011b].
- To what extent have plume fallout and accretion of E-ring particles affected the surface physical properties of Enceladus' surface materials [cf. Schenk et al. 2017]? Is there evidence that these interactions have changed over time producing observable records in:
  - Spectral properties and regolith composition?
  - Surface physical properties like regolith porosity and macroscopic texture, particle properties such as grain transparency and particle microstructure?
- Are there observable spectral and/or photometric effects of sintering by thermal hot spots that are diagnostic of the age and persistence of eruptive activity and/or subsurface convection on Enceladus [cf. Helfenstein 2012]?

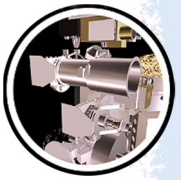


Main icy satellites (except Enceladus)

- What is the absolute timing of all surface-modifying events on the moons?
- How old (or young) is Saturn's satellite system? Based on the hypotheses that orbital instability caused massive collisions within a previous generation of Saturnian mid-sized moons inside the orbit of Titan, it has been speculated that the icy moons (except Iapetus) might be very young relative to the age of the Solar System, maybe just in the order of ~100 Ma [Ćuk et al. 2016]. This possibility is at least not precluded by the geologic record of these mid-sized bodies, but appears to pose major theoretical problems [Schenk et al. 2018]. How likely is it that all moons underwent major formation processes in a short period of time, but look old today? What would be diagnostic signatures of such a scenario? How could kilometer-sized topography of large basins like Evander or Odysseus survive in such a scenario? What is the source of the numerous impact craters?
- Determine the source of the impactors: Is the assumption of heliocentric projectiles (mainly Centaurs/ecliptic comets) as the origin causes of the craters really correct? Or could planetocentric sesquinary impactors (these are secondaries that remained in orbit around Saturn for a while before falling back on a surface) from impacts on the inner moon system and/or from catastrophic break-ups of moons within Titan's orbit [Movshovitz et al. 2015; Ćuk et al. 2016] and/or from the outer irregular moon system (which experienced a violent collisional history, but less likely except for Iapetus and possibly Hyperion because Titan appears to be an effective barrier [Denk et al. 2018] do the job? Alternatively, could there be a completely different impactor population? In case the Ćuk et al. [2016] scenario of a young satellite system is correct, the majority of the craters on the moons inside Titan must come from a planetocentric impactor population.
- How should any early bombardment events be incorporated into the rates? [Kirchoff et al. 2018]. (Only relevant if the moons are old.)
- Crater counts revealed relative paucities of craters with D < ≈10 km on Rhea and Iapetus, and of craters 10–20 km < D < ≈200 km on Mimas, Enceladus, Tethys, and Dione. Cryovolcanism, tectonism, or viscous relaxation are likely not the cause for these differences [Kirchoff et al. 2018]—but what else?
- How have the thermal profiles and physical structure of each satellite evolved over time?
  - How do visible geological and tectonic features record these changes?
- What past or current heating sources ever modified the mid-sized moons of Saturn?
- Why do we see no central pits in craters on these moons, while we do see them on water or ice-bearing bodies like Ceres, Ganymede, Callisto, Europa, Mars, and even examples on Earth?



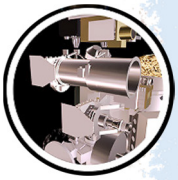
- What is the origin(s) of crater chains on Rhea, Dione, Tethys, and Iapetus? (Are they mostly from secondary cratering, or do split projectiles also form crater chains at Saturn?)
- To what extent have subsurface oceans been present over the geological evolution of each main icy satellite and what role have they played in shaping the present-day surface of each?
  - Is there evidence of tectonism that would require a subsurface water layer?
  - Are there geological features present that are diagnostic of ancient cryovolcanic activity?
  - If such features are present, is there stratigraphic information about their placement in time?
- To what extent have interactions between the outer diffuse rings and the regoliths on the main icy satellites affected the surface physical properties of the regoliths?
  - Spectral properties and regolith composition.
  - Surface physical properties like regolith porosity and macroscopic texture, particle properties such as grain transparency and particle microstructure.
  - Is there any observable evidence that the ring-satellite interactions have changed over time?
- Mimas is similar in size to neighboring, active Enceladus and the closest midsize icy satellite to Saturn, but it is devoid of any but the most rudimentary deformation. Why are these two bodies so different?
- What is the origin of Mimas's trough system?
- Has Mimas an irregularly shaped core or even a sub-surface ocean?
- Did a potential core of Mimas focus seismic energy during the Herschel impact, resulting in the irregular troughs and knobs found antipodal to the crater? (also known as, a scenario somewhat similar to Mercury and the Caloris basin?)
- Why is Tethys so geologically complex despite its very low density (~1 g/cm^3) and the consequently low abundance of radiogenic nuclides?



- Are the Odysseus basin and Ithaca Chasma on Tethys genetically linked? Giese et al. [2007] say no, but this has been questioned [Schenk et al. 2018]. What are the relative, what are the absolute ages of these two major features on Tethys?

What is the nature, age, and origin of the enigmatic red streaks on Tethys?

- What is the nature, age, and origin of the enigmatic red streaks on Tethys?
  - Are such spectral features observable on other Saturnian icy satellites? If not, why not?
- Smooth plains emplacement on Tethys and Dione: How did the smooth plains become smooth? The volcanic hypothesis remains, but many challenging questions do so as well: Cassini did not resolve flow fronts on the smooth plains unit—the margins of the smooth terrain grade into heavily cratered highlands over a significant distance, implying that there may be no recognizable discrete contact (boundary) between the two terrains [Kirchoff and Schenk 2010]. Could the smooth plains instead be the result of crater erasure by extremely high heat flow (despite the lack of any cryptic rings representing nearly flattened impact craters)?
- How are thermal anomalies such as those on Tethys and Mimas manifested in terms of surface physical properties of the regolith?
  - Are thermally anomalous features like the Pac-Man terrain observable or more subdued on other main icy satellites of Saturn?
- Does Dione host an ocean [Beuthe et al. 2016]? Difficult to confirm geologically—if the outer shell is on order of 100 km deep as suggested, it may be difficult to fracture.
- Is large basin Evander so much relaxed due to a sub-surface ocean?
- Origin of the wispy terrains (fracture networks) on Dione and Rhea.
- On Rhea, rare high-resolution views (at < 20 m/pixel, e.g., ISS frame N1741547885) reveal occasional isolated fault scarps. Are these far more common than might be guessed from lower resolution global imaging? [Schenk et al. 2018].
- Rhea's blue pearls—on Saturn's mid-sized icy moons, bluish colors are usually associated with young features and fade with time. Thus, we would expect that a color signature like Rhea's equatorial blue spots would also fade with time, implying that it might be a geologically recent phenomenon. Is this really the case? If so, how has a young ring feature formed around Rhea in more recent times? If not, how could the bluish color be preserved?
- Why does Iapetus have so many more large basins and a much more rugged topography than the inner moons? (Was the incoming projectile flux different? Was there a major heating event on the inner moons, erasing the topographic record of early giant impacts? Were the inner moons formed later? Was Iapetus formed elsewhere? ...?)



- Iapetus—how did the equatorial ridge form?
- Why is the shape of the cumulative crater size-frequency distribution of Iapetus so close to the size-frequency distribution of the Earth's moon [Denk et al. 2010 Figure 3]?

Satellite orbits and orbital evolution

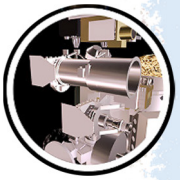
- Are the orbits of the inner satellites stable in the long-term?
- Did the small inner satellites form from the rings?
- What are the masses of Anthe, Methone, Pallene, Polydeuces and Aegaeon?
- What mechanism determines the secular evolution of the Saturnian satellites, in particular Enceladus?

Small satellites

- Do the mean densities of the satellites restrict possible origin mechanisms?
- Can we assign relative ages to the small satellites and relate those to surface ages of large satellites, or to the age of the main ring system?
- How many types of surface grooves are there, and do any reveal internal structures?
- What are the mechanisms that allow small (few km) objects to assume a hydrostatic shape?

Phoebe and the irregular satellites

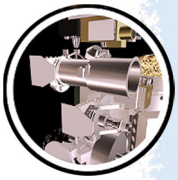
- What are the spin rates of the 13 irregular moons not observed by Cassini?
- What are the precise sizes of Saturn's irregular moons?
- How are they looking like? (What are their shapes?)
- What are their exact albedos, how much do they differ between the objects?
- What are their densities? Might they be even lower than ~500 kg/m^3, as indicated by the rotational periods? Are the irregulars indeed rubble piles of cometary nature?
- Are there noticeable albedo variations on the surfaces (other than Phoebe)?
- Is there any irregular moon with color variations on the surface?
- Are there really significant color variations between different objects, as suggested from ground-based observations?
- Is the distribution of pole-axis orientations random, or is there a preferred orientation?



- How are the phase curves looking like, and what will they tell us about the surface properties?
- Do contact-binary irregular moons exist; might they even be common in the Saturn system?
- Do binary moons exist?
- Is there a spin-orbit resonance of Tarqeq with Titan?
- How old are the irregulars that exist today?
- How many progenitor objects were captured by Saturn? When did this happen (when was the first, when the last capture event)? How did Saturn do that? How many of them (or what fraction) were trapped in prograde, in retrograde, in low-tilted, in highly tilted orbits?
- Where in the solar nebula did they originally form? (Inside or outside the Saturn orbit? Were they former asteroids, Hildas, Trojans, Centaurs, Kuiper-Belt objects, comets?)
- Might some of the retrograde moons (especially the Mundilfari and the Suttungr families) be ejecta from large impacts on Phoebe?
- Likely non-random correlations were found between the ranges to Saturn, the orbit directions, the orbit tilts, the object sizes, and the rotation periods. While there are reasonable hypotheses for some of these correlations, a compelling physical cause for size and spin relations to orbital elements is not known.

Saturn

- Does Saturn actually have a much stronger equatorial jet than Jupiter, or are estimates of Saturn's rotation period biased? If Saturn actually has a stronger jet, what makes the two planets different in this regard?
- What is the water abundance at depth on Saturn? If Saturn is wetter than Jupiter, why? Does the water abundance dictate the frequency of major convective storms? Why are giant storms preferentially observed at about the same latitude in both hemispheres?
- Does the sign of the mean meridional circulation at cloud level reverse in the upper troposphere? How does the circulation at cloud level relate to the circulation between cloud level and the water condensation level?
- To what extent do processes deep in Saturn's atmosphere versus processing operating above the water condensation level contribute to the dynamical behavior observed at cloud level? What process provides the energy that drives the eddies at cloud level?
- Why do the north and south poles of Saturn differ in their dynamical behavior?

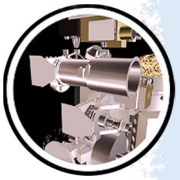


- What explains the lack of coherence between the latitudinal variation of Saturn's visible albedo and the jets at cloud level? Why do cloud features observed at deeper levels by VIMS look different from those observed by ISS at somewhat higher altitude?
- What constituent in Saturn's upper tropospheric haze explains the absence of a near-IR ammonia feature?

Why do cloud features observed at deeper levels by VIMS look different from those observed by ISS at somewhat higher altitude?

Rings

- What causes the C-ring plateaus and sharp optical-depth jumps within the B-ring?
- Are all of the irregular structures in the high optical depth regions of the A-ring and B-ring caused by overstabilities?
- Why are the inner edges of the A-ring and B-ring, and the edges of the C-ring plateaus, sharp only in optical depth, while their mass density profiles are much more gradual?
- What causes the red color of the A-ring and B-ring, and its dramatic increase inwards across the B-ring?
- Why do different ring textures appear in sharp-edged belts that are adjacent to each other? What do these textures tell us about ring particle properties?
- What is the velocity distribution of ring impact ejecta? How does it vary across the radial extent of the rings? How does ballistic transport sculpt the structural and compositional character of the rings?
- What are the kronoseismology waves in the rings telling us about the structure and history of Saturn's interior?
- Are there cyclic, self-limiting processes of growth and disruption of small planetesimal-sized objects, especially in the outer A-ring and F-ring?
- What is the mass of the F-ring?
- Why does the F-ring precess uniformly despite all the local variability? (Collisions? Self-gravity?)
- Is the F-ring in a stable, long-term location or will it eventually dissipate?
- What is the origin and long-term fate of propeller moons? What do they teach us about astrophysical disks?
- Why do propellers have such complex photometry? What do these characteristics tell us about the particles and their properties?



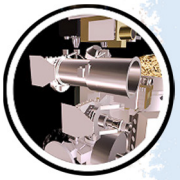
- How was Peggy formed—evolving propeller object or formed from streamline bunching due to 7:6 resonance?)
- What is Peggy's ultimate fate? Will it move inwards, or will it move outwards and escape?
- What forms the spokes?
- How old are the rings?
- How are small dust grains transported, confined and lost throughout the Saturn system?
- What controls the shape and brightness of narrow dusty ringlets within gaps in Saturn's rings?
- What controls the distribution and evolution of bright clumps in the Encke Gap ringlets? Why are such clumps rare in other narrow dusty ringlets?
- What determines the distribution of dust in the D-ring and Roche Division?
- How do the dusty rings respond to seasonal changes in solar radiation forces and magnetospheric asymmetries?
- How much do the dusty rings change over time?

ISS Non-Saturn Science Results

Jupiter Atmosphere and Rings

During a several-month approach to Jupiter, the ISS NAC captured the evolution of a large spot near latitude 65 degrees [Porco et al. 2003]. The lifetime of this UV Great Dark Spot is apparently a few months. A nearly-identical spot was seen in earlier Hubble near-UV images, but only once [West et al. 2004]. Initially the spot resides near System III longitude 180 degrees, coincident with the location Jupiter's deep thermal-IR auroral emission. Over the course of a few months repeated images from Cassini show that the spot morphs and shears, apparently from Jupiter's differential zonal flow field at high latitude. The spot is not visible at wavelengths longer than near-UV, and not seen in methane filters, indicated the absence of particles.

The Cassini ISS took images every ~2 hours as it approached Jupiter starting on October 1, 2000 [Porco et al. 2003]. The phase angle was 20° at the start and passed through 0° in mid-December. In this way, every point on the planet up to ±60° latitude was viewed in sunlight at least once per Jovian day, which is about 10 hours. The images at a given longitude could be played in sequence to make an ~70-day movie with a time step of 10 hours that showed the clouds in motion in Jupiter's atmosphere. This data set was an invaluable aid in measuring the winds, lightning, waves, clouds, turbulence, and discrete features, leading to a greater understanding of the planet's weather.



The colored cloud bands that circle Jupiter on lines of constant latitude are an obvious visible feature. The bands are accompanied by zonal winds—the eastward and westward jets that are strongest at the north and south boundaries of the bands. The winds are measured by tracking the positions of clouds in sequences of images, usually with a time step of ~10 hours. The jets are more stable than the cloud colors, and a comparison of jet speeds over the 20-year period from Voyager to Cassini shows almost no change [Porco et al. 2003].

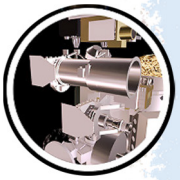
Comparison of data from Cassini, Voyager, and Hubble Space Telescope reveals small changes with a 4–5 year period near the equator [Simon-Miller and Gierasch 2010]. These oscillations are similar to the quasi-biennial oscillation in Earth's atmosphere. The high-speed jet at 24° N varied from 2000 to 2008 [Asay-Davis et al. 2011], but generally the zonal jets are remarkably stable.

Cassini ISS documented changes in the large ovals like the Great Red Spot and the Oval BA. The Red Spot, an anticyclonic vortex that has existed for at least 150 years, was found to be shrinking from 1996–2006 [Asay-Davis et al. 2009; Shetty and Marcus 2010]. The wind speeds in the Oval BA did not change in 2005–2006 when the cloud color became redder [Hueso et al. 2009]. The wind structure around Oval BA is ring-like, and the winds at the periphery strengthened from 1997 to 2007 [Choi et al. 2010; Sussman et al. 2010]. Lifetime is proportional to size. A study of 500 spots over the 70 days of the Cassini movie reveals lifetimes of 3.5 days for convective spots and 16.8 days for all other spots [Li et al. 2004].

Cassini ISS revealed important properties of wave clouds visible in Jupiter's atmosphere. The small-scale (300 km wavelength) gravity waves seen in Voyager and Galileo images were remarkably absent in the Cassini 70-day movie [Arregi et al. 2009]. A chevron-shaped pattern centered on a high-speed (140 m/s) jet at 7.5° S could be an inertia-gravity wave or a Rossby wave [Simon-Miller et al. 2012]. On a larger scale, the equatorial plumes and hot spots seem to form a wave that circles the planet at constant latitude [Li et al. 2006a; Choi et al. 2013]. Hot spots are holes in the clouds, and it is important to understand them if one is to properly interpret the Galileo probe results. Slowly varying westward propagating waves are likely to be Rossby waves, and these were observed in ISS images of the Polar Regions [Barrado-Izagirre et al. 2008].

Around closest approach, Cassini imaged Jupiter over a wide range of phase angles. Cassini ISS observed four clusters of lightning on the night side, where a cluster is a site that produces multiple lightning flashes. Cassini saw lightning flashes that were more than 10 times more powerful than any seen before on Jupiter [Dyudina et al. 2004]. Brightness versus phase angle revealed scattering properties, color, and number of chromophores of the clouds [Ordonez-Etxeberria et al. 2016]. Jupiter provided surface truth for use in interpreting exoplanet phase curves [Dyudina et al. 2016]. The phase angle dependence was useful in inferring vertical structure in Jupiter's clouds [Li et al. 2006b; Garcia-Melendo et al. 2011b; Sato et al. 2013; Dyudina et al. 2016].

> Cassini ISS confirmed a result from Voyager that the eddies, … , are accelerating the zonal jets … .



The high-resolution and dense coverage of the Cassini ISS images made possible a number of fundamental statistical studies of turbulence, eddies, and eddy mean flow interaction. Cassini ISS confirmed a result from Voyager that the eddies, which are transient structures ranging in size up to a few thousand km, are accelerating the zonal jets [Salyk et al. 2006]. Other processes, invisible to Cassini, must be decelerating the jets in order to maintain a steady state.

Other fundamental properties of the flow include the scale and power spectrum of the motions [Barrado-Izagirre et al. 2009, 2010; Choi and Showman 2011], for which one often uses brightness variations as a proxy for the wind itself. When the spatial resolution is good enough, as it is with Cassini ISS, one can use the derived velocity field to get the kinetic energy spectrum. The spectral slope implies an inverse cascade of kinetic energy from small scales to the scale of the zonal jets [Galperin et al. 2014; Young and Read 2017]. The velocity field derived from the Cassini movie was used to derive the transport barriers to horizontal mixing [Hadjighasem and Haller 2016].

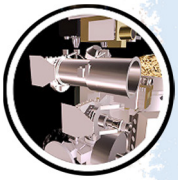
The basic dynamical features (the zonal wind profile versus latitude, the flow around the large ovals, and their time-dependent behavior) become the target quantities that numerical models try to reproduce. Thus the published zonal wind profiles from Voyager and Cassini were used to compute potential vorticity, which is an important dynamic quantity in modeling studies [Read et al. 2006]. Specific features of the flow within the Red Spot were matched with numerical models to solve for uncertain atmospheric parameters [Morales-Juberias and Dowling 2013]. Finally, the general features of the zonal jets were used to address the basic question of whether the flow is shallow or deep [Heimpel et al. 2005].

Cassini images of the Jovian main ring sampled a broad range of wavelengths and viewing geometries over a period of 37 days during the Jupiter flyby [Porco et al. 2003]. The ring's phase curve was found to be flat from low to medium phase angles.

The color of the Jupiter ring is indicative of the parent bodies' intrinsic color, and not an effect of scattering by small dust grains [Throop et al. 2004]. The main ring is composed of a combination of small grains with a normal optical depth of ~4.7×10^{-6}, and larger bodies of optical depth ~1.3×10^{-6}. The ring's flat phase curve between 1° and 130° confirms the irregular-sized, rather than spherical, particles.

Jupiter/Exoplanet Studies

Disk-integrated reflected light curves derived from Cassini images indicate that for gas giant exoplanets, an assumption that they behave as Lambertian scatterers will underestimate stellar absorption and thus equilibrium temperature of the atmosphere. Saturn-size rings can be confused for a larger planet size, but produce an asymmetry in the phase curve that may help to resolve the ambiguity [Dyudina et al. 2005, 2016].



Jupiter Satellites

Discovery of previously unseen ~400 km high plume over the north pole of Io. Joint Galileo imaging showed that the location of the vent was Tvashtar Catena [Porco et al. 2003].

Spatially resolved images of Europa in eclipse show that its visible aurorae are brightest around the limb, indicating an atmospheric rather than surface source [Porco et al. 2003].

First disk resolved imaging of a Jovian outer satellite. The measured size range of Himalia is four to six NAC pixels indicating that it is not spherically shaped. These values correspond to a diameter of 150 ±10 km × 120 ±5 km, if the principal axes (or diameters close to them) were measured. From this size, the surface albedo is calculated as 0.05 ±0.01 [Porco et al. 2003].

The fitted orbital parameters of the inner satellites Amalthea and Thebe confirm the relatively high inclinations of these satellites, equivalent to maximum vertical displacements from the equatorial plane consistent with current estimates of the half-thickness of the Amalthea and Thebe gossamer rings [Cooper et al. 2006]. This supports the conclusion that these satellites are sources of the ring material.

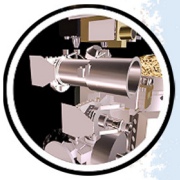
There are no undiscovered satellites between 2.6 R_J and 20 R_J with inclinations < 1.6°, eccentricities < 0.0002 and visual magnitudes (as seen from 40 million km) brighter than 14.5 [Porco et al. 2003].

Observations of auroral emissions in Io's atmosphere throughout the duration of eclipse indicate that the atmosphere must be substantially supported by volcanism [Geissler et al. 2004].

Open Questions for Non-Saturn Science

Jupiter's atmosphere

- Are the zonal winds shallow, or do they extend downward thousands of km along cylinders concentric with the rotation axis? This question applied immediately after Cassini's encounter with Jupiter in 2000. It may have been answered since then by Juno observations of Jupiter and Cassini observations of Saturn.
- What powers the eddies, given that the eddies seem to be powering the zonal jets? The possibilities are: horizontal gradients of temperature due to excess sunlight absorbed at the equator, and unstable vertical gradients due to internal heat from below.
- What limits the speed of Jupiter's zonal jets compared to the higher speeds of the zonal jets of the other giant planets?
- How does the Red Spot maintain itself against turbulent friction? Does it cannibalize smaller spots? Why is the Red Spot shrinking?



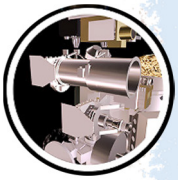
- What caused the three white ovals to merge into the single Oval BA after almost 60 years of separate existence?
- What generates the waves seen in the Jovian clouds? Can one feature act as an obstacle to the flow and generate lee waves? Can an energetic transient event generate waves radiating off to infinity? What role do breaking waves play in redistributing energy and momentum? The question applies to each wave type separately.
- What are the visible clouds made of, and what gives them their color?
- What does lightning tell us about the atmosphere below the cloud tops? Does lightning imply water, or could charge separation occur in the ammonia cloud?
- What do the numerical flow models tell us about the depth of the flow, the source of energy for the flow, and the processes that operate below the tops of the clouds?

Jupiter/exoplanet studies

- What do ISS measurements of disk-integrated polarization of Jupiter and Saturn tell us about what can be learned from exoplanet polarization measurements (cloud and haze particle properties)?
- What do ISS measurements of disk-integrated reflected flux from Jupiter and Saturn tell us about what can be learned from time-series measurements of flux from exoplanet flux (rotation rates, differential rotation)?
- What can ISS measurements of Jupiter and Saturn tell us about the amplitudes of flux and polarization variations for giant planets, providing insight for signal/noise estimates for exoplanet time-series measurements?

Jupiter's satellites

- What are the masses and densities of the small inner satellites Metis, Adrastea and Thebe?
- What are the rotational periods of the irregular satellites? So far, a reliable spin period is only available for Himalia. For the other 60 known irregulars, none has been published to date. An inventory is highly desired.
- Determine to good accuracy the sizes, albedos, colors, pole-axis orientations, object shapes, phase curves of the Jovian irregulars.
- What are the densities, composition and internal structure of the Jovian irregulars?
- Does Jupiter have binary or contact-binary satellites?



- For the Saturnian irregulars, likely non-random correlations were found between ranges to the planet, orbit tilts, object sizes, and rotation periods. Do the Jovian irregulars show something similar as well?
- Origin—are the irregulars former Jupiter Trojans, or do they come from the inner solar system, or the outer solar system? Was it the same source that also fed Saturn's irregular moon system?
- Origin—how many progenitor objects did Jupiter capture, and when? How massive were they? What is their collisional history?

Science Objectives and Traceability Matrices

Table ISS-1 is the Cassini Solstice Mission Science Objectives. Tables ISS-2 through ISS-6 are the Saturn, Rings, Magnetospheres, Icy Satellites, and Titan Cassini Solstice Mission detailed Traceability Matrices.

Cell codes for Table ISS-1 through Table ISS-6 are as follows:

- First letter = discipline (**S**aturn, **R**ings, **M**agnetospheric and Plasma Science (**M**APS), **I**cy Satellites, **T**itan)
- Second letter = objective type (**C**hange related or **N**ew question)
- Third number = priority level (**1**, **2**)
- Fourth letter = distinction within priority level (**a**, **b**, **c**, etc.)

Color key for Table ISS-1 through Table ISS-6 are as follows:

- Not an ISS objective
- Measurement objectives satisfied
- Measurement objectives partially satisfied
- Measurement objectives not satisfied

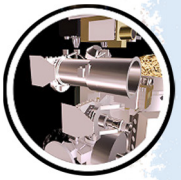


Table ISS-1. Cassini Solstice Mission Science Objectives—Prioritized Summary. Goal: Observe seasonal change in the Saturn system, to understand the underlying process and prepare for future missions.

Saturn	Rings	MAPS	Icy Satellites	Titan
Seasonal-Temporal Change				
Priority 1				
SC1a: Observe seasonal variation in temperature, clouds, and composition in three spatial dimensions.	**RC1a:** Determine the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near Solstice.	**MC1a:** Determine the temporal variability of Enceladus' plumes.	**IC1a:** Identify long-term secular and seasonal changes at Enceladus, through observations of the south polar region, jets, and plumes.	**TC1a:** Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport.
SC1b: Observe seasonal changes in the winds at all accessible altitudes coupled with simultaneous observations of clouds, temperatures, composition, and lightning.	**RC1b:** Determine the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations.	**MC1b:** Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.		**TC1b:** Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.
Priority 2				
SC2a: Observe the magnetosphere, ionosphere, and aurora as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.	**RC2a:** Focus on F-ring structure, and distribution of associated moonlets or clumps, as sparse observations show clumps, arcs, and possibly transient objects appearing and disappearing.	**MC2a:** Observe seasonal variation of Titan's ionosphere, from on Solstice to the next.		**TC2a:** Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.
New Questions				
Priority 1				
SN1a: Determine Saturn's rotation rate and internal structure despite the planet's unexpected high degree of axisymmetry.	**RN1a:** Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejects trapped on field lines.	**MN1a:** Determine the dynamics of Saturn's magnetotail.	**IN1a:** Determine the presence of an ocean at Enceladus as inferred from induces magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associate with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.	**TN1a:** Determine the types, composition, distribution, and ages, of surface units and materials, most notably lakes (i.e., filled versus dry and depth; liquid versus solid and composition; polar versus other latitudes and lake basin origin).

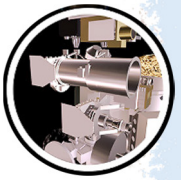

Table ISS-1. Cassini Solstice Mission Science Objectives—Prioritized Summary. Goal: Observe seasonal change in the Saturn system, to understand the underlying process and prepare for future missions.

Saturn	Rings	MAPS	Icy Satellites	Titan
SN1b: Observe the aftermath of the 2010–2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon.	**RN1b:** Determine the composition of the close-in ring moons as targets of opportunity.	**MN1b:** Conduct in situ and remote sensing studies of Saturn's ionosphere and inner radiation belt.	**IN1b:** Complete the comparative study of Saturn's mid-sized satellites, their geological and cratering histories, and interactions with the Saturn system, with remote sensing of Mimas at the highest resolution possible in order to understand the mechanisms behind its unique thermal properties discovered by Cassini.	**TN1b:** Determine internal and crustal structure: Liquid mantle, crustal mass distribution, rotational state of the surface with time, intrinsic and/or internal induced magnetic field.
SN1c: Measure the spatial and temporal variability of trace gases and isotopes.	**RN1c:** Determine structural and compositional variations at high-resolution across selected ring features of greatest interest, using remote and in situ observations.	**MN1c:** Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the SKR periods are imposed from close to the planet (3–5 R_S) out to the deep tail.	**IN1c:** Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.	**TN1c:** Measure aerosol and heavy molecule layers and properties.
		Priority 2		
SN2a: Monitor the planet for new storms and respond with new observations when the new storms occur.	**RN2a:** Conduct in-depth studies of ring microstructure such as self-gravity wakes, which permeate the rings.	**MN2a:** Determine the coupling between Saturn's rings and ionosphere.	**IN2a:** Determine whether there is ring material orbiting Rhea, and if so, what its spatial and particle size distribution is.	**TN2a:** Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission).
	RN2b: Perform focused studies of the evolution of newly discovered propeller objects.		**IN2b:** Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population.	**TN2b:** Determine icy shell topography and viscosity.
			IN2c: Determine the extent of differentiation and internal inhomogeneity within the icy satellites, especially Rhea and Dione.	**TN2c:** Determine the surface temperature distribution, cloud distribution, and tropospheric winds.

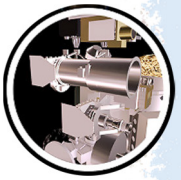

Table ISS-1. Cassini Solstice Mission Science Objectives—Prioritized Summary. Goal: Observe seasonal change in the Saturn system, to understand the underlying process and prepare for future missions.

Saturn	Rings	MAPS	Icy Satellites	Titan
			IN2d: Observe selected small satellites to quantify the movement of Enceladus material through the system, the history of satellite collisions/breakup, interaction with ring material as indicated by surface properties/ composition, and cratering rates deep in the Saturnian system.	

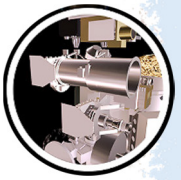

Table ISS-2. Cassini Solstice Mission Saturn Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
Seasonal-Temporal Change					
Priority 1					
SC1a - Observe seasonal variations in temperature, clouds, and composition in three spatial dimensions.	1. Investigate seasonal distribution of clouds.	1a. Observations at medium spatial resolution of visible-near-infrared cloud reflectivity, cloud-top altitude, and opacity. Full global daylit and nightside views (10.5 hrs continuous for each dayside and nightside observation) every ~6 months.	1a. VIMS (may be combinable with ISS designs).	1a. Dayside views: phase angle lower than 80 deg; distance between 12 and 20 R_S; Nightside views: phase angle greater than 120 degrees; Distance between 12 and 20 R_S. Polar views every ~6 months during high-inclination revs.	
		1b. Apoapse imaging every ~6 months in ~10 filters. May or may not be combined with part of 1a. Spread out over an orbit to get ~10 uniformly spaced phase angles from 0 to 165 degrees.	1b. ISS/WAC (may or may not be combined with VIMS/UVIS).	1b. Must be done over one almost complete rev to get phase angle coverage. Needs to be done in the range 20-40 R_S.	Phase angle coverage in the F-ring and proximal orbits was sparse due to close proximity to Saturn and fast sweep of phase angle near Periapse.
		1c. Apoapse high-res global map in true color (3 filters) every 2 years for public outreach, 10 hour observation.	1c. ISS/NAC (may or may not be combined with VIMS/UVIS).	1c. At < 90 deg phase angle (dayside). Distance of >30 R_S. From the equatorial plane.	
	2. Characterize seasonal distribution of aerosols.	2c. Observe the sunlight limb from pole to pole every ~6 months.	2c. ISS/NAC	2c. Spacecraft must be in eclipse.	
	4. Determine seasonal changes in the high latitude atmosphere, specifically the north and south polar vortices.	4b. Image both poles every ~6 months at start of Solstice Mission, only the north pole later in Solstice Mission.	4b. ISS (may be combined with other ORS instruments).	4b. Phase angles < 90 degrees. Need duration of ~5 hours for winds. Inclined orbits (i > 20 degrees is sufficient).	

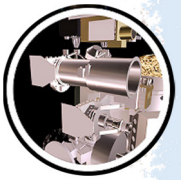

Table ISS-2. Cassini Solstice Mission Saturn Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
SC1b - Observe seasonal changes in the winds at all accessible altitudes coupled with simultaneous observations of clouds, temperatures, composition, and lightning.	1. Study the winds at high spatial resolution by observing the planet on successive rotations. Derive thermal winds from temperatures.	1a. Pairs of blocks (each of duration several hours): the second block should begin 11 hours after the first block begins. Cover each latitude every ~6 months.	1a. ISS Observation may be part of the VIMS/UVIS/CIRS template, e.g., 5-6-5 hour template.	1a. At < 100 deg phase angle, equatorial orbits, use 2-9-2 template if time is limited. Need ~8 repetitions to cover all latitudes (fewer than 8 at > 50 R_S).	Study of winds is best done at low phase angle. At high phase angle the contrast is too low. Too little time was available at low phase angle during the F-ring and Proximal orbits.
		1b. 5 µm observations of deep clouds. Pairs of blocks (each of duration several hours): the second block should begin 11 hours after the first block begins. Cover each latitude every ~6 months.	1b. VIMS; observation may be part of the ISS/UVIS template, e.g., 5-6-5 hour template.	1b. Distance between 3 and 15 R_S encompassing both 11 hour observation blocks.	
	3. Study seasonal change in convective storms and lightning.	3a. Night side visible images to see lightning, multiple short exposures to minimize scattered light. Cover each latitude every ~6 months.	3a. ISS; VIMS may ride along.	3a. Phase angle 90 to 130 degrees.	
		3c. Look for sudden appearance of convective storms. Day side imaging at Saturn waypoint. This is a monitoring activity. The idea is to have minimum impact on spacecraft operations.	3c. ISS.	3c. WAC in 1–3 filters whenever pointing at Saturn waypoint, range > 20 R_S, phase angle < 135 deg. Try to repeat every 2 hours, but whenever conflict arises, drop it.	
Priority 2					
SC2a - Observe the magnetosphere, ionosphere, and aurora as they change on all time scales - minutes to years - and are affected by seasonal and solar cycle forcing.	1. Investigate the northern and southern aurora using remote sensing.	1a. High spatial resolution imaging of visible aurora. An 80 hour movie every ~6 months plus ride-alongs.	1a. ISS rides along with UVIS/VIMS/CAPS auroral campaign.	1a. Phase angle > 90 degree (night side).	

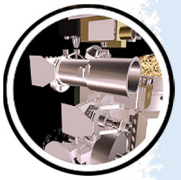

Table ISS-2. Cassini Solstice Mission Saturn Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
New Questions					
Priority 1					
SN1b - Observe the aftermath of the 2010-2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon.	1. Study Saturn atmospheric features (special features, defined by their latitudes) including the 2010–2011 northern storm region, the north polar vortex and hexagon, the ribbon, donuts, the string of pearls at 30 N, the QXO near the equator, the thunderstorm region at 35 S, and the eye region of the south polar vortex.	1a. High-resolution (few km/pix) visible observations of special latitudes. 11 hour repeat cycle to measure winds. Observe each feature every year.	1a. ISS may be combined with VIMS.	1a. At < 100 deg phase angle.	Study of winds is best done at low phase angle. At high phase angle the contrast is too low. Too little time was available at low phase angle during the F ring and Proximal orbits.
Priority 2					
SN2a - Monitor the planet for new storms and respond with new observations when the new storms occur.	1. Investigate recently active northern storm latitudes and storm alley at 35 S for new lightning storms and other phenomena.	1a. Visible imaging of both hemispheres: 2010–2011 active northern region and southern hemisphere and the "dragon storms" at ~35 S. Take 1–3 images every time the spacecraft is already pointed toward Saturn's center, up to once every 2 hours.	1a. ISS/WAC; VIMS may or may not ride along.	1a. Dayside only (phase angle < 90). ~3.5 Mbits/image.	

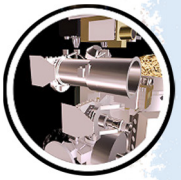

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
Seasonal-Temporal Change					
Priority 1					
RC1a -Determine the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near Solstice.	1. Determine seasonal variability of ring particle temperature.	1c. Measure ring particle albedo at visible-IR wavelengths as a function of radius using radial scans in inclined orbits throughout Solstice Mission.	1c. ISS, VIMS	1c. Take photometric measurements in 3 filters and VIMS plus clear at 5–10 phase angles and 3–5 ring opening angles (lit and unlit face). Distance from Saturn of around 20 R_S is acceptable.	In many or perhaps most cases, there was inadequate data volume to make all the images 12 bits, but this was not a serious problem because the SNR was high. In some cases, allocated time backed us off from 8 filters to maybe 7. But overall, the spirit of them was satisfied. Two of them (RN1b1a and RN1b2c) were more VIMS-emphasis.
	2. Investigate how spoke occurrence varies with season.	2a. Point and Stare observations pointed at a fixed position in the B-ring to look for spokes before they fade in ~2013. Long time baseline needed for accurate measurement of periodicity. 500 h of observation time is required for each of the three types of observations shown in the geometric constraints. (1500 h total.)	2a. ISS	2a. Observations must be performed before the spokes fade out as the ring plane opening angle to the Sun increases beyond 20.5 degrees (~late 2013). Observations must be performed for low phase (less than 50 degrees) lit face, high phase (greater than 100 degrees) lit face and high phase dark face. Spacecraft elevation angle must be greater than 3 degrees.	For the CSM, we were assigned about 1072 hours' worth of observing time, but only about 718 of those hours happened before the spokes faded out. So we roughly got half of the 1500 hours that we were looking for.
	3. Characterize seasonal variation of Saturn's E-ring structure.	3a. Edge-on images of both ansa of the E-ring every 1–2 years to measure changes in sun-driven warp of the rings.	3a. ISS/WAC	3a. Ring opening angle must be less than 0.1 degrees, and range must be greater than 20 R_S, greater than 30 R_S is preferred. There are no strong constraints on the phase angle for these observations. Low (< 30 degrees), high (> 120 degrees) and moderate (~90 degrees) are preferred.	

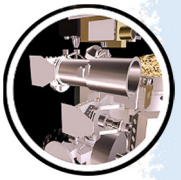

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
		3b. Imaging of all longitudes in the E-ring at high signal-to-noise in multiple filters every 2 years to measure changes in the spatial distribution of different sized particles.	3b. ISS/WAC	3b. Ideally performed while Cassini is in Saturn's Shadow and more than 10 R_S from the planet. Additional information can be obtained at phase angles between 130 and 145 degrees and ring elevations between 5 and 15 degrees.	We were able to observe all longitudes in 2012 and 2013, and a large fraction of longitudes in 2017 during eclipse periods. We did not have a similar opportunity in the 2014–2016 time frame.
	5. Determine ring microstructure, especially in the optically-thickest regions.	5d. Image rings at 50 meter resolution. One complete lit-face radial profile and one complete unlit-face radial profile are required.	5d. ISS	5d. Range must be less than 0.1 R_S, and spacecraft elevation angle must be greater than 10 degrees. Lit and unlit faces are desired.	Practically no images achieved the stated resolution, much less with full radial coverage. Regions of particular interest were imaged at 400 meter resolution, full coverage at 800 meter resolution.
		5f. Radial profiles of ring brightness of A-ring and B-ring, and Cassini Division over at least 6 longitudes at 3 or more tilt angles to measure amplitude of azimuthal asymmetry at radial resolution better than 5 km. Coverage of the C-ring is desirable, but not required.	5f. ISS	5f. Observations that cover A-rings, Cassini division and B-rings. Sampling is spacecraft relative and should occur over at least 6 longitudes at 3 or more tilt angles (> 20 degrees, 10–20 degrees, and < 20 degrees). Range must be less than 13 R_S, and phase angle must be less than 60 degrees to minimize Saturn-shine.	
	6. Characterize ring properties in geometries that are comparable to Voyager and Earth observations for purposes of cross comparison.	6c. Multi-color radial profiles of lit ring brightness in at least 5 broadband filters in the near-UV, visual wavelengths and near-IR that cover A-rings, Cassini division, B-rings and C-rings at 5 or more solar elevation angles.	6c. ISS	6c. Observations of the lit face of the rings at 5 or more solar elevation angles in the range 5-27 degrees to compare with HST and ground-based observations of the rings. Range must be less than 25 R_S. Phase angles should be as small as possible, preferably < 7 degrees, to allow direct comparison with ground-based data.	

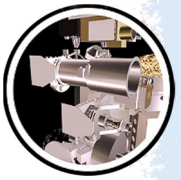

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
RC1b - Determine the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations.	1. Study Encke gap, other gaps and associated ringlets over long-time baseline.	1a. Ansa stare for one full orbital period in each of 5 zones at resolutions of better than 15 km/pixel: i) Inner C/D: Huygens, Russell and Herschel gaps; ii) Outer C/D: Laplace and Jeffreys gaps; iii) Outer C-ring: 1.470, 1.495 R_S gaps; iv) Maxwell gap; v) Columbo gap.	1a. ISS	1a. Phase angle must be less than 60 degrees. Prefer unlit rings, but observation can be performed on lit rings if necessary. Ranges must be between 15 and 40 R_S, and ring opening angles must be greater than 5 degrees.	
		1b. Image multiple longitudes in Laplace Gap, Huygens Gap, Maxwell Gap and D68 at resolutions of better than 15 km/pixel every 1–2 years to measure time evolution of eccentric and heliotropic features.	1b. ISS	1b. For Laplace Gap and D68, no strong constraints on phase angles (although higher phase has higher SNR). For Huygens and Maxwell Gaps, phase angles greater than 130 degrees are preferred. Ranges must be between 15 and 40 R_S and ring opening angles must be greater than 5 degrees.	
	2. Study the D-ring over long-time baseline.	2a. High-Resolution (3-5 km/NAC pixel) imaging of the outer part of the D-ring every year to measure time evolution of corrugation.	2a. ISS	2a. No strong constraints on phase angle. Range must be between 8 and 15 R_S. Both low (0.3–5 degree) and high (5–20 degree) ring opening angles are useful.	
		2b. 12-hour (1 Saturn Rotation) ansa movies of the D-ring between 71,500–74,500 km and the Roche Division between the A-ring and F-ring where a related pattern appears. Desire 2–3 movies of each region within a time span of 6–12 months every 2–3 years to measure structures in the rings tied to SKR.	2b. ISS	2b. Phase must be above 140 degrees. Ring opening angle must be above 5 degrees, and range must be between 15 and 40 R_S.	

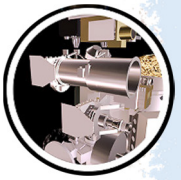

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
	3. Characterize the G and other narrow faint rings over long time baselines.	3a. Ansa movies of J/E-ring, G-ring, Pallene Ring, Anthe and Methone Rings every 1–2 years. Movies should be longer than 12 hours (1/3 rotation period) and include time when the appropriate moon moves through the ansa.	3a. ISS	3a. No strong constraints on phase angle. Range must be greater than 20 R_S, and ring opening angle must be less than 10 degrees.	For G-ring/ Pallene/Anthe/ Methone the goal was basically achieved, in that we have images around each of these moons with appropriate exposures for the arcs/rings. For the J/E-ring, we made a few attempts to image the relevant region, but it was not clearly visible outside of the HIPHASE/ eclipse periods. We therefore have more limited data on this, but we do have looks in 2013 and 2016/2017.
	4. Determine the temporal evolution of individual propeller.	4a. Scan the outer A-ring (from 133700-136700 km from Saturn Center) at all longitudes at least annually.	4a. ISS	4a. Range must be between 3.5 and 10 R_S. Sub-S/C latitude must be greater than 10 degrees. Observations must be at least 16–18 hours in duration. Observations need not be contiguous, but must be in the same periapse and configured such that all co-rotating longitudes can be sampled.	
		4b. Perform follow-up images of known propellers roughly twice monthly during RTWT segments.	4b. ISS	4b. Range must be less than 15 R_S. (Less than 23 R_S is acceptable for one of the known targets.) Sub-spacecraft latitude must be greater than 10 degrees. Duration of observations require at least 5 minutes (actual dwell time) per target. No connection with 4a is required.	For the J/E-ring, we made a few attempts to image the relevant region, but it was not clearly visible outside of the HIPHASE/ eclipse periods. We therefore have more limited data on this, but we do have looks in 2013 and 2016/2017.

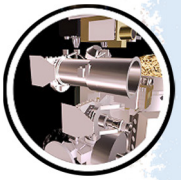

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
Priority 2					
RC2a - Focus on F-ring structure, and distribution of associated moonlets or clumps, as sparse observations show clumps, arcs, and possibly transient objects appearing and disappearing.	1. Study apse anti-alignment (F-ring/ Prometheus).	1a. Follow Prometheus for one orbital period (15 hours) twice per year, 4–6 times in all, to observe one complete cycle of streamer-channel feature raised in F-ring.	1a. ISS	1a. Range must be between 13 and 22 R_S. Spacecraft elevation angle must be greater than 15 degrees. Execute once early in IN1, the rest later.	
		1b. Ansa stare observations with a duration of 15 hours once per apoapse. Observe complete co-rotating 360 degrees of F-ring as material passes through the NAC field of view.	1b. ISS, VIMS	1b. Range must be less than 30 R_S, and spacecraft elevation angle must be greater than 15 degrees.	We had > 100 FMOVIE observations over the duration of the tour but only ~30 covered the full 360 degrees. Some of the FMOVIEs were intentionally split between ansae to highlight effect of eccentricity. It was impossible to make the "once per apoapse" requirement on every orbit.
	2. Search for and characterize new clumps/strands.	2a. Ansa stare observations with a duration of approximately 15 hours once per apoapse. Observe complete co-rotating 360 degrees of F-ring material as it passes through the NAC field of view.	2a. ISS, VIMS, CIRS	2a. Range must be less than 30 R_S, and spacecraft elevation angle must be greater than 15 degrees.	We had > 100 FMOVIE observations over the duration of the tour but only ~30 covered the full 360 degrees. Some of the FMOVIEs were intentionally split between ansae to highlight effect of eccentricity. It was impossible to make the "once per apoapse" requirement on every orbit.

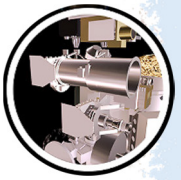

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
	3. Investigate clumps and moonlets on short timescales.	3a. Obtain high-resolution maps and movies on short time scales for clump and moonlet tracking purposes. Ansa stare observations with a duration of approximately 15 hours should occur once every 2–3 months. Observe F-ring material as it passes through the NAC field of view.	3a. ISS, VIMS	3a. Range must be less than 15 R_S for both instruments, and spacecraft elevation angle must be greater than 15 degrees. If possible, observations should also capture the A-ring edge into ~136000 km without impacting F-ring science in order to partially address RN1c(4a).	We did obtain partial high-resolution coverage but never for the full 360 degrees in this geometry (given the time constraints at peripase this would have been difficult) and never at a frequency of once every 2–3 months. Nevertheless, we did manage to observe and track moonlets.
New Questions					
Priority 1					
RN1b - Determine the composition of the close-in "ringmoons" as targets of opportunity.	1. Obtain spatially resolved spectral and color maps of ringmoons at UV, visual, and NIR wavelengths.	1a. 12-bit images in multiple filters. RED, GRN, BL1, UV3, IR3 and clear at a minimum. Observational opportunities are rare and will be taken as available.	1a. ISS, VIMS, UVIS, CIRS	1a. Phase angle at the satellite must be less than 90 degrees, and ranges must be less than 50,000 km. VIMS requires a minimum object diameter of 1 mrad in order to get at least one filled pixel on the moon. ISS demands are less restrictive. Target will depend on opportunity.	(RN1b1a and RN1b2c) were more VIMS-emphasis
	2. Characterize radial structure of rings at high-resolution.	2b. Two or more multi-filter (at least 8 filters, 12 bit) radial scans across ansa from 68000 km to 141000 km.	2b. ISS, UVIS rider	2b. Observe lit-side. Range must be less than 15 R_S. Elevation angle must be greater than 15 degrees. Phase angle must be less than 60 degrees.	

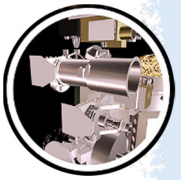

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
		2c. Radial scans of the entire main ring system during the proximal orbits, supplemented by observations of selected regions such as the outer C-ring and outer B-ring with targeted pointings and/or continuous drift scans. Resolutions better than 30 km/VIMS pixel desired. Require at least two full scans and at least two targeted observations. (RN1b1a and RN1b2c) were more VIMS-emphasis.	2c. VIMS, ISS rider	2c. Range less than 2-3 R_S to observation target and ring opening angles greater than 20 degrees. Lit side preferred. Only proximal orbits will provide these geometries.	
		2d. Radial scans of entire main ring system: 4 lit face and 4 unlit face, at multiple phase angles in at least 4 filters.	2d. ISS	2d. Range must be less than 20 R_S. At least 4 observations of the lit face *and* 4 observations of the unlit face are required, covering a range of phase angles.	
RN1c - Determine structural and compositional variations at high-resolution across selected ring features of greatest interest, using remote and in situ observations.	3. Study gap edges for azimuthal and temporal variations at varying scales and search for potential wakes produced by gap-embedded satellites.	3c. Map the edges of known empty gaps for one full orbital period at least once each.	3c. ISS	3c. Satisfied by requested surveys for undiscovered moonlets and for propellers. Both the lit and unlit sides are acceptable for mapping gap edges.	
		3d. Image Encke and Keeler Gaps at least three times at all available longitudes at 45 degree intervals in less than two hours to disentangle azimuthal and temporal effects.	3d. ISS	3d. Range must be less than 10 R_S, and spacecraft elevation angle must be greater than 15 degrees.	People freaked out about anything that sounded like an "azscan," so this was not done.

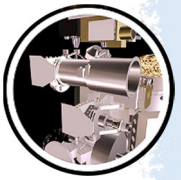

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
RN2a - Conduct in-depth studies of ring microstructure such as self-gravity wakes, which permeate the rings.	4. Study A-ring and B-ring outer edge modes to improve our understanding of them.	4a. Ansa-stare movies on the ring edges at least twice per year. B-ring requires at least 12 hours per observation, and A-ring requires at least 15 hours per observation. A minimum of 100 images is required for each movie.	4a. ISS	4a. Observe lit side. Elevation angle must be greater than 15 degrees, and phase angle must be less than 60 degrees. A-ring range must be less than 15 R_S. B-ring range must be less than 30 R_S.	
	1. Study self-gravity wakes and over stabilities in depth.	1c. Perform multi-filter lit face radial drift scan from 74,000 km to 141,000 km during the proximal phase of the tour. At least three scans are required.	1c. ISS	1c. Range less than 1 R_S. Lit face required.	
	2. Study "straw" and other packing effects.	2d. Perform multi-filter radial scans from 74,000 km to 141,000 km during the proximal phase of the tour. At least three scans are required.	2d. ISS	2d. Range less than 1 R_S. Lit and unlit face desired, but lit is preferred.	
Priority 2					
RN2b - Perform focused studies of the evolution of newly discovered "propeller" objects.	1. Investigate propeller structure and photometric properties.	1a. Perform focused studies to refine propeller structure and photometric properties at a range of sizes. Scan the "Propeller Belts" in the mid A-ring (from 127000–130000 km from Saturn center) at all longitudes, at least once. Observations must be at least 16–18 hours in duration.	1a. ISS	1a. Range must be between 3.5 and 10 R_S. Sub-spacecraft latitude must be greater than 10 degrees. Observations need not be contiguous, but must be in the same periapse and configured such that all co-rotating longitudes can be sampled.	
		1b. Obtain very-high-resolution images of propellers in the "Propeller Belts" of the mid A-ring. Use multiple color filters while keplerian tracking. Must target at least 3 different radii, at least once each.	1b. ISS	1b. Range must be less than 4 R_S. Sub-spacecraft latitude must be greater than 10 degrees. Observation length (dwell time) of at least 20 minutes per target location required.	Close-range imaging of the Propeller Belts was done, but color imaging proved impractical.

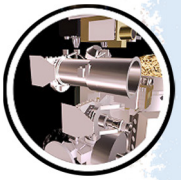

Table ISS-3. Cassini Solstice Mission Rings Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
		1c. Obtain very-high-resolution images of known large propellers in the outer A-ring. Use multiple color filters while keplerian tracking. Must target at least 3 known propellers once each.	1c. ISS	1c. Range to the known propeller's position must be less than 4 R_S. Sub-spacecraft latitude must be greater than 10 degrees. Observation length (dwell time) of at least 20 minutes per target required.	Targeted imaging of three propellers was done, but color imaging proved impractical.
		1d. Obtain lit and unlit face images at a range of phase angles and sub-spacecraft latitudes (as shown in the geometric constraints) of known large propellers in the outer A-ring. Use multiple color filters while keplerian tracking. Require at least one observation in each of the eight geometries described.	1d. ISS	1d. Range must be less than 7 R_S. Observe targets for at least 20 minutes when: 1) Sub-spacecraft latitude is between 10 and 20 degrees and phase angle is less than 30 degrees; 2) Sub-spacecraft latitude is between 10 and 20 degrees and phase angle is greater than 130 degrees; 3) Sub-spacecraft latitude is greater than 40 degrees and phase angle is less than 30 degrees; and 4) Sub-spacecraft latitude is greater than 40 degrees and phase angle is greater than 130 degrees. Both lit and unlit faces are desirable.	
		1e. Perform full azimuthal scans of the outer C-ring and Cassini Division, once each.	1e. ISS	1e. Satisfied by the constraints for RC1b(1a).	See RC1b(1a)

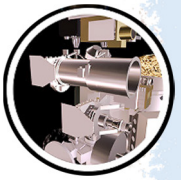

Table ISS-4. Cassini Solstice Mission Magnetospheres Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
New Questions					
Priority 1					
MN1b - Conduct in situ and remote sensing studies of Saturn's ionosphere and inner radiation belt.	1. Investigate the effects on aurora of solar wind and seasons.	1a. Sample auroral photon emission, ENA emission, SKR, solar wind conditions.	1a. HST, UVIS, VIMS and/or ISS auroral images; CAPS ions, electrons; MIMI INCA ENA; MAG, RPWS.	1a. In sheath or solar wind, -Y to Saturn aurora.	

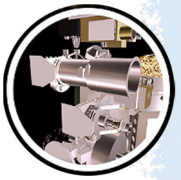

Table ISS-5. Cassini Solstice Mission Icy Satellites Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
Seasonal-Temporal Change					
Priority 1					
IC1a - Identify long-term secular and seasonal changes at Enceladus, through observations of the south polar region, jets, and plumes.	1. Understand seasonal changes in Enceladus' south polar region.	1c. Visible imaging of the south polar region illuminated by the sun or Saturn shine with 40 m or better resolution during at least 2 flybys.	1c. ISS	1c. Flybys with views of south pole; 2,000-7,000 km altitude.	As subsolar latitudes moved further north over time, secondary illumination was too poor for imaging surface details except near terminator. However, excellent coverage was obtained early during the CSM. Final high-resolution images of the active SPT region was not obtained in December 2015. However excellent imaging was obtained just outside of the south polar province.
	2. Understand seasonal changes in Enceladus' jets.	2a. High-resolution imaging of jets on temporal scales of at least every 2 months.	2a. ISS	2a. Observations at a range of viewing geometries, including latitudes and longitudes.	As subsolar latitudes moved further north over time, imaging of jets at the surface became problematic due to solar terminator geometry.
	3. Understand seasonal changes in Enceladus' plumes.	3c. Plume imaging, evenly spaced throughout Solstice mission, with observations at a minimum of every two months if possible.	3c. ISS	3c. Very high phase distant views, ideally with spacecraft in Saturn shadow (for plume "tendril" movies).	
		3d. Plume monitoring throughout Solstice mission, with observations at a minimum of every two months if possible.	3d. ISS	3d. Imaging from 60,000 km altitude, 140–165 deg phase, throughout tour.	
	4. Investigate effects on the inner mid-sized and small satellites due to interaction with the E-ring.	4a. Medium and high-resolution imaging and compositional mapping of satellites out to and including Rhea.	4a. ISS, VIMS, UVIS	4a. Medium and high-resolution flybys of leading/trailing hemispheres (1000-100,000 km) at least once per satellite.	

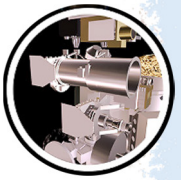

Table ISS-5. Cassini Solstice Mission Icy Satellites Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
New Questions					
Priority 1					
IN1a - Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.	3. Determine internal structure and any possible anomalies.	3b. Imaging to determine a more accurate shape model for Enceladus (to determine bulk density and regions of isostatic compensation) on at least 3 compensation) on at least 3.	3b. ISS	3b. Flybys in the 2000-50,000 km range with a range of viewing geometries as available from the mission design.	
	4. Determine mechanisms of activity using in situ observations and remote sensing.	4e. High-resolution (40 m or better in the visible, 0.5 km or better in the IR) imaging, compositional mapping and radiometry of south polar.	4e. ISS, VIMS, RADAR	4e. Flybys with views of south pole; 2,000-7,000 km altitude.	
		4f. Measure dust in plume using visible & IR imaging, every two months if possible.	4f. ISS, VIMS	4f. Long stares (1-2 hours) of plumes.	
IN1b - Complete the comparative study of Saturn's mid-sized satellites, their geological and cratering histories, and interactions with the Saturn system, with remote sensing of Mimas at the highest resolution possible in order to understand the mechanisms behind its unique thermal properties discovered by Cassini.	1. Investigate Mimas' geological and cratering history	1a. Imaging of both leading and trailing hemispheres to complete mapping coverage.	1a. ISS	1a. At least 4 flybys in the 100,000 km range.	

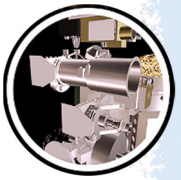

Table ISS-5. Cassini Solstice Mission Icy Satellites Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
IN1c - Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.	1. Investigate Dione's level of current activity.	1f. Seek forward scattered component in solar phase function during flybys by making high phase angle measurements.	1f. VIMS, ISS, UVIS	1f. Observations at large solar phase angles (150-165 degrees; the higher the better).	
		1g. Search for tenuous atmosphere using off-limb.	1g. VIMS, ISS, UVIS	1g. Long integration times off limb.	
	2. Investigate Dione's past geologic activity.	2a. Imaging surface to complete mapping coverage.	2a. ISS	2a. Medium and high-resolution mapping (3000-50,000 km).	
Priority 2					
IN2a - Determine whether there is ring material orbiting Rhea, and if so, what its spatial and particle size distribution is.	1. Investigate Rhea and its environment to search for a ring (or debris disk).	1a. High-resolution imaging of the surface to complete mapping coverage.	1a. ISS	1a. Flybys in 3000-50,000 km altitude range.	
IN2b - Determine whether Tethys contributes to the E ring and the magnetospheric ion and neutral population.	2. Investigate Tethys's level of current activity.	2d. High phase angle measurements to complete phase angle coverage & seek forward-scattered component to the solar phase curve.	2d. VIMS, ISS, UVIS	2d. Observations at large solar phase angles (150-165 degrees, the larger the better).	
	3. Investigate whether Tethys appears to be currently geologically active.	3b. High-resolution imaging of the surface to complete mapping coverage.	3b. ISS	3b. Flybys at 3000-150,000 km.	
	4e. Investigate whether Tethys has a tenuous atmosphere.	4a. Off-limb imaging of Tethys, at least once during Solstice.	4a. VIMS, UVIS, ISS	4a. Long integration time near limb.	
IN2c - Determine the extent of differentiation and internal inhomogeneity within the icy satellites, especially Rhea and Dione.	2. Determine a more detailed shape model for Rhea and Dione.	2a. Medium and high-resolution imaging of Rhea to complete coverage.	2a. ISS	2a. Flybys in the 3000-50,000 km range	
		2b. Medium and high-resolution imaging of Dione to complete coverage.	2b. ISS	2b. Flybys in the 3000-50,000 km range.	

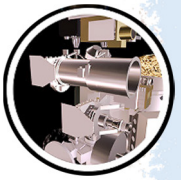

Table ISS-5. Cassini Solstice Mission Icy Satellites Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
IN2d - Observe selected small satellites to quantify the movement of Enceladus material through the system, the history of satellite collisions/ breakup, interaction with ring material as indicated by surface properties/compo sition, and cratering rates deep in the Saturnian system	1. Observe Epimetheus, Janus, Methone, Prometheus, and others as opportunities arise.	1a. Visible imaging of surface	1a. ISS	1a. Flybys in the 1000-100,000 km range over solar phase angles 0-120 degrees	Some close flyby images were not obtained due to ephemeris and/or pointing errors especially during very close flybys. This was especially true for close flybys of Helene (2008, 2010), Atlas (2015) and Daphnis (2016).

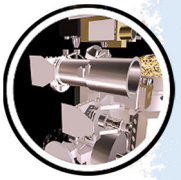

Table ISS-6. Cassini Solstice Mission Titan Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
Seasonal-Temporal Change					
Priority 1					
TC1a - Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport.	1. Determine the seasonal distribution of the lakes.	1c. Repeated, as allocated by TOST, medium resolution (≤ 10km/pixel), high-latitude (> 70° N and S; > 50° N for Kraken Mare) observations to look for changes (preferably close (in time) to RADAR observations for comparison and to provide context).	1c. ISS	1c. High latitude (> 70 N and S); > 50° N for Kraken Mare); resolution ≤ 10 km	Limited constraints on the rate of surface changes and extent of seasonal interaction between surface, atmosphere, and subsurface methane reservoirs due to later than predicted onset of summer weather at the north pole. Another question is what is the nature of the bright north-polar surface deposit and how does it relate to the lakes and seas?
	2. Determine the seasonal distribution of clouds.	2b. Repeated, ideally weekly, low-resolution (≤ 50 km/pixel) imaging throughout a seasonal cycle. Desire several opportunities/month throughout the Solstice Mission.	2b. ISS	2b. Phase angle < 120°; any longitude and any latitude—high northern latitudes (> 60°) preferred for development of summer clouds; pixel scale ≤ 50 km (range < 8.4e6 km)	Onset of north-polar cloud activity did not occur before EOM; timing of predicted seasonal weather pattern remains unknown. What causes differences from model predictions and how typical are the weather patterns we observed? What is the nature of the north-polar cloud features VIMS detected at 2.1 μm starting in June 2016 that were not visible at other wavelengths?

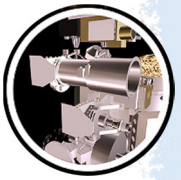

Table ISS-6. Cassini Solstice Mission Titan Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
	3. Characterize the seasonal distribution of aerosols.	3c. Repeated limb observations at various latitudes, and resolutions (few to several km) Desire several opportunities/year during distant/non-targeted encounters (or at distant times during targeted encounters) throughout Solstice Mission.	3c. ISS	3c. Variety of phase angles (0–180°) and latitudes (90° S to 90° N) desired	
TC1b - Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.	1. Study wintertime polar vortices.	1b. Repeated polar imaging throughout Solstice Mission at pixel scales of a few to several km. Desire a few opportunities per month throughout the Solstice Mission.	1b. ISS	1b. Latitude > |70°|; resolutions ≤ few to several km	
	2. Understand the tilted pole.	2b. Whole-disk imaging in methane bands, with a frequency of a few opportunities per month throughout the Solstice Mission.	2b. ISS	2b. Phase angles < 90°; latitudes > |60| deg	
New Questions					
Priority 1					
TN1a - Determine the types, composition, distribution, and ages of surface units and materials, most notably lakes (i.e. filled versus dry and depth; liquid versus solid and composition; polar versus other latitudes and lake basin origin).	1. Characterize lakes as liquid or dry and their composition.	1c. ISS context beyond the swaths. ISS/VIMS/RADAR comparisons, i.e. overlapping coverage, for interpretation beyond RADAR swaths/VIMS noodles. (As much ISS coverage overlapping RADAR and VIMS swaths as possible within TOST allocation.)	1c. ISS	1c. Previous RADAR/VIMS observations	Detailed compositions of different geologic surface units and interactions between materials on the surface and in the subsurface remain unknown. What is the bright north-polar surface unit? How does it relate to the lakes and seas? What are the implications of a lack of a comparable surface unit at the south pole?

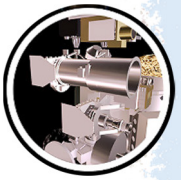

Table ISS-6. Cassini Solstice Mission Titan Traceability Matrix.

Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
	3. Study surface modifications due to geological activity. Determine the origin of depressions, Xanadu, fluvial features, and crypto-circles	3d. Repeated, as allocated by TOST, medium-high resolution (≤few km) observations throughout the Solstice Mission, especially at high latitudes. Most important to get some observations near equinox and some near northern summer solstice to extend the temporal baseline as long as possible	3d. ISS	3d. Phase < 90 deg; resolutions ≤ few km	Limited constraints on the rate of surface changes and extent of seasonal interaction between surface, atmosphere, and subsurface methane reservoirs due to later than predicted onset of summer weather at the north pole.
TN1c - Measure aerosol and heavy molecule layers and properties.	1. Characterize aerosol properties	1b. Repeated limb observations at various latitudes, and resolutions (few to several km). Desire several opportunities/ year during distant/non-targeted encounters (or at distant times during targeted encounters) throughout Solstice Mission.	1b. ISS	1b. Variety of phase angles (0–180°) and latitudes (90° S to 90° N) desired	
Priority 2					
TN2c - Determine the surface temperature distribution, cloud distribution, and tropospheric winds.	1. Study tropospheric cloud distribution	1a. Repeated (ideally weekly) low-resolution (≤ 50 km/pixel) imaging throughout a seasonal cycle. Desire several opportunities/month throughout the Solstice Mission.	1a. ISS	1a. Phase angle < 120°; any longitude and any latitude—high northern latitudes (> 60°) preferred for development of summer clouds; NAC pixel scale ≤ 50 km (range < 8.4e6 km)	Onset of north-polar cloud activity did not occur before EOM; timing of predicted seasonal weather pattern remains unknown. What causes differences from model predictions and how typical are the weather patterns we observed? What is the nature of the north-polar cloud features VIMS detected at 2.1 μm starting in June 2016 that were not visible at other wavelengths?

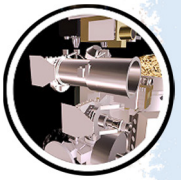

Table ISS-6. Cassini Solstice Mission Titan Traceability Matrix.

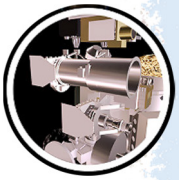
Science Objective	Science Investigation	Measurement	Instrument(s)	Geometric Contraint(s)	Science Investigation Achieved? If No, Explain Further. New/Open Questions.
	3. Infer surface and tropospheric winds	3b. Repeated medium-resolution (≤ few to several km/pixel) imaging over several hours; can be distant, e.g. non-targeted encounters (range < 1e6 km)—these are more opportunistic observations than tour/encounter drivers, with as many opportunities as are available throughout the Solstice Mission.	3b. ISS Cloud Tracking	3b. Phase angle < 120°; high northern latitudes (> 60°) preferred for development of summer clouds; resolutions ≤ few to several km (range < 1e6 km)	Onset of north-polar cloud activity did not occur before EOM; timing of predicted seasonal weather pattern remains unknown. What causes differences from model predictions and how typical are the weather patterns we observed? What is the nature of the north-polar cloud features VIMS detected at 2.1 µm starting in June 2016 that were not visible at other wavelengths?



ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

BIU	Bus Interface Unit
CAPS	Cassini Plasma Spectrometer
CCD	Change Coupled Device
CDS	Command & Data System
CER	Co-rotation-eccentricity Resonance
CIRS	Composite Infrared Spectrometer
CSM	Cassini Solstice Mission
DTM	Digital Terrain Model
EFC	Engineering Flight Computer
FOV	Field of View
GM	Gravitational Mass
ILR	Inner Lindblad Resonance
IR	Infrared
ISS	Imaging Science Subsystem
MAG	Magnetometer
MAPS	Magnetospheric and Plasma Science
MIMI	Magnetospheric Imaging Instrument
NAC	Narrow Angle Camera
RADAR	Titan Radar Mapper
SKR	Saturn Kilometric Radiation
SOI	Saturn orbit insertion
SPT	South Polar Terrain
TPW	True Polar Wander
USGS	United States Geological Survey
UV	Ultraviolet
UVIS	Ultraviolet Imaging Spectrometer
VIMS	Visual and Infrared Mapping Spectrometer
WAC	Wide Angle Camera

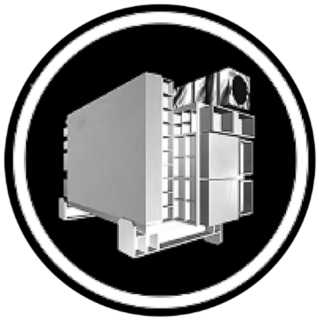
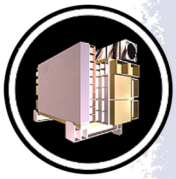
Ultraviolet Imaging Spectrograph



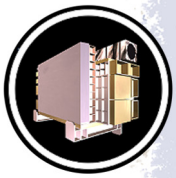
The Ultraviolet Imaging Spectrograph (UVIS) measured ultraviolet light (from 55.8 to 190 nanometers) invisible to the human eye from the Saturn system's atmospheres, rings, and surfaces. The **science objectives** of UVIS were to produce ultraviolet maps of Saturn's rings and many moons, to study the composition of atmospheres of the planet and its moon Titan, and also to look at how light from the Sun and the stars passed through atmospheres and rings in the Saturn system to determine their size characteristics and composition.

UVIS had two spectrographic channels: the extreme ultraviolet channel (EUV) and the far ultraviolet (FUV) channel, and also included a high-speed photometer (HSP) to perform stellar occultations, and a hydrogen-deuterium absorption cell (HDAC). The spectrograph could determine the atomic composition of those gases by splitting the light into its component wavelengths.



CONTENTS

Tables



Mission Objectives and Science Objectives and Results

The top ten discoveries from UVIS are listed here:

1. Enceladus icy jets spew 200 kg/sec of water, with no significant variations over the mission. The strongest jets are more variable, though.

2. Titan's airglow is primarily from sunlight and photoelectrons, but the weak night airglow is from magnetospheric particle impacts.

3. An atomic oxygen torus surrounds Saturn, peaking at its source, Enceladus.

4. The Europa atmosphere is dominated by atomic oxygen at low density, inconsistent with water plume activity at the time of the Cassini Jupiter flyby. The Enceladus plumes are significantly different from those found at Europa.

5. UVIS observations of propellers, gaps, ghosts, kittens, self-gravity wakes indicate ongoing aggregation in Saturn's rings; ring statistics, wavelet analysis, haloes, small particles show aggregation/disaggregation on an orbital time scale; we can understand this with an analogy to a predator-prey ecosystem.

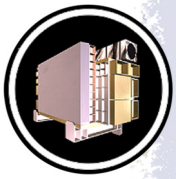
6. UVIS and Visual and Infrared Imaging Spectrometer (VIMS) comparisons find small particles in the outer A-ring, and other regions that are strongly perturbed by moon resonances.

7. The ultraviolet (UV) spectrum of Saturn's rings can be matched by pure water ice polluted over the age of the solar system by material having the reflectance of Comet 67P (as measured by Rosetta's Alice). Using Cassini results for the ring mass from Radio Science Subsystem (RSS) and the polluting flux from Cosmic Dust Analyzer (CDA), we constrain the ring age to less than about 200 million years.

8. A solitary wave is excited by the Janus-Epimetheus swap, when Janus moves inward every eight years. This is evidence for non-linear dynamics, and may limit the application of previous conclusions based on a linear theory.

9. UVIS star and solar occultations quantify the profiles of aerosols, nitriles and organics in Titan's atmosphere; and show that Saturn's thermosphere breathes in and out. It was 'in' at the Grand Finale.

10. UVIS sees the auroral footprint of Enceladus and also time varying arcs and spots that indicate magnetospheric variations. Bombarding charged particle radiation may explain the dark color of the polar hexagon.



KEY OBJECTIVES

The UVIS science objectives include determination of the composition, structure and processes in the atmospheres of Saturn and Titan, composition of neutrals in the Saturn magnetosphere, morphology and active processes in the Saturn aurora, icy satellite surface and exosphere properties, the deuterium-to-hydrogen ratio in the atmospheres of Saturn and Titan, and the structure, dynamics and history of Saturn's rings.

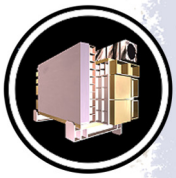
SCIENCE ASSESSMENT, WITH TABLES

UVIS met or exceeded all science objectives with the exception of those related to D/H, which was due to a failure of the HDAC oxygen cell.

UVIS AO Mission Science Objectives

The UVIS instrument is designed to produce spatial UV maps, map ring radial structure, and to determine hydrogen/deuterium ratios. Specific science objectives for the Cassini mission are as follows.

1. Saturn System Scans
    a. EUV and FUV low resolution spectra of magnetosphere neutral and ion emissions.
    b. System scans at every apoapsis.
2. Satellites
    a. Latitude, longitude, and phase coverage coordinated through Satellite Surfaces Working Group (SSWG).
    b. Distant stellar occultations to determine satellite orbits and Saturn reference frame.
3. Atmosphere
    a. Vertical profiles of H, H_2, hydrocarbons, temp in exo, thermosphere.
    b. Long integrations map of hydrocarbons, airglow.
    c. Map emissions with highest resolution at the limb.
    d. Auroral Map: H and H_2 emissions over several rotations.



4. Ring Stellar Occultation Objectives

    a. Highest Radial resolution (20 m) structure of rings

    b. Discovery and precise characterization of dynamical features generated by ring-satellite interactions.

        - Density waves and bending waves.
        - Edge waves and ring shepherding.
        - Embedded moonlets and discovery of new moons from dynamical response in rings.

    c. Discovery and precise characterization of azimuthal structure in rings.

        - Eccentric rings.
        - Density waves and edge waves.
        - Small-scale self-gravitational clumping in rings.

    d. Measure temporal variability in ring structure.

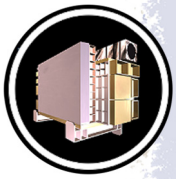
    e. Simultaneously measure UV reflectance spectrum of rings.

        - Determine microstructure on particle surfaces.
        - Compositional information on ring particles.

    f. Measure size distribution of large particles through occultation statistics.

    g. Measure dust abundance in diffraction aureole.

    h. Simultaneously search for flashes from 0.1 m–1.0 m meteoroid impacts.



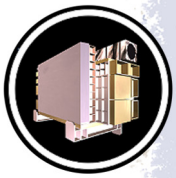
Science Assessment Table

This table is an Assessment of Data collected to satisfy an objective. It is not an assessment of the status of data analysis/publications.

Table UVIS-1. Assessment of data collected to satisfy an objective.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

UVIS Science Objectives	AO and TM Science Objectives	Science Assessment	Comments—if yellow (partially fulfilled)
1) Saturn System Scans			
EUV and FUV low resolution spectra of magnetosphere neutral and ion emissions.	S_AO4		
System scans at every apoapsis.	S_AO4, S_AO5, T_AO2, TN1c		Not every apo
2) Satellites			
Latitude, longitude and phase coverage coordinated through SSWG.	I_AO3		
Distant stellar occultations to determine satellite orbits and Saturn reference frame.			Not done
3) Atmosphere			
Vertical profiles of H, H2, hydrocarbons, temp in exo, thermosphere.	S_AO1		
Long integrations map of hydrocarbons, airglow.	S_AO1		
Map emissions with highest resolution at the limb.	S_AO1		
Auroral Map: H and H2 emissions over several rotations.	S_AO1		
4) Ring Stellar Occultation Objectives			
Highest Radial resolution (20 m) structure of rings.	R_AO1, R_AO3, R_AO4, RC1a, RC1b, RC2a, RN1c, RN2a, RN2b		
Discovery and precise characterization of dynamical features generated by ring-satellite interactions.	R_AO1, RC1a, b		
Density waves and bending waves.	R_AO1, RC1a, b		
Edge waves and ring shepherding.	R_AO1, RC1a, b		
Embedded moonlets and discovery of new moons from dynamical response in rings.	R_AO1, RC1a, b		
Discovery and precise characterization of azimuthal structure in rings.	R_AO1, RC1a, b		
Eccentric rings.	R_AO1, RN1c		
Measure temporal variability in ring structure.	R_AO1, RC1b		
Simultaneously measure UV reflectance structure.	R_AO1, R_AO2, RC1a		
Measure size distribution of large particles through occultation statistics.	R_AO1, R_AO2, RC1a		
Measure dust abundance in diffraction aureole.	R_AO2		
Simultaneously search for flashes from 0.1 m—1.0 m meteoroid impacts.	R_AO4		



SATURN SYSTEM RESULTS, INCLUDING SYNERGISTIC SCIENCE AND OPEN QUESTIONS

Saturn Atmosphere

Koskinen et al. [2015]; West et al. [2009]; Shemansky et al. [2012] give details of some of the UVIS results, which show the variability of Saturn's thermosphere; clouds and hazes in Saturn's atmosphere; and the structure of Saturn's upper atmosphere. Saturn's thermosphere was cooler at the time of the Grand Finale.

Titan Atmosphere

Solar and stellar occultations provide a probe of the Titan atmosphere [Shemansky et al. 2005]. Hazes [West et al. 2014] are created by photochemical processes [Liang et al. 2007a; Kammer et al. 2016]. The Titan airglow is primarily from sunlight and photo-electrons [Ajello et al. 2007, 2008b, 2012]. The weak nightside airglow is from magnetospheric particle impacts [Royer et al. 2017].

Saturn Magnetosphere

Contrary to pre-Cassini expectations, [Sittler et al. 2009], Saturn's magnetosphere is dominated by neutrals, unlike Jupiter [Shemansky et al. 2009; Melin et al. 2009]. This is the result of water vapor eruptions from Enceladus [Hansen et al. 2006].

Saturn Aurora

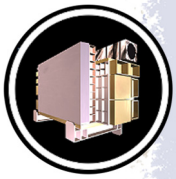
UVIS auroral observations have been correlated with those from Hubble Space Telescope (HST) [Gérard et al. 2005, 2013; Grodent et al. 2011, 2015; Gustin et al. 2010, 2012, 2013, 2017] to characterize the interactions with Saturn magnetosphere that give rise to these emissions [Radiotti et al. 2011, 2013a, 2013b, 2014a, 2014b, 2016a, 2016b, 2017a, 2017b].

Titan Airglow and Aurora

Stevens et al. [2011, 2015] and Lavvas et al. [2015] characterize the Titan airglow and compare the Nitrogen emissions to Earth's.

Icy Satellite Surfaces

The long Cassini mission provided full longitudinal and phase angle coverage of the icy satellites. The strong UV water absorption band is diagnostic of water ice, a major component of all the icy surfaces. This allows significant constraints on the surface composition and the processes that



control the evolution of their surfaces [Hendrix et al. 2008a, 2008b, 2010a, 2012, 2017, 2018a, 2018b; Royer et al. 2014].

Icy Satellite Atmospheres

UVIS used stellar occultations and remote sensing to search for thin atmospheres. This was spectacularly successful for Enceladus [Hansen et al. 2006], see section entitled Enceladus Plumes and Jets. Searches at Tethys, Rhea and Dione showed no detectable atmosphere [Hansen et al. 2018].

Enceladus Plumes and Jets

The search for an atmosphere around Enceladus was successful when a stellar occultation probed the region above the south pole [Hansen et al. 2006]. Subsequent stellar and solar occultations mapped the structure and variability of the Enceladus plume and jets [Hansen et al. 2008, 2011, 2017]. Enceladus eruptions are mostly water vapor, with a variable amount of ice grains [Hedman et al. 2018]. No significant variations in the amount of water vapor is seen over the course of the mission, although the strongest jets, which lift the most icy grains, are more variable [Hansen et al. 2017].

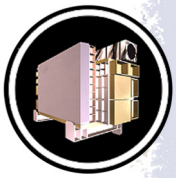
Saturn's Rings

UVIS star, sun occultations and remote sensing of UV reflectance provide clues to the structure and composition of Saturn's rings.

UVIS star, sun occultations and remote sensing of UV reflectance provide clues to the structure and composition of Saturn's rings. In turn, these results constrain the dynamics, history and origin of the rings, and parallels to other flattened systems, like proto-planetary disks. UVIS observations of propellers [Sremcevic et al. 2007], gaps, ghosts [Baillié et al. 2013], kittens [Esposito et al. 2008; Meinke et al. 2012], self-gravity wakes [Colwell et al. 2006, 2007] indicate ongoing aggregation in Saturn's rings; ring statistics [Colwell et al. 2017b], wavelet analysis [Esposito et al. 2012], haloes [Madhusudhanan et al. 2018], small particles [Colwell et al. 2009a, 2018b; Becker et al. 2016, 2018; Jerousek et al. 2016] show aggregation/disaggregation on an orbital time scale; we can understand this with an analogy to a predator-prey ecosystem [Esposito et al. 2012].

UVIS and VIMS comparisons find small particles in the outer A-ring, and other regions that are strongly perturbed by moon resonances [Colwell et al. 2018b].

The UV spectrum of Saturn's rings can be matched by pure water ice polluted over the age of the solar system by material having the reflectance of Comet 67P (as measured by Rosetta's



Alice). Using Cassini results for the ring mass from RSS and the polluting flux from CDA, we constrain the ring age to less than about 200 million years [Esposito 2018].

A solitary wave is excited by the Janus-Epimetheus swap, when Janus moves inward every eight years [Rehnberg et al. 2017]. This is evidence for non-linear dynamics, and may limit the application of previous conclusions based on a linear theory.

Key Open Questions

1. What is the mechanism that creates the Enceladus plume, giving rise to its stability over the Cassini mission and the variability of its individual jets? How does it re-supply the E-ring?

2. How do magnetospheric processes mediate Titan's airglow emissions?

3. How do the possible plumes on Europa compare to Enceladus?

4. What is the basic mechanism for creation of aggregates in Saturn's rings and their subsequent dis-aggregation? What does this say about planet formation?

5. What is the origin of Saturn's rings, consistent with Cassini data?

6. How do chemical processes in Titan's haze layers give them seasonal variability?

7. What is the cause of the variability of Saturn's thermosphere?

8. How do magnetospheric phenomena produce the Saturn auroral variations?

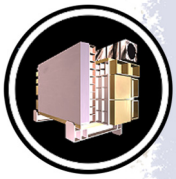
Non-Saturn Results, including heliosphere, Venus, Moon, and Jupiter system

Heliosphere

Background

IPHSurvey (Interplanetary Hydrogen Survey) data were taken by the Cassini UVIS instrument with the EUV, FUV, and HDAC instruments throughout the mission, generally when not looking at a planet or moon. The objectives were to:

1. Monitor interstellar hydrogen and helium and their brightness variations in response to changing solar illumination at the H Lyman-alpha 121.6 nm and He 58.4 nm lines, changing solar EUV photoionization, and changing solar wind flows. In the case of H,



solar wind charge exchange of protons with neutral H is a dominant loss process for slow interstellar H passing through the solar system.

2. Monitor changes in instrumental flat-fields and spectral response because the emissions are spatially extended and always available.

3. Obtain information on H, He, O and other gases that may be present in the Saturn system.

Additional detail on the IPHSurveys can be found in Chapter 11 of the Cassini UVIS Users Guide written by Wayne Pryor.

Operational lessons

There was intense competition for observation time throughout the mission, except during downlink periods when the Cassini spacecraft was pointed to Earth. For this reason, we requested IPHSurveys for most downlink periods, and were usually granted these requests. In some later orbits, additional IPHSurveys were requested in non-downlink periods.

IPHSurveys were usually at low data rates, such as 74 bits per second, or 76 bits per second, but proved adequate for our purposes. The HDAC instrument participated in these IPHSurveys, and has obtained partial maps of the sky at Lyman-alpha.

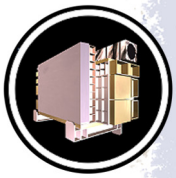
Careful attention to Lyman-alpha degradation is necessary before analyzing UVIS IPHSurvey FUV data. The standard calibration pipeline degradation corrections may not be adequate and future work to improve corrections is needed.

Science lessons

There is interest in the heliospheric community in future studies of the Cassini IPHSurvey data.

Interplanetary hydrogen has been extensively studied on other missions and is fairly well understood. Pryor et al. [2008] explored how varying solar brightness (27-day variations as seen from Earth) varied going from solar observations at Earth to observations of hydrogen at Cassini and on out to observations of hydrogen at Voyager. As discussed previously by Quemerais et al. [1996], the initial 27-day brightness wave becomes increasingly damped with distance in the outer heliosphere due to multiple scattering effects, constraining the still poorly-known absolute H density values.

There is interest in the heliospheric community in future studies of the Cassini IPHSurvey data. For example, mutual observations—e.g., Hall [1992] obtained by two spacecraft looking towards and away from each other are useful for determining their relative calibrations. Future proposers to data analysis programs should be aware that there is a tremendous amount of data



available obtained with varying geometries. H and He brightness data is available throughout the mission. We have recently applied interstellar wind He models developed for Mariner 10 [Ajello 1978] to Lunar Reconnaissance Orbiter (LRO) Lyman-Alpha Mapping Project (LAMP) heliospheric observations [Grava et al. 2018]; these models may be adapted for future Cassini studies. IPHSurvey Observations obtained near Saturn especially merit further study as they may contain magnetospheric H and O, as was found by Melin et al. [2009] in Cassini UVIS system scan observations.

Venus

Cassini observed the Venus airglow during the Cassini Venus flyby [Gérard et al. 2011a, 2011b]

Moon

Cassini observed the lunar reflectance during the Cassini Earth flyby [Hendrix 2005].

Jupiter System

UVIS observed the Io plasma torus for a period of six months surrounding the Cassini Jupiter flyby [Steffl et al. 2004a, 2006] showing radial and temporal variations that extend the Voyager and Galileo measurements.

Europa's oxygen atmosphere and torus were also characterized by these data [Hansen et al. 2004, 2005]. These results place an upper limit on eruptive activity on Europa at the time of the Cassini Jupiter flyby [Shemansky et al. 2014].

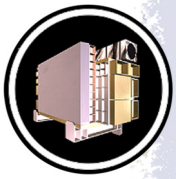
Key Open Questions for Non-Saturn Science

1. How do the different eruptive styles of Europa and Enceladus lead to the remarkably different effects in the Jovian and Saturnian magnetospheres?

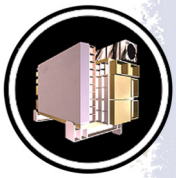
UVIS Investigations

Planned UVIS Science Investigations with Saturn AO and Solstice Mission Objectives

The UVIS instrument is designed to produce spatial UV maps, map ring radial structure, and determine hydrogen/deuterium ratios. Specific Announcement of Opportunity (AO) science objectives for the Cassini mission are:



1. Saturn System Scans
    a. EUV and FUV low resolution spectra of magnetosphere neutral and ion emissions.
    b. System scans at every apoapsis.
2. Satellites
    a. Latitude, longitude and phase coverage coordinated through SSWG.
    b. Distant stellar occultations to determine satellite orbits and Saturn reference frame.
3. Atmosphere
    a. Vertical profiles of H, H2, hydrocarbons, temp in exo, thermosphere.
    b. Long integrations map of hydrocarbons, airglow.
    c. Map emissions with highest resolution at the limb.
    d. Auroral Map: H and H2 emissions over several rotations.
4. Ring Stellar Occultation Objectives
    a. Highest Radial resolution (20 m) structure of rings
    b. Discovery and precise characterization of dynamical features generated by ring-satellite interactions.
        - Density waves and bending waves.
        - Edge waves and ring shepherding.
        - Embedded moonlets and discovery of new moons from dynamical response in rings.
    c. Discovery and precise characterization of azimuthal structure in rings.
        - Eccentric rings.
        - Density waves and edge waves.
        - Small-scale self-gravitational clumping in rings.
    d. Measure temporal variability in ring structure.
    e. Simultaneously measure UV reflectance spectrum of rings.



- Determine microstructure on particle surfaces.
- Compositional information on ring particles.

f. Measure size distribution of large particles through occultation statistics.

g. Measure dust abundance in diffraction aureole.

h. Simultaneously search for flashes from 0.1 m–1.0 m meteoroid impacts.

Implementation Challenges and Achievements

a. Distributed operations was a challenge, but gave the science team control.

b. Data limitations forced binning and windowing of the UVIS spectral images.

c. Evil pixels limited photometric accuracy and the spectral/spatial resolution.

d. UVIS calibration involved disparate approaches by different team members: Investigators used the approach most suited to their science.

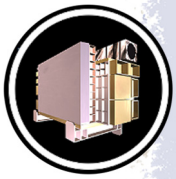
e. Loss of the near ultraviolet (NUV) channel during mission de-scoping limited science for Saturn and icy satellites.

f. New scientific discoveries motivated new observational strategies to address them: Tracking occultations, shorter occultation integration periods, Enceladus star and solar occultations, Dione, Tethys and Rhea plume searches.

g. The multiplicity of ring occultations allowed investigations and discoveries not expected from our original proposal: Self-gravity wakes, gaps and ghosts, kittens and clumps, solitary waves.

Summary and Suggestions

The broad capability of UVIS allowed us to address our prime objectives and many new science questions that arose during the long mission. We were able to corroborate and/or extend findings from other instruments by riding along whenever possible.



AO OBJECTIVES

Table UVIS-2 shows the prioritized summary of the Cassini Solstice Mission Science Objectives.

Table UVIS-2. Prime Mission AO Science Objectives.

Saturn	Rings	MAPS	Icy Satellites	Titan
		Cassini		
Determine temperature field, cloud properties, and composition of the atmosphere of Saturn.	Study configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.	Determine the configuration of the nearly axially symmetric magnetic field and its relation to the modulation of Saturn Kilometric Radiation (SKR).	Determine the general characteristics and geological histories of the satellites.	Determine abundance of atmospheric constituents (including any noble gases), establish isotope ratios for abundant elements, constrain scenarios of formation and evolution of Titan and its atmosphere.
Measure the global wind field, including wave and eddy components; observe synoptic cloud features and processes.	Map composition and size distribution of ring material.	Determine current systems, composition, sources, and sinks of magnetosphere charged particles.	Define the mechanisms of crustal and surface modifications, both external and internal.	Observe vertical and horizontal distributions of trace gases, search for more complex organic molecules, investigate energy sources for atmospheric chemistry, model the photochemistry of the stratosphere, study formation and composition of aerosols.
Infer the internal structure and rotation of the deep atmosphere.	Investigate interrelation of rings and satellites, including embedded satellites.	Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and rings.	Investigate the compositions and distributions of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles.	Measure winds and global temperatures; investigate cloud physics, general circulation, and seasonal effects in Titan's atmosphere; search for lightning discharges.
Study the diurnal variations and magnetic control of the ionosphere of Saturn.	Determine dust and meteoroid distribution both in the vicinity of the rings and in interplanetary space.	Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.	Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.	Determine the physical state, topography, and composition of the surface; infer the internal structure of the satellite.
Provide observational constraints (gas composition, isotope ratios, heat flux, …) on scenarios for the formation and evolution of Saturn.	Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.	Investigate interactions of Titan's atmosphere and exosphere with the surrounding plasma.		Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.
Investigate the sources and the morphology of Saturn lightning (Saturn Electrostatic Discharges (SED), lightning whistlers).				

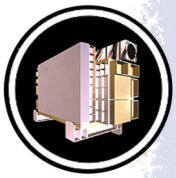


Table UVIS-2. Prime Mission AO Science Objectives.

Saturn	Rings	MAPS	Icy Satellites	Titan
		Huygens		
				Huygens: Determine abundances of atmospheric constituents (including any noble gases); establish isotope ratios for abundant elements; constrain scenarios of formation and evolution of Titan and its atmosphere.
				Huygens: Observe vertical and horizontal distribution of trace gases; search for more complex organic molecules; investigate energy sources for atmospheric chemistry; model the photochemistry of the stratosphere; study formation and composition of aerosols.
				Huygens: Measure winds and global temperatures; investigate cloud physics, general circulation and seasonal effects in Titan's atmosphere; search for lightning discharges.
				Huygens: Determine the physical state, topography and the composition of the surface; infer the internal structure of the satellite.
				Huygens: Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.

UVIS Traceability Matrix (TM)

Table UVIS-3 shows the prioritized summary of the Cassini Solstice Mission Science Objectives, and the goals to observe seasonal change in the Saturn system to understand the underlying process and prepare for future missions.

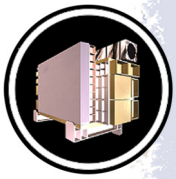

Table UVIS-3. Seasonal-Temporal Change and New Questions. Source: 2014 Senior Review Traceability Matrix (Table) + N2e (Hyperion) and IN2f (Iapetus) from 2010 Senior Review Traceability Matrix.

Saturn	Rings	MAPS	Icy Satellites	Titan
Seasonal-Temporal Change				
Priority 1				
SC1a: Observe seasonal variation in temperature, clouds, and composition in three spatial dimensions.	**RC1a:** Determine the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near Solstice.	**MC1a:** Determine the temporal variability of Enceladus' plumes.	**IC1a:** Identify long-term secular and seasonal changes at Enceladus, through observations of the south polar region, jets, and plumes.	**TC1a:** Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport.
SC1b: Observe seasonal changes in the winds at all accessible altitudes coupled with simultaneous observations of clouds, temperatures, composition, and lightning.	**RC1b:** Determine the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations.	**MC1b:** Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.		**TC1b:** Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.
Priority 2				
SC2a: Observe the magnetosphere, ionosphere, and aurora as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.	**RC2a:** Focus on F-ring structure, and distribution of associated moonlets or clumps, as sparse observations show clumps, arcs, and possibly transient objects appearing and disappearing.	**MC2a:** Observe seasonal variation of Titan's ionosphere, from on Solstice to the next.		**TC2a:** Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.
New Questions				
Priority 1				
SN1a: Determine Saturn's rotation rate and internal structure despite the planet's unexpected high degree of axisymmetry.	**RN1a:** Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejects trapped on field lines.	**MN1a:** Determine the dynamics of Saturn's magnetotail.	**IN1a:** Determine the presence of an ocean at Enceladus as inferred from induces magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associate with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.	**TN1a:** Determine the types, composition, distribution, and ages, of surface units and materials, most notably lakes (i.e., filled versus dry and depth; liquid versus solid and composition; polar versus other latitudes and lake basin origin).

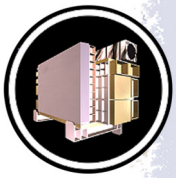

Table UVIS-3. Seasonal-Temporal Change and New Questions. Source: 2014 Senior Review Traceability Matrix (Table) + N2e (Hyperion) and IN2f (Iapetus) from 2010 Senior Review Traceability Matrix.

Saturn	Rings	MAPS	Icy Satellites	Titan
SN1b: Observe the aftermath of the 2010–2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon.	**RN1b:** Determine the composition of the close-in ring moons as targets of opportunity.	**MN1b:** Conduct in situ and remote sensing studies of Saturn's ionosphere and inner radiation belt.	**IN1b:** Complete the comparative study of Saturn's mid-sized satellites, their geological and cratering histories, and interactions with the Saturn system, with remote sensing of Mimas at the highest resolution possible in order to understand the mechanisms behind its unique thermal properties discovered by Cassini.	**TN1b:** Determine internal and crustal structure: Liquid mantle, crustal mass distribution, rotational state of the surface with time, intrinsic and/or internal induced magnetic field.
SN1c: Measure the spatial and temporal variability of trace gases and isotopes.	**RN1c:** Determine structural and compositional variations at high resolution across selected ring features of greatest interest, using remote and in situ observations.	**MN1c:** Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the SKR periods are imposed from close to the planet (3–5 R_S) out to the deep tail.	**IN1c:** Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.	**TN1c:** Measure aerosol and heavy molecule layers and properties.
Priority 2				
SN2a: Monitor the planet for new storms and respond with new observations when the new storms occur.	**RN2a:** Conduct in-depth studies of ring microstructure such as self-gravity wakes, which permeate the rings.	**MN2a:** Determine the coupling between Saturn's rings and ionosphere.	**IN2a:** Determine whether there is ring material orbiting Rhea, and if so, what its spatial and particle size distribution is.	**TN2a:** Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission).
	RN2b: Perform focused studies of the evolution of newly discovered propeller objects.		**IN2b:** Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population.	**TN2b:** Determine icy shell topography and viscosity.
			IN2c: Determine the extent of differentiation and internal inhomogeneity within the icy satellites, especially Rhea and Dione.	**TN2c:** Determine the surface temperature distribution, cloud distribution, and tropospheric winds.

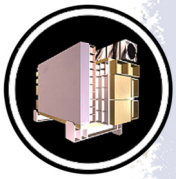

Table UVIS-3. Seasonal-Temporal Change and New Questions. Source: 2014 Senior Review Traceability Matrix (Table) + N2e (Hyperion) and IN2f (Iapetus) from 2010 Senior Review Traceability Matrix.

Saturn	Rings	MAPS	Icy Satellites	Titan
			IN2d: Observe selected small satellites to quantify the movement of Enceladus material through the system, the history of satellite collisions/breakup, interaction with ring material as indicated by surface properties/ composition, and cratering rates deep in the Saturnian system.	
			IN2e: Understand the unusual appearance of Hyperion with remote sensing observations of the highest resolution possible.	
			IN2f: Use remote sensing of Iapetus to test models for the albedo heterogeneity of the satellite. Quantify the effect of the newly-discovered Phoebe ring on the properties of Iapetus' surface.	

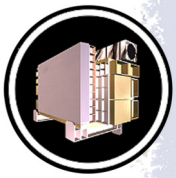
Cell Codes:

First Letter = Discipline (**S**aturn, **R**ings, **M**agnetospheric and Plasma Science (MAPS), **I**cy Satellites, **T**itan)

Second Letter = Objective Type (**C**hange related or **N**ew question)

Third number = Priority Level (**1**, **2**)

Fourth Letter = Distinction within Priority Level (**a**, **b**, **c**, etc.)



ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AO	Announcement of Opportunity
CDA	Cosmic Dust Analyzer
EUV	extreme ultraviolet channel
FUV	far ultraviolet channel
HDAC	hydrogen-deuterium absorption cell
HSP	high-speed photometer
HST	Hubble Space Telescope
LAMP	Lyman-Alpha Mapping Project
LRO	Lunar Reconnaissance Orbiter
MAPS	Magnetospheres and Plasma Science
NUV	near ultraviolet
RSS	Radio Science Subsystem
SED	Saturn Electrostatic Discharges
SKR	Saturn Kilometric Radiation
SSWG	Satellite Surfaces Working Group
TM	Traceability Matrix
UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph
VIMS	Visual and Infrared Imaging Spectrometer

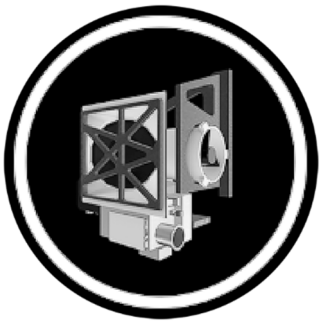
Visible and Infrared Mapping Spectrometer



The Visual and Infrared Mapping Spectrometer (VIMS) was a pair of imaging grating spectrometers that were designed to measure reflected and emitted visible and near-infrared light from atmospheres, rings and surfaces over wavelengths from 0.35 to 5.1 microns. The **science objectives** of VIMS were to determine the composition and structure of atmospheres, rings and surfaces in the Saturn system using visual and infrared spectral mapping. Of Cassini's instruments, VIMS was uniquely capable of simultaneously collecting both images and spectra of satellite surfaces, the rings, and the atmospheres of Saturn and Titan without having to scan to make images.

VIMS separated the light into its various wavelengths providing information about the composition of materials from the measured reflected or emitted light. The instrument had the capability to detect 352 different wavelengths of light, many of which are beyond the capability of the human eye to detect. Images could be created from light collected at the various VIMS wavelengths.

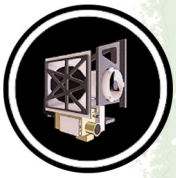
Instrument Description

The development, performance specifications and detailed design of the Cassini VIMS are well described in the literature and will not be repeated here. For detailed technical descriptions, the reader is referred to the refereed literature [Miller et al. 1996; Reininger et al. 1994; Brown et al. 2004] and Cassini project documents that describe the technical aspects of the VIMS instrument. For a complete discussion of the operational aspects of the Cassini VIMS the reader is directed to the VIMS User's Manual (JPL document D-14200).

> … the Team of people that eventually designed, built and used the VIMS instrument managed to extend the reach of the investigation well beyond what was envisioned by NASA … .

The VIMS instrument is an imaging spectrometer that is a composite of two channels: the VIMS visible (V) channel and the VIMS infrared (IR) channel. In its normal operating mode, the VIMS-V channel covers the wavelength region 0.35–1.05 μm in 96 spectral channels, with a spectral resolution of 0.0073 μm, an angular resolution of 0.5 microradians (mrad) and a 3.6 degree field of view. In its normal operating mode, the VIMS IR channel covers the wavelength region 0.85–5.1 μm in 256 channels at a spectral resolution of 0.0166 μm, an angular resolution of 0.5 mrad and a 3.6 degree field of view. The VIMS-V channel uses push-broom scanning to cover its 64 × 64 pixel field of view, while the IR instrument uses whisk-broom scanning to cover its 64 × 64 pixel field of view. The VIMS instrument is capable of a large range of operating modes, varying scan sizes and shapes, varying exposure times, and varying angular and spectral resolution, while incorporating a wide range of options for onboard processing of data such as spectral summing and spectral editing. For a detailed description of VIMS' various operating modes and parameters, the reader is again referred to the papers cited above. This document will focus on the scientific output of the VIMS investigation, and a few post-selection changes in the instrument and the investigation team that had a major effect on the scope and depth of the VIMS science investigation.

Several changes and developmental branches occurred during the designing and building of the VIMS instrument, and were not in the original specifications of the instrument as described in the Cassini Mission Announcement of Opportunity (AO), or in the original selection of the investigation team. Those changes, nevertheless, had dramatic and transformative effects on the science accomplished by the VIMS investigation. In essence, the Team of people that eventually designed, built and used the VIMS instrument managed to extend the reach of the investigation well beyond what was envisioned by NASA, the review panels that determined the original

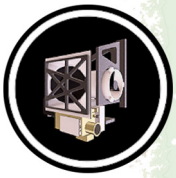


specifications of the instrument, its notional development budget, and the team of scientists originally chosen to use the instrument.

VIMS, as a facility instrument with its associated investigation team, was originally defined by several groups of people, most of whom had relevant expertise, but who would have no direct connection to the VIMS investigation, determination of its ultimate design and its development budget, or its overall scientific objectives. In addition, other individuals would judge the proposals submitted by scientists interested in becoming part of the VIMS science investigation team, and as such would determine to a great extent the depth and scope of the notional VIMS science investigation. Such an approach, though legitimate, necessarily cannot provide the deeply integrated vision and planning inherent in an instrument proposed by a principal investigator and a carefully picked team of associate scientists. Such teams have a more detailed and deeper understanding of the important scientific problems to be addressed, as well as the required specifications and capabilities of the instrumentation needed to achieve the science objectives, than that of a team and an instrument designed by committees. As such, though the committees that provided the initial input did as well as they could be given the constraints lain out by NASA, both the instrument configuration and the composition of the core VIMS science team changed significantly prior to and after Cassini's launch, reflecting the core team's vision of the scope and range of the eventual VIMS science investigation. As such, the VIMS investigation has far exceeded the scope and depth originally envisioned for it. For that, the entire team of scientists and engineers that have contributed to the development and use of VIMS on Cassini deserve a great amount of credit.

Changes to Hardware, Software and Personnel Post Announcement of Opportunity

There were several major changes made to the configuration of the VIMS instrument relative to that which was originally specified in the Cassini AO. The most significant of those changes were: i) incorporation of a separate channel to cover the visible spectral region from 0.35–1.05 microns; ii) incorporation of the ability to operate the VIMS instrument in a mode that resembled that of an occultation photometer; iii) the loss of the calibration plaque originally envisioned for the instrument, which drove the addition of a solar port to calibrate VIMS, along with the evolution of in-flight calibration strategies addressing that loss and the resulting capability to use the solar port to conduct solar-occultation studies of objects in the Saturn system; iv) the loss of Cassini's scan platform necessitating large changes in the operation plans envisioned for the entire package of remote-sensing instruments on Cassini; v) the addition of a second, orthogonal scanning direction for the VIMS secondary mirror, allowing for greater operational flexibility and scientific utility, specifically enabling collaborative studies with other remote sensing instruments having entrance slits; and vi) the use of H_3^+ emission measurements to study magnetospheric processes in the Saturn system. There were also several, minor changes to the flight software developed for the VIMS instrument, allowing for greater operational and scientific flexibility, among which were modes that allowed onboard processing of VIMS data such as data compression, spectral summing and spectral editing.



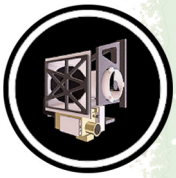
In addition to changes to both the hardware and software of the VIMS instrument relative to its AO configuration, after the original selections the VIMS core science team was embellished to better exploit the hardware and software changes. In particular, Dr. Phillip Nicholson was added to the team by NASA in response to a VIMS team request, specifically in the area of ring science and the use of occultation data to probe the structure and dynamics of Saturn's ring system. Dr. Alberto Adriani, Dr. Giancarlo Bellucci and Dr. Ezio Bussoletti were added to provide more expertise for scientific investigations using the VIMS-V channel. To enhance the expertise in the area of icy satellite surfaces, the VIMS team requested that Dr. Bonnie Buratti be added to the team. There have been other additions and subtractions to the VIMS core science team over the 29 years of its existence, but the aforementioned people were specifically added to expand the scope and depth of the VIMS investigation.

Another fundamental change in the scope of the VIMS investigation accrued from the realization that the lower atmosphere and surface of Titan could be imaged by VIMS. This opened up an entire sub discipline of the VIMS investigation concerning Titan geology, lakes, and methane cloud meteorology. The Titan sub-discipline grew explosively in the years following Cassini Saturn Orbit Insertion (SOI), eventually growing to become the largest of the VIMS sub-disciplines, both in number of investigators as well as production of scientific papers.

Stellar Occultation Mode

Were Cassini able to point its instruments at a specified celestial position (i.e., a star) with accuracy significantly better than 1 VIMS pixel, then occultation observations would be straightforward. In reality, however, the spacecraft's a priori pointing error was designed to be no worse than ~2 mrad, and in practice was approximately 1 mrad. It was thus impossible to predict in which VIMS pixel the stellar image would fall, though the uncertainty was at most 2–4 pixels. Fortunately, however, the spacecraft pointing was extremely stable once a new target was acquired, with typical pointing variations being only a few tens of narrow angle camera (NAC) pixels, or <<1 VIMS pixel. To solve the problem of initial targeting on board, the VIMS instrument was reprogrammed during cruise to first obtain a small image of the star 5–10 min before the predicted start of an occultation. Hardware constraints required this image to contain 64 pixels; in practice it was fixed at 16 × 4 pixels. The instrument's internal data compression software was then used to identify the brightest pixel in the scene (assumed to be the star of interest), and this was used to calculate the 2-D mirror offset necessary to place the star in the single pixel to be observed for the remainder of the occultation period. The star-finding cube was also returned to the ground, should it prove necessary to examine this later, as were the 2-D scanning mirror coordinates selected by the on-board star-finding software.

Although this simple procedure had its limitations, chiefly that it did not cope well with situations where the star fell more or less midway between two pixels, in practice it worked well in over 90% of the occultations we attempted. In only 4 cases out of 190 ring occultations did VIMS fail to acquire the star, or lose it after the initial acquisition, and in a further 11 cases (or 5% of the time) the occultation was recorded but the stellar signal was observed to be less than one-third of



the predicted level, suggesting that the stellar image was not in fact centered within the pixel selected by the onboard algorithm.

Because the addition of both the stellar and solar occultation modes was such a substantial contributor to the overall VIMS science legacy, we detail the observation statistics in Table VIMS-1.

Table VIMS-1. Stellar and solar occultation mode observation statistics.

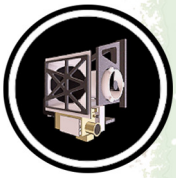
Type	Number tried	Successful	Failures	Comments
Ring stellar	190	182	8	~20 (10%) have poor SNR due to bad pointing
Saturn stellar	106	92	14	~10 (10%) have poor SNR due to bad pointing
Titan stellar	14	13	1	2 have poor SNR due to bad pointing
Ring solar	31	30	1	
Saturn solar	28	26	2	
Titan solar	16	12	1	3 were confused by bright limb in main port

A quick inspection of the above will reveal that VIMS attempted 310 stellar occultation measurements of Saturn, Saturn's rings and Titan, with only 23 failing to produce useful data. The remaining 287 produced data which was in general very high quality, resulting in 15 important scientific papers, and many new insights into the Saturn system. Those new insights ranged from atmospheric composition measurements for both Saturn and Titan, to studies of the structure and dynamics of Saturn's rings, to discovering features in Saturn's rings that resulted from gravitational perturbations driven by oscillations of Saturn's interior, thus allowing the VIMS team to virtually pioneer the field of space-based, observational Krono-seismology. In addition, VIMS attempted 75 solar occultation measurements of Saturn, Saturn's rings and Titan, all but four of which produced useful data, resulting in new insights into the composition and dynamics of those objects. It is useful to again note that the capabilities to conduct solar and stellar occultation measurements using VIMS were never envisioned by the committees that defined ether VIMS' notional design, or its complement of science team members. These capabilities, and the subsequent large contribution of scientific knowledge that resulted from their employ, were a huge bonus delivered to NASA by the talented people of the VIMS core science and engineering teams.

Impacts on the Scientific Community

As these efforts continue to grow over the next few years, the impact of the VIMS effort will continue to grow as well.

Further evidence of the seminality of the VIMS investigation is in the impact of its people and data on Planetary Science. At the time of writing, VIMS has had over 100 collaborators, postdocs and students associated with the investigation who are or have been participating in the analysis and publication of the data. Over 10 Ph.D. dissertations have made extensive use of the VIMS data, and there are at least four research groups studying Titan using VIMS data that have nucleated at the University of Idaho, M.I.T., Cornell, and The University of Paris around former students and postdocs who went on to become faculty at those institutions. As these efforts



continue to grow over the next few years, the impact of the VIMS effort will continue to grow as well.

In the following we summarize the most significant of the VIMS science results in each of the disciplines where VIMS made contributions; i.e., atmospheres, magnetospheres, icy satellites, rings and Titan. After the science summaries follow detailed descriptions of the important results in the disciplines mentioned above. This document will then conclude with a bibliography of publications that have resulted from both the use of VIMS data and VIMS science results in scientific research driven and inspired by Cassini.

Summary of the Main Scientific Contributions of VIMS

In the following, we summarize in a list the most important scientific accomplishments of the VIMS investigation, organized by discipline.

Atmospheres and magnetospheres

1. Study and characterization of discrete clouds, silhouetted by 5-μm thermal radiation from Saturn's interior, resulting in important new insights into Saturn's atmospheric structure and circulation.

2. Study and characterization of Saturn's north-polar hexagon using 5-μm illumination while Saturn's north pole was in total darkness.

3. Discovery and characterization of Saturn's north polar vortex.

4. First spectral identification of ammonia ice in Saturn's clouds.

5. Discovery of carbon soot as a component of Saturn's dark clouds, likely produced by lightning in Saturn's atmosphere.

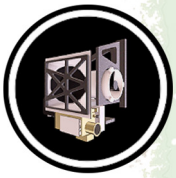
6. First detection of water ice in Saturn's clouds, from studies of the great storm of 2011–2012.

7. Determination of the abundance and spatial/temporal distribution of phosphine and arsine in Saturn's atmosphere.

8. Provision of additional constraints on Saturn's important He/H ratio.

9. Detailed mapping of the spatial and temporal character of Saturn's wind fields.

10. Discovery and characterization of Saturn's string of pearls storm system.



11. Extensive imaging of H_3^+ emission from Saturn's aurorae at the highest resolution ever resulting in new insights into Saturn's magnetospheric processes.

12. Discovery of a temperature asymmetry in Saturn's aurorae with the southern aurora being hotter than that of the north.

13. Elucidation of magnetospheric-ionospheric coupling in Saturn's aurorae.

14. First observations of surface emission features at sub-micron wavelengths on Venus.

15. Proved the existence of spectrally-identifiable ammonia and ammonium hydrosulfide ices in most zones and belts across Jupiter.

16. Provided new insights into the identity of the potential red chromophores responsible for the reddish tint of Jupiter and its Great Red Spot.

17. Discovery of a 3% asymmetry in Jupiter's thermal emission possibly due to hemispherical differences in the structure of Jupiter's interior.

Satellites

1. Discovery of widespread water on Earth's Moon at concentrations of 10 to 1000 parts per million, and locally higher.

2. Discovery of a surprisingly high opposition surge on Europa.

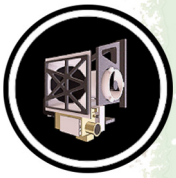
3. Discovery of a 3-μm feature in Himalia's spectrum of Jupiter's satellite Himalia, suggestive of the presence of water, either free, bound, or incorporated in layer-lattice silicates.

4. Provided the first near-IR phase curve of Europa, suggesting that neither coherent backscatter nor shadow hiding provide a complete description of Europa's opposition surge below 1°.

5. First spatially resolved spectra of Phoebe showing iron-bearing minerals, bound water, trapped CO_2, probable phyllosilicates, organics, and NH-bearing compounds, showing Phoebe to be one of the most compositionally diverse objects yet observed in our Solar System.

6. The recognition, through both chemical and isotopic composition measurements by VIMS, that Phoebe is very likely a captured object, probably from well beyond the orbit of Saturn.

7. The recognition that the water ice on the icy satellites is crystalline, rather than amorphous as had been thought.



8. The discovery that CO_2 is present on the surface of most of Saturn's icy moons, extensive mapping of the spatial distribution of that CO_2, and elucidation of its physical state, both bound and free.

9. Discovery of spectral absorptions attributed to the presence of aromatic hydrocarbons on Iapetus and Phoebe.

10. Tentative identification of trapped H_2 and ammonia on the surfaces of several of Saturn's icy satellites.

11. Discovery of Deuterium on Phoebe, Iapetus, Hyperion, Rhea, Dione, Enceladus and the Saturn's rings, and measurement of the associated D/H ratios.

12. Detection of ^{13}C on Phoebe and Iapetus.

13. Recognition that VIMS' measurements of high D/H and $^{13}C/^{12}C$ isotopic ratios imply that the materials comprising Phoebe's surface came from a different reservoir than that of the other icy satellites of Saturn, and its rings.

14. Discovery that the plumes of Enceladus vary in intensity with mean anomaly over short-timescales in VIMS data, with subsequent attribution to tidal stresses induced by variations in Enceladus' orbital distance from Saturn.

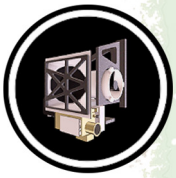
15. Derived a temperature of 197 ±20 K, and a linear size of 9 meters for one of the plume sources on Enceladus using VIMS observations at 5 μm.

16. Discovered that the particulate component of Enceladus' plumes consist primarily of fine-grained water ice, ejected at velocities of 80 and 160 m/s, with size distributions strongly depleted in particles with radii larger than 3 μm, and that only a small fraction of 3-μm particles can escape from Enceladus.

17. Particle sizes on Enceladus are correlated with geologic features and surface ages, suggesting a stratigraphic relationship between tectonic features and cryovolcanic activity.

18. Constructed daytime temperature maps of the icy satellite surfaces using temperature-dependent spectral changes observed by VIMS in the spectrum of water ice on their surfaces.

19. Discovery of nano-phase iron oxides and metallic iron together explain the varied color and ultraviolet (UV) absorber on Iapetus, Phoebe, and Hyperion. The metallic iron must be embedded in another material like a silicate, thus characteristic of space-weathered meteoric dust. The 3-μm absorber in the Iapetus dark material is only matched by hydrated iron oxides. The 1.9-micron bound water absorption in



spectra of the dark material is also a constraining absorption characteristic of hydrated iron oxides.

Saturn's rings

1. VIMS spectral observations at SOI revealed that the mysterious red coloring agent in the rings resides within the water ice grains that make up the regolith on the ring particles.

2. Observations of ring occultations of o Ceti (aka Mira) in 2005 confirmed the existence of strong self-gravity wakes in the A-ring, leading to the first reliable estimates for the ring thickness of ~6 meters in this region.

3. Observations of multiple stellar and radio occultations in 2005–2009 leading to the discovery that the amplitude of the radial perturbations at the outer edge of the B-ring (due to the Mimas 2:1 resonance) varies from ~70 km to < 5 km, and that these may also be indirectly responsible for the regular spacing of the multiple gaps within the Cassini Division.

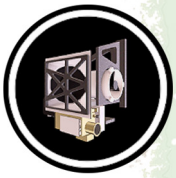
4. The observation of reststrahlen bands of H_2O ice in a stellar occultation by the F-ring permitted discrimination between clumps of macroscopic source bodies and the background of micron-sized dust.

5. A comparative analysis of visible-infrared (VIS-IR) spectral indicators (slopes and band depths) of rings, regular satellites and small moons has allowed VIMS to map the distribution of water ice and red contaminant materials across the Saturn system. However, in the main rings, the abundance of the red coloring agent is lower and there is at present no way to distinguish definitively between the nano-iron model and more traditional carbon-tholin models. Recent modeling results obtained with Hapke theory indicate that both intimate and intra-particle mixing of water ice, amorphous carbon and organic material (Titan tholins) can reproduce the observed ring spectra.

6. VIMS investigations of numerous small-scale wavelike structures in the C-ring have provided strong evidence that several of these are density waves driven by global oscillations within Saturn itself, opening up a new window on the planet's internal structure and rotation rate.

7. A pair of stellar occultations with turnaround radii in the inner A-ring yielded strong evidence for viscous over-stability in the denser parts of Saturn's rings, supporting previous work based on radio occultation data.

8. Together with occultation data from Radio Science Subsystem (RSS) and Ultraviolet Imaging Spectrograph (UVIS), VIMS data from more than 100 stellar occultations has led to the characterization of numerous non-circular features in the C-ring and



Cassini Division, including the discovery of a large number of normal mode oscillations on the edges of both narrow gaps and their associated ringlets.

9. Ring temperature maps have been built from VIMS spectra by using an indirect method based on the wavelength of the temperature-dependent reflectance peak at 3.6 μm.

10. Application of a new, phase-sensitive wavelet analysis technique to selected VIMS stellar occultation profiles has led to the identification of several satellite-driven density waves in the optically-thick B-ring, resulting in the first estimates of surface mass density in this most opaque part of Saturn's rings. The results are unexpectedly low, and imply a total mass for the rings of ~40 percent that of Mimas.

Titan

1. Observation and characterization of the first specular reflection from an extraterrestrial body of liquid.

2. Detection of liquid ethane in Ontario Lacus.

3. First observation and characterization of waves on Titanian lakes.

4. Discovery and characterization of cryovolcanic deposits near Hotei Regio and Tui Regio on Titan.

5. Discovery and characterization of evaporite deposits on Titan's surface.

6. Global mapping of Titan's surface composition.

7. Discovery of solid benzene on Titan.

8. Discovery of acetylene on Titan.

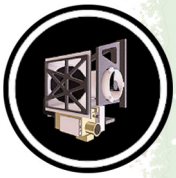
9. Mapping of the composition and distribution of material near or around Selk crater on Titan.

10. Discovery and characterization of dust storms on Titan.

11. Mapping, characterization and analysis of the global cloud distribution on Titan during the entire 13-year orbital tour.

12. Discovery and characterization of the extreme smoothness of Ontario Lacus during the early part of the Cassini orbital tour.

13. Discovery of CO nighttime emissions on Titan.



14. Discovery and characterization of precipitation-induced surface brightening seen on Titan.

15. Discovery of fog at the south pole of Titan.

16. Discovery of giant, infrared palimpsest on Titan's Xanadu region.

17. Observation and characterization of the shoreline of Ontario Lacus showing no changes over five years.

18. Discovery of ethane in Titan's rainfall.

19. Characterization of fluvial erosion and post-erosional processes on Titan.

20. Characterization of the evolution of Titan's north polar hood.

21. Evidence for tropical and temperate lakes on Titan.

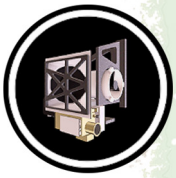
Details of the Most Significant Scientific Results

Jupiter's Atmosphere, Saturn's Atmosphere and Aurorae

Cloud properties

Upon arrival at Saturn, VIMS used its 5-μm thermal spectral imaging capability to quickly discover that discrete clouds lie below the traditional levels observed in reflected sunlight. Across the planet, localized clouds were observed in silhouette against the planet's indigenous background thermal radiation and found to reside near the 1.5-bar level [Baines et al. 2005, 2009b; Fletcher et al. 2011a], revealing that a different dynamical atmospheric regime resides below the visible cloud tops. Upon observing the north polar region during the first set of inclined orbits in 2006 under full nighttime polar winter conditions, these clouds allowed the north polar hexagon to be clearly imaged for the first time and revealed the existence of a classical polar vortex via the determination of the north polar windfield by VIMS 5 μm cloud-tracking [Baines et al. 2009b].

Ammonia ice was found by VIMS to be a spectrally-identifiable component of thunderstorm-related clouds in southern mid-latitudes, the first spectral identification of ammonia ice in Saturn [Baines et al. 2009a]. Neighboring clouds were found to be exceptionally dark over all visible and near-IR reflective wavelengths, consistent with carbon soot being a significant component of these features, as perhaps produced by lightning observed in the region by Radio and Plasma Wave Spectrometer (RPWS) [Baines et al. 2009a]. More recent modeling by Sromovsky et al. [2018] confirms the excellent spectral fits for both the bright spectrally-identifiable ammonia-ice clouds and the dark neighboring features. This paper also finds excellent fits for the dark clouds via relatively bright cloud models characterized by depressed cloud tops, although depressed cloud tops are



dynamically inconsistent with the anticyclonic nature of these features found by Imaging Science Subsystem (ISS).

Water ice was spectrally identified by VIMS in the cloud tops of the Great Storm of 2010–2011, the first identification of water ice on Saturn [Sromovsky et al. 2013]. The particle size, number density, and structure of the clouds in the nucleus of the Great Storm clouds were also determined from VIMS spectral imagery. The high cloud tops found (near 300 mbar) where the water ice is seen by VIMS implies that water is lofted over 150 km within this storm from its condensation level near the 20 bar level.

Composition

VIMS constrained the gaseous abundances of phosphine and arsine in Saturn's north polar region [Baines et al. 2009b], in the Great Storm of 2010–2011 [Fletcher et al. 2011b], and across the planet in various zonal structures [Fletcher et al. 2011a]. As noted above, VIMS also determined spectroscopically the presence of both ammonia and water ice in a variety of clouds. The He/H_2 ratio (important for understanding Saturn's internal heat) was constrained from VIMS 4– to 5-μm spectroscopy from a unique analysis of the unusually aerosol-free mid-northern-latitude band created in the aftermath of the Great Storm of 2010–2011, leveraging the effect of helium on the pressure/temperature gradient [Sromovsky et al. 2016].

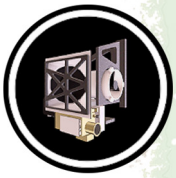
Global and regional wind fields

The zonal wind field was mapped globally over the planet from ~60 degrees north latitude to 30 degrees south latitude by Choi et al. [2009]. In the north polar region, the zonal winds were mapped under winter nighttime conditions from Cassini's highly-inclined orbit in 2006, revealing the presence of a classical polar vortex [Baines et al. 2009b]. As well, a similar vortex structure was mapped by VIMS for the south pole [Dyudina et al. 2009] observed under the daylit conditions of southern summer, confirming the simultaneously-measured ISS cloud-tracked results obtained at significantly higher spatial resolution.

Synoptic cloud features and processes

VIMS followed the enigmatic String of Pearls which it discovered (and named) for five years, until its demise with the eruption of the Great Storm in December 2010 [Del Genio et al. 2009; Baines et al. 2018]. This feature was likely a Vortex Street, perhaps stimulated by undetected upwellings from below that eventually erupted into the Great Storm of 2010–2011.

The aftermath of the Great Storm of 2010–2011 left an unexpectedly clear atmosphere over the ~10 degrees of latitude that had been occupied by the storm. With its 5-μm observing capabilities, VIMS followed the evolution of this region, quantifying its rate of recovery back to its pre-storm state [Sromovsky et al. 2016].



Auroral science

VIMS imaged Saturn's infrared aurora, emitted by the ionized molecule H_3^+, at unprecedented spatial and temporal resolution. New features were identified, including polar infilling for which no ultraviolet counterpart has yet been identified [Stallard et al. 2008]. Limb observations showed that the aurora peaks at ~1100 km altitude, similarly to the UV aurora, but has a narrower profile [Stallard et al. 2012a].

Observations of both hemispheres (not possible from Earth-based telescopes) revealed that the southern auroral oval was brighter than the north, implying a higher temperature [Badman et al. 2011b]. The southern temperature was estimated to be 440 ±50 K [Melin et al. 2011].

Comparison with UV observations showed that the infrared H_3^+ emission has a lifetime of ~500 s, and is morphologically identical to the UV H and H_2 emission only at the main auroral arc [Badman et al. 2011a; Melin et al. 2011, 2016].

Magnetosphere-ionosphere coupling was revealed in arcs conjugate with energetic ions and electrons [Badman et al. 2012a] and modulated by a rotating current system [Badman et al. 2012b; Lamy et al. 2013].

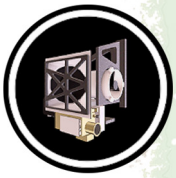
Venus science

During the Venus flyby in June 1999, the visual channel of VIMS was able to obtain the first observations of surface emission features at sub-micron wavelengths surface emission, proving the previously theorized existence of emissions at 0.85 and 0.90 μm [Baines et al. 2000]. This result extended the number of spectral windows useful for surface spectroscopy from 3 to 5 μm, expanding the useful surface-sensitive spectral range from 1.01 to 1.18 μm pre-VIMS/Cassini to 0.85–1.18 μm post-VIMS.

Jupiter science

During the Jupiter flyby of late 2000–early 2001, VIMS 0.35– to 5.1-μm spectral maps of the planet obtained at higher spatial resolution than available heretofore resulted in proving the existence of spectrally-identifiable ammonia and ammonium hydrosulfide ices in most zones and belts across the planet [Sromovsky et al. 2010]. Visual spectral imagery in the 0.35– to 0.6-μm range proved particularly useful for modeling the potential red chromophores responsible for the reddish tint of the planet [Sromovsky et al. 2017]. Spectral fits were particularly fine in the core of the Great Red Spot [Baines et al. 2019], providing significant clues to the centuries-long mystery of why the Great Red Spot is red.

Jupiter's emitted power was evaluated over latitude from a combination of VIMS and Composite Infrared Spectrometer (CIRS) and observations [Li et al. 2012]. The analysis found a north/south hemispherical difference of a 3% in emitted power, with the northern hemisphere being warmer. This is despite the low obliquity of the planet that theoretically prevents



seasonal/hemispherical variations. The cause may then be due to hemispherical differences in the structure of Jupiter's thermally-emitting interior.

VIMS observed the night-side auroral emission with a peak at the equatorward edge of the main emission attributed to enhanced H_3^+ density, but very little emission, and hence particle precipitation, at the equator [Stallard et al. 2015].

Some open questions

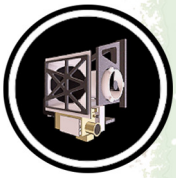
1. What is the helium abundance on Saturn? The answer may still rest in the proper interpretation of the joint VIMS/CIRS data sets, but perhaps by better joint observational scenarios by future VIMS occultation and mid-IR thermal mapping instruments on a future mission are needed (or, finally, measured directly by an in situ atmospheric probe).

2. What, exactly, occurs in the initial development of major storms on Saturn? VIMS-like studies of the development of a major storm (particularly the composition of condensates seen in the early stages) would be able to determine more accurately what the energetics are in lofting materials from 100s of km down. Continued studies would then be able better constrain the energetics throughout the lifetime of a storm.

3. More studies are needed of smaller storms in the mid-southern-latitude storm alley, in particular, looking for and characterizing the dark carbon soot observed in storms in this region. VIMS had just one amazing set of images that revealed these, but that then limited us to just one set of lighting and viewing angles. Had we had some views of the these features near the limb or at a different phase angle we could have distinguished better between different scenarios of just how much of what we were seeing was actually due to soot vs unexpected but perhaps large depressions in both cloud tops and cloud thinning.

4. The String of Pearls. How often and why do such features appear? Like the Hexagon, this was a very strange phenomenon unseen on any other planet. The huge storm of 2010–2011, which actually erupted amongst the Pearls, obliterated it. Were these connected? Was the String of Pearls a harbinger of the Great Storm (somewhat like earthquakes can be a harbinger of volcanic eruptions).

5. The polar hexagon. What is its lifetime/variability? The very large shear in the winds rising from a more typical 10–20 m/s to over 125 m/s in just a few degrees of latitude, and then back down again to 10–20 m/s on the other side of the hexagon, is still perplexing. Why does not it diffuse away? Something is organizing it which is still very poorly understood. In addition, the whole north polar region seems to have some seasonal variability in its upper atmosphere aerosol coloring which should be studied by a VIMS or ISS instrument (or both) on a future mission. It is possible that Hubble



Space Telescope (HST) and some ground-based telescopes will continue to observe this, but as Saturn tilts back to its northern fall season it will be problematic to view.

6. What is Saturn's bulk rotation rate (or perhaps set of rates, if there are actually different rates for various 10,000 km depth-scale regimes, as some folks are starting to suggest)? The new Krono-seismology technique that Matt Hedman and Phil Nicholson have developed from VIMS observations may be a key contributor to answering this with future missions.

Icy Satellites and the Earth's Moon

Earth's moon

Clark [2009] wrote:

> *"Data from the Visual and Infrared Mapping Spectrometer (VIMS) on Cassini during its flyby of the Moon in 1999 show a broad absorption at 3 micrometers due to adsorbed water and near 2.8 μm attributed to hydroxyl in the sunlit surface on the Moon. The amounts of water indicated in the spectra depend on the type of mixing and the grain sizes in the rocks and soils but could be 10 to 1000 parts per million and locally higher. Water in the polar regions may be water that has migrated to the colder environments there. Trace hydroxyl is observed in the anorthositic highlands at lower latitudes."*

The discovery of widespread water on the Moon was evident in the data returned right after the Earth flyby, … .

See Figure VIMS-1 for image.

The discovery of widespread water on the Moon was evident in the data returned right after the Earth flyby, but calibration of the VIMS data was uncertain at that time. It was not until after Cassini orbit insertion at Saturn had the VIMS calibration been refined enough to be certain of the water signature. The VIMS results were later verified by the Moon Mineralogy Mapper on Chandrayan-1, and EPOXI on Deep Impact and the three instruments showed proof that the water signature was real, changing our understanding of the Moon.

Jupiter system

Brown et al. [2003] presented results from the Jupiter flyby. VIMS documented a surprisingly high opposition surge on Europa, the first visual-near-IR spectra of Himalia. Himalia has a slightly reddish spectrum, an apparent absorption near 3 μm, and a geometric albedo of 0.06 to 0.01 at 2.2 μm (assuming an 85 km radius). If the 3-μm feature in Himalia's spectrum is eventually confirmed, it would be suggestive of the presence of water in some form, either free, bound, or incorporated in layer-lattice silicates.

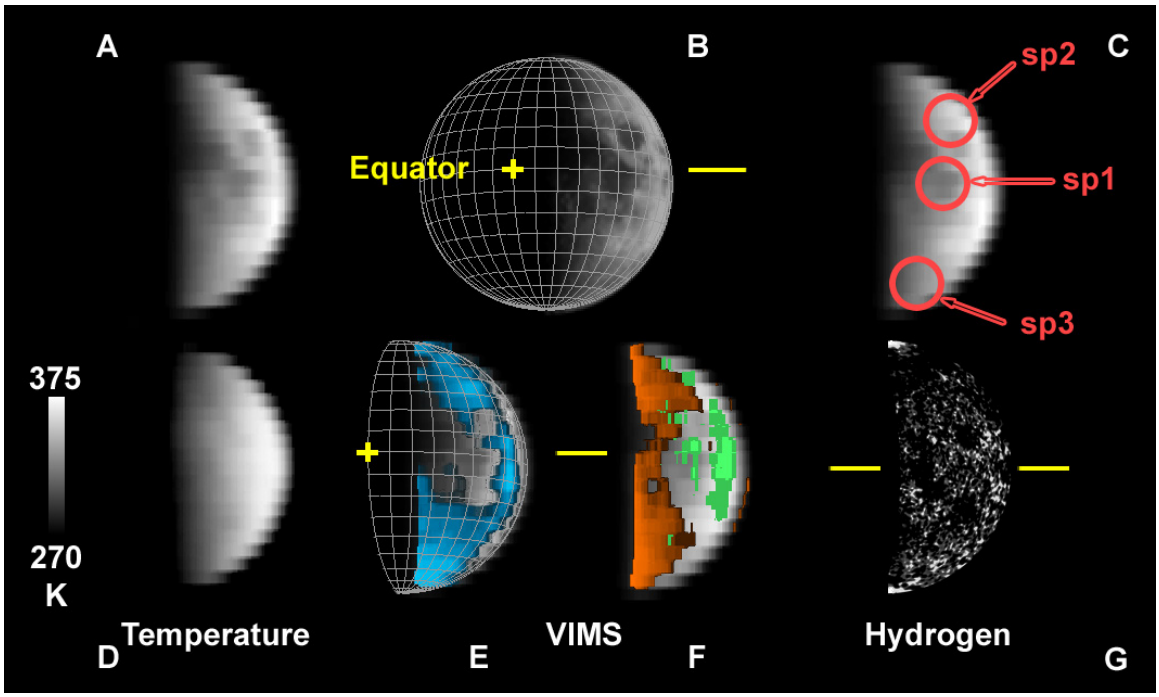


Figure VIMS-1. Cassini VIMS observations of the Moon on August 19, 1999. *A*: VIMS 2.4 µm apparent reflectance. *B*: Cassini Imaging Science Subsystem image obtained during the flyby. The yellow bars indicated the equator position. The yellow cross indicates latitude 0, longitude 0. *C*: Locations of VIMS spectra discussed in Clark [2009]. *D*: VIMS-derived temperatures. Maps of *E*: the 3 micron absorption strength (blue), and *F*: the 2.8 µm OH strength (orange and green). *G*: Hydrogen map from LP [Feldman et al. 2000] masked to give a similar view as the VIMS observation. Figure from Clark [2009].

VIMS spectra of the Galilean satellites confirmed the spectral features in the Near Infrared Mapping Spectrometer Subsystem (NIMS) data. Brown et al. [2003] also noted similar spectral structure as in NIMS data attributed to a CN bond near 4.5 µm. This structure was also seen in VIMS data of the Saturnian satellites—for example, Clark et al. [2005, 2008]—but as later found to be due to a calibration error [Clark et al. 2012]. VIMS data also provided the first near-IR phase curve of Europa. Europa exhibits a remarkable surge in brightness (~0.2 mag/deg) under 1°, comparable to the lunar opposition surge measured by Clementine [Buratti et al. 1996]. Furthermore, data at small phase angles show a clear trend with albedo, such that wavelengths corresponding to higher albedos have smaller surges, consistent with shadow illumination. The VIMS results suggest that neither CBE nor shadow hiding provide a complete description of Europa's opposition surge below 1° [Brown et al. 2003].

Saturn system

The first VIMS observations of the Saturnian satellites were of Phoebe on June 11, 2004, before Saturn orbit insertion [Clark et al. 2005]. VIMS spatially resolved the surface of Phoebe, and data have been registered and projected into simple cylindrical maps: low to medium resolution with near hemispheric coverage, and high resolution of a small area. Clark et al. [2005] mapped ferrous-

iron-bearing minerals, bound water, trapped CO_2, probable phyllosilicates, organics, nitriles and cyanide compounds. Detection of these compounds on Phoebe makes it one of the most compositionally diverse objects yet observed in our Solar System. It is likely that Phoebe's surface contains primitive materials from the outer Solar System, indicating a surface of cometary origin. Improved calibration [Clark et al. 2012] showed that the nitrile detection was due to an error in the calibration to reflectance. The ferrous-iron-bearing minerals was subsequently shown by Clark et al. [2012] to be nano-iron oxides plus nano-metallic iron (e.g., in space-weathered silicates) and scattering effects.

This nitrile identification error originated in the NIMS calibration and propagated into the VIMS calibration from cross instrument calibrations. A calibration target was descoped early in the mission, which led to the error. The diversity of targets and phase angles during the Cassini orbital tour led to continuing improvements in the VIMS calibration [Clark et al. 2016b, 2018]. Figure VIMS-2 shows the quality of spectra obtained using the new calibration.

We now know that the iron signatures in Phoebe's spectrum are due to a combination of nano-phase iron oxides and nano-metallic iron [Clark et al. 2012]. This is the same composition as the dark material on Iapetus (Figure VIMS-2). The 3-μm absorber was also identified as a definitive match by Clark et al. [2012] as a unique signature of hydrated nano-iron oxides (the water may be adsorbed water). The nano-phase metallic iron must be embedded in another matrix, e.g., silicates.

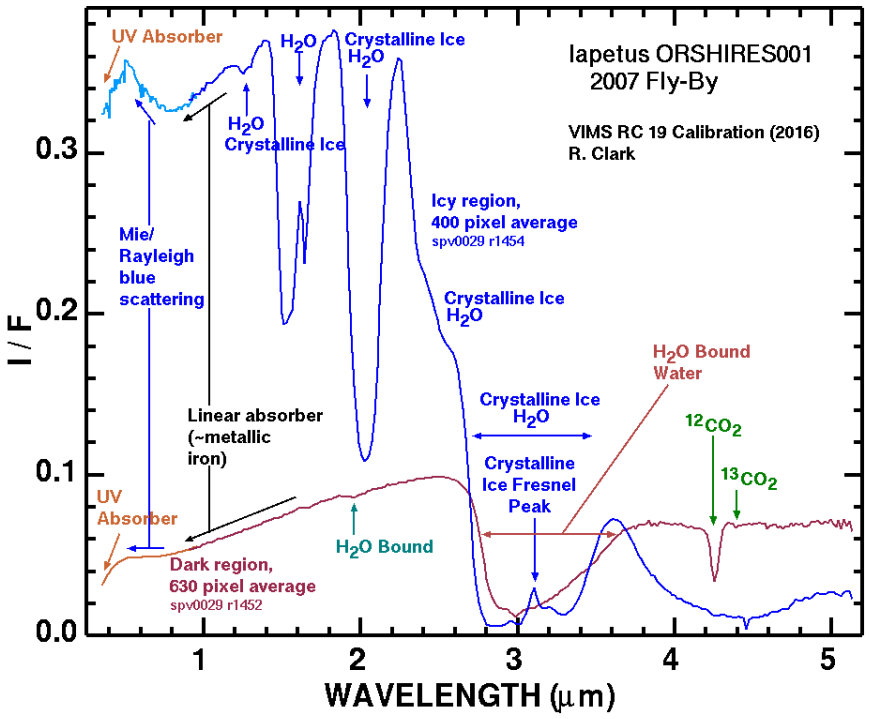

Figure VIMS-2. Illustration of VIMS spectra of two regions on Iapetus with causes of spectral features labeled. After Clark et al. [2012] with the RC 19 calibration [Clark et al. 2016b].

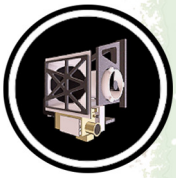

VIMS has shown that the water ice on the icy satellites is crystalline. While initial reports showed indications of amorphous ice, it was subsequently found that sub-micron ice grains modify the reflectance spectrum mimicking some aspects of amorphous ice signatures. Mastrapa et al. [2008] publication of crystalline and amorphous ice optical constants enabled better comparisons to observed spectra, and along with improved radiative transfer models that included diffraction effects of small particles [Clark et al. 2012], the differentiation between amorphous and crystalline ice could be made with more confidence. These results are summarized in Buratti et al. [2018a].

CO_2 is present on the surface of most of the moons [Buratti et al. 2005; Brown et al. 2006; Clark et al. 2005, 2008, 2012; Cruikshank et al. 2010 and references therein], but there are still spectral identifications that are uncertain. Clark et al. [2012] showed that a weak feature at 2.42 μm is due to trapped molecular hydrogen and is observed in dark material on multiple icy satellites, but this feature needs confirmation by an independent instrument. A weak absorption at 2.97 μm corresponds to ammonia [Clark et al. 2008, 2012] and is seen on multiple icy satellites, but the absorption overlaps an order-sorting filter gap in the VIMS instrument where instrument errors are larger. Observations of ammonia need confirmation either by a better calibration of the VIMS data, or by other instruments. Iapetus and Hyperion have many unidentified spectral bands in the 1- to 5-μm region [Cruikshank et al. 2007; Clark et al. 2012; Dalton et al. 2012] that may be the signature of higher order hydrocarbons, some of which have not been measured in the laboratory. Absorptions attributed to aromatic hydrocarbons have been detected in the spectrum of Iapetus and Phoebe [Cruikshank et al. 2008, 2014; Dalle Ore et al. 2012].

All of the icy Saturnian moons are absorbing in the ~0.2 to 0.5 μm region, making them dark at far ultraviolet channel (FUV) wavelengths. For instance, Filacchione et al. [2012, 2016] used Cassini VIMS data to show that the spectral slope (0.35–0.55 μm) increases (becomes redder) with distance from Enceladus. While the UV absorber causes reddening, sub-micron grains induce increased scattering, causing a bluing effect, so there are competing signatures of these two components throughout the Saturn system.

Deuterium has been found on Phoebe, Iapetus, Hyperion, Rhea, Dione, Enceladus and the Rings and carbon 13 has been detected on Phoebe and Iapetus (Figure VIMS-2) [Clark et al. 2018, 2017a, 2017b, 2016, 2012] and the D/H ratio derived. Phoebe is an outlier with D/H more than seven times higher than terrestrial, which the other satellites and rings are close to terrestrial ocean water values, an unexpected result not predicted by current models of Solar System formation.

The plumes of Enceladus were observed by VIMS to vary in intensity with mean anomaly over short-timescales [Hedman et al. 2013a]. Results from the VIMS, which measured the short-wavelength end of the blackbody curve for the south pole of Enceladus, calculated a temperature of 197 ±20 K and a linear size of 9 meters [Goguen et al. 2013]. Further analysis of VIMS data will enable this result to be refined and will place limits on additional emitting regions. The amount and/or size of particles spewing from the fissures varies as a function of the orbital position of Enceladus, implicating tidal forces as the source of energy driving eruptive activity [Hedman et al. 2013a; Nimmo et al. 2014]. Hedman et al. [2009] analyzed VIMS plume spectra as a function of altitude to derive composition and grain sizes. These spectra show that the particulate component

of the plume consists primarily of fine-grained water ice. The spectral data are used to derive profiles of particle densities versus height, which are in turn converted into measurements of the velocity distribution of particles launched from the surface between 80 and 160 m/s (i.e., between one-third and two-thirds of the escape velocity). The size distributions show that the parts of the plume observed by VIMS are strongly depleted in particles with radii larger than 3 μm. Furthermore, the velocity distributions indicate that only a small fraction of 3-μm particles can escape from Enceladus.

One of the most intriguing results of the mission was the discovery of global red streaks on Tethys and blue pearls on Rhea that do not appear to be connected to any underlying geologic structures [Schenk et al. 2011, 2015] VIMS analysis of the streaks on Tethys shows a clear spectral difference [Buratti et al. 2017], but it is not clear whether this difference is caused by composition, such as an enhanced amount of organic material, magnetospheric effects, or simply grain size.

Another intriguing result was the detection on December 15, 2004, of a transient aura-like ring around Dione at 2.65 μm that suggested the existence of an atmosphere [Clark et al. 2008] (Figure VIMS-3). Magnetometer data obtained on October 11, 2005, show a weak field perturbation in the upstream region, indicating a tenuous atmosphere [Simon et al. 2011]. Observing with Cassini Plasma Spectrometer (CAPS), Tokar et al. [2012] discovered a thin atmosphere (~0.01-0.09 particles/cm^3) of O_2^+ during the close (500 km) flyby on April 7, 2010. A search for forward scattered radiation at solar phase angles >150°, indicating a plume, was negative [Buratti et al. 2011]. No clear evidence of ongoing activity on Dione was discovered during the mission, although more thorough inspection of the 2.65-μm band is an ongoing task.

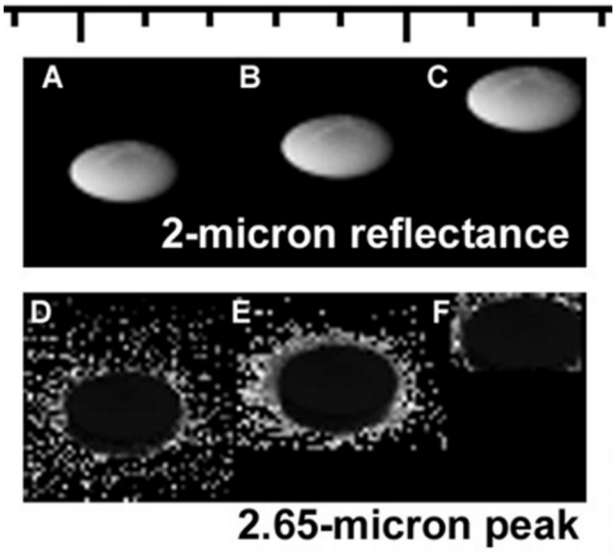

Figure VIMS-3. The 2.65-μm transient atmosphere on Dione [Clark et al. 2008].

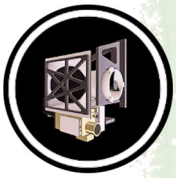

IR spectroscopy is sensitive to grain size of materials, and the multiple absorption in ice allow grain size mapping to be done with VIMS data. On Enceladus, the sizes of ice particles are generally well correlated with geologic features and surface ages, indicating a stratigraphic correlation between tectonic features and cryovolcanic activities [Jaumann et al. 2008b]. Grains much smaller than the wavelength of light cause enhanced blue scattering, including a Rayleigh scattering effect. This bluing effect is observed in the Saturn system and quantified by Clark et al. [2008, 2012].

Scipioni et al. [2017] produced image-cube maps of Enceladus,mapped ice grain sizes and identified plume deposits across the surface. The map showing the band-depths-ratio 1.50/2.02 μm overall shows a good agreement with the predicted plumes' deposits on the trailing side, where the amount of sub-micron particles decreases with increasing accumulation of ejecta material. However, this correlation is much weaker, or even absent, on the leading side of Enceladus, where the abundance of sub-micron particles is the highest across the entire surface.

Stephan et al. [2012] showed that the distribution of spectral endmembers as well as global band-depth variations of Dione's water-ice absorptions measurements imply that the bombardment with charged particles from Saturn's magnetosphere is one of at least two major global processes affecting Dione's surface. Ice deposits dominating its leading hemisphere appear rather associated with rays of the fresh impact crater Creusa on the northern leading hemisphere. These rays cross almost the whole hemisphere masking here any effects of possibly existent, but less dominant, processes as evident in the transition from the bright to dark regions on the Saturn-facing hemisphere (~0° W). CO_2 is evident in the dark material pointing to a possibly formation due to the interaction of the surface material with the impacting particles from Saturn's magnetosphere. Local spectral differences are consistent with impacting particles from the trailing side as described by Clark et al. [2008] with a pronounced ice signature on crater walls facing the leading side direction and shielded from impacting particles and dark material concentrated on interior crater walls facing the trailing hemisphere.

Spectra of ice also vary with temperature, so the surface temperatures of cold icy surfaces can be sensed without needing to measure longer wavelength thermal emission. Filachione et al. [2016] analyzed the ice spectra to produce daytime temperature maps of the satellite surfaces, just one more indication of the diversity of science that an imaging spectrometer can provide.

Observations of the small inner moons of Saturn were also obtained during the mission, including five best ever flybys of the ring moons Pan, Daphnis, Atlas, Pandora, and Epimetheus that were obtained between December 2016 and April 2017 during the Ring-grazing Orbits. An example of an observation is shown in Figure VIMS-4. Views of the moons' morphology, structure, particle environment, and composition were obtained, as well as VIMS maps in its full spectral range, except for Daphnis, which as of now is lacking a visible VIMS spectrum [Buratti et al. 2018b]. The optical properties of the moons are determined by two competing processes: contamination by a red chromophore in Saturn's main ring system, and accretion of bright particles from the E-ring originating from Enceladus.

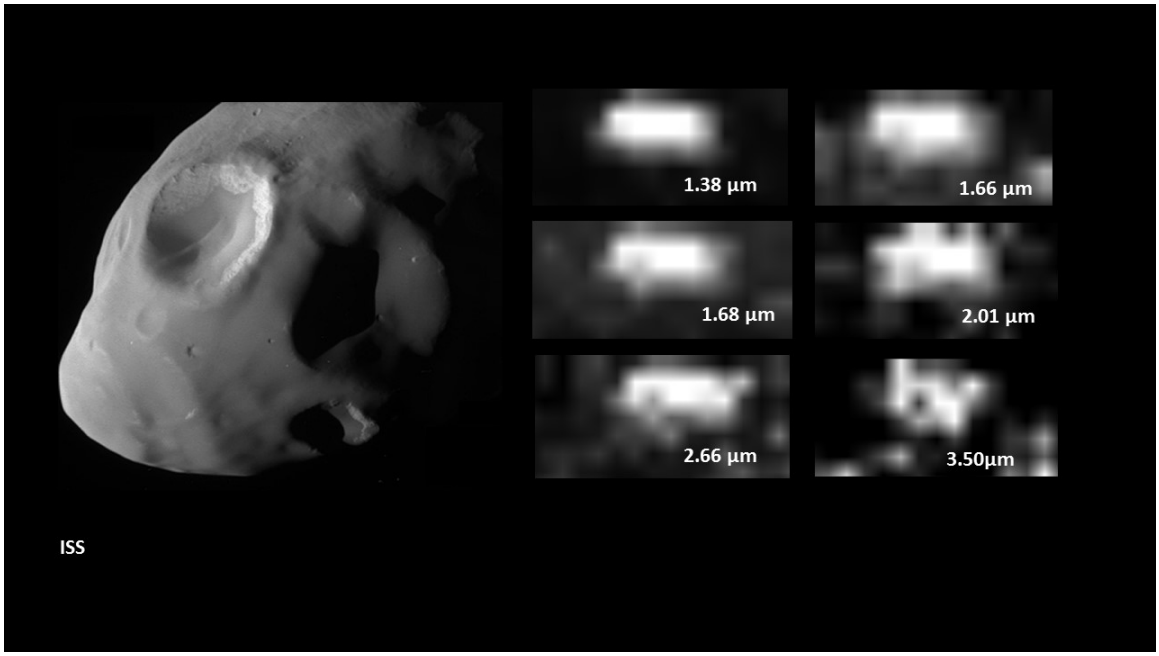

Figure VIMS-4. VIMS images of Pandora (*Right*), obtained on December 12, 2016 during a flyby that approached the shepherd moon to within a distance of 22,000 km. The ISS image is shown (*Left*) for context.

Open questions

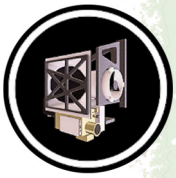
Is there a connection between the composition of the plume and the regions on Enceladus where plume deposits exist, for example, Schenk et al. [2011]. How are the plume fallout zones compositionally different from the other zones on Enceladus that are affected by particles from the E-ring? What is the chemical make-up of the trailing side of Tethys, and why is it so reddish [Schenk et al. 2011] compared to regions dominated by the in-fall of E-ring grains?

What is the nature of possible activity on Dione? Is this moon still active, or has it been active in the recent past?

Similar to Dione, Tethys exhibits regions of smooth plains in which large craters have been removed. Cryovolcanic activity on Tethys is problematic: with a density even less than that of water, what is the driver for the activity?

What is the cause of the red streaks on Tethys and the blue dots on Rhea? Are they compositionally different, or can their appearance be explained solely by the effects of grain size?

What is the time scale for plume variability on Enceladus beyond the simple correlation with distance from Saturn, which is due to the magnitude of tidal effects? Is there a correlation with seasons? Can the variability be monitored from the ground?



What is the identity of the red chromophore on the inner icy satellite surfaces? Is it nano-iron or organic material (tholins), and what are the transport processes to move this material around the Solar System? We have excellent evidence that Iapetus', Phoebe's and Hyperion's color is dominated by nano-iron and nano-iron oxide, but the red absorber is weaker on the inner satellites, and it cannot be established which possibility is correct for those satellites. Does radiation play a greater role in surface modification of these materials on the inner satellites?

What are some of the minor constituents of the Saturnian moons, and are the endogenic or exogenic? If exogenic, is the accretional process still ongoing?

How does the D/H ratio compare with that of other regions of the solar system, and what does that imply about the transport of volatiles on a large scale?

Is the detection of ammonia hydrate on the surfaces of the moons definitive?

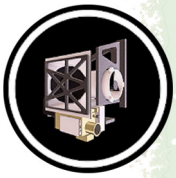
Some of these unanswered questions might be answered with further research with the vast trove of archived data and with continuing ground-based observations, including the James Webb Space Telescope (JWST).

Science Assessment Summary

The VIMS instrument illustrated that the data an imaging spectrometer can deliver led to an amazing diversity in science. For icy satellites alone, from unexpected compositions, to geologic mapping, grain size distribution, temperature mapping, isotopic ratios, to plume dynamics, VIMS and the science team delivered far more than what was envisioned at the start of the mission. No single other instrument has shown such science diversity.

No single other instrument has shown such science diversity.

While the above science assessment documents huge accomplishments in satellite science with imaging spectroscopy data obtained by VIMS, interpretation of such data has been and remains difficult due to limited laboratory data and sophistication of models. For example, one of the main, seemingly simple, science questions yet to be answered is the nature of the coloring agent(s) on the inner icy Saturnian satellites and rings. While we obtained a definitive answer for the satellites beyond Titan, the origin of the coloring on the icy moons inside the orbit of Titan remain uncertain. This is largely due to lack of lab data and sophistication of radiative transfer models. Similarly, it was not until near the end of the prime mission before it was realized that the spectral effects of sub-micron ice particles affected the spectra in such profound ways, because there was no lab work or radiative transfer models for those conditions. Early on we wondered if there were calibration errors in VIMS causing unusual shapes of ice absorptions in VIMS data. If we had more extensive spectral libraries at the start of the mission, so much time would not have been lost going down blind alleys. Similar blind alleys were also traveled trying to identify other spectral features, like the 2.42 micron absorption. Initial thoughts were it was due to a C-N bond,



but the stronger absorptions of C-N bearing compounds at longer wavelengths were not seen. It took substantial resources to find the origin as trapped H_2. To date, the organics absorptions observed in VIMS data on several satellites still have not been precisely identified, only general categories like aliphatic versus aromatic can be determined. What major chemistry and implications are we missing with this lack of knowledge? Only additional resources put into lab work and modeling, funded by future NASA research programs will solve these problems. This should also be a lesson for future missions: the science output of the mission will be limited by current knowledge, including laboratory data and models.

Ring science

This part of the VIMS efforts had five principal components that are described below, along with their principal scientific goals, and major scientific results.

Ring macrostructure and dynamical processes

Our goal here was to study the radial structure of the main rings at the sub-km scale, at a variety of ring opening angles, and to examine their large-scale azimuthal variations (eccentricities, normal modes, etc.). Also of interest is the vertical structure of the rings, in those regions where it can be resolved.

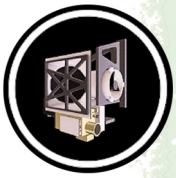
Stellar occultations provide radial structure; over 170 were observed over the course of the mission, using ~40 different stars to provide different ring opening angles. A number of different investigations have been carried out using these data, as documented below. Particularly valuable for low-optical-depth regions such as the C-ring have been occultations of bright, low-latitude stars such as alpha Ori, omicron Ceti, and alpha CMa. But probably our most scientifically-productive data set is a sequence of ~17 occultations of the bright, high-latitude star gamma Crucis done on nearly-successive orbits with very similar geometry in 2008 and 2009.

Ring Plane Crossing observations were done on several near-equatorial orbits in order to provide measurements of the rings' photometric thickness as a function of radius and phase angle. Modeling of these data confirms that the ring's edge-on brightness is dominated by the vertically-extended F-ring.

Extended movies were obtained of the F-ring to study its complex azimuthal variations and also obtain high-quality spectra. Most of these observations were efficiently done as riders on ISS movies.

Ring microstructure and particle size distribution

Cassini observations, primarily radio and stellar occultations, have revealed the presence of various types of small-scale structure in the rings, notably self-gravity wakes (due to a completion between Keplerian shear and self-gravity) and radial oscillations caused by a viscous over-stability in dense



parts of the rings. The ring particle size distribution is critical to numerical models of ring structure and evolution, but can only be approached indirectly by Cassini.

Stellar occultations are again our main tool here, providing 100-m scale resolution or even better in some cases. The most useful observations here are occultations where the track of the star reaches a minimum radius in the rings. In hindsight, more of these events would have been useful. Occultations of low-latitude stars also provide quantitative data on the azimuthal variations in optical depth produced by self-gravity (S-G) wakes.

VIMS solar occultations by the main rings have provided valuable (and unique) information on the distribution of the smallest ring particles, in the mm–cm size range.

Spectral images of the rings obtained at phase angles of 165° or higher have provided very valuable data on the particle size distributions of the diffuse D-ring, F-ring, G-ring and E-ring that are not obtainable in any other way short of in situ sampling. Because the key scattering parameter in this geometry is the ratio $\Theta\lambda/r$, where Θ is the scattering angle, lambda is the wavelength, and r is the mean particle radius. VIMS 1– to 5-μm spectra effectively extend the range of observed scattering angles by a factor of 5.

Compositional variations

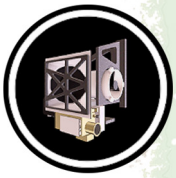
A primary goal of VIMS ring observations, not surprisingly, was to establish their composition and map radial variations in the fraction of non-icy material, suspected on the basis of Earth-based spectroscopy. This has turned out to be a very difficult problem, chiefly because of the very tiny amounts of non-icy material, estimated to be a few tenths of a per cent in most places. Although radial variations in the rings' spectral characteristics have been well-established, in the form of ice band depths and continuum slopes, there is still no consensus on the nature of the non-icy material. Recent Hapke modeling of spectra in selected regions indicate that both intimate and intra-particle mixing of water ice, amorphous carbon and organic material (modeled as Titan tholins) can reproduce the observed ring spectra, but nano-phase Fe-bearing materials such as these seen on Iapetus remain a possibility. A large variety of both Prime and Rider observations have been devoted to this problem.

VIMS radial scans generally provide the highest-quality data. This includes several high-resolution (30–60 km/pixel) complete radial scans obtained on the F-ring and Proximal orbits in 2017.

A unique set of radial scans were done at Saturn orbit insertion in 2004 that still provide our highest-resolution spectral data of the unlit side of the rings.

VIMS scans along the edge of Saturn's shadow on the rings are lower in resolution but were designed to minimize interference from Saturn-shine.

Several riders on ISS high-resolution radial scans also provide excellent-quality VIMS spectral data.



A large number of riders on lower-resolution CIRS radial scans provide useful data at a variety of ring opening and phase angles.

PHOTOMETRY AND LIGHT-SCATTERING PROCESSES

A number of observations were designed to provide lower spatial resolution spectral data on the rings at a wider range of observing geometries than are covered by the above compositional scans. The goal was to provide data with which to model light-scattering processes in the main rings, in particular the degree of multiple scattering between particles and the characteristics of the rings' well-known opposition brightening at low phase angles. The principal sets of observations are:

a. Standardized ring ansa mosaics done at ~20 R_S.

b. Scans and small mosaics at phase angles of 165° or higher.

c. Full system mosaics at distances of 30–40 R_S.

d. Radial scans across the rings immediately before and after the Equinox in August 2009, when the solar illumination was almost edge-on.

e. Riders on ISS photometry observations.

DIFFUSE RING STRUCTURE, PARTICLE SIZE, AND COMPOSITION

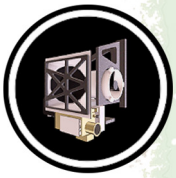
VIMS was well-suited to obtain reflected-light observations of Saturn's diffuse rings, including the D-ring, F-ring G-ring and E-ring as well as several smaller-scale structures such as narrow ringlets and clumps within gaps in the main rings and arcs associated with the small satellites such as Aegaeon. This is because of the instrument's very low level of scattered off-axis light (unlike the ISS-wide angle camera (WAC), which is also used for such studies), its spectral range, and its capacity to take long exposures. A mixture of VIMS-prime and ISS-rider observations was employed, with most observations being made at high phase angles where dust-sized particles are brightest. The principle sets of observations are:

a. Radial mosaics of one ansa of the E-ring at various phase angles.

b. Image cubes targeted to one ansa of the G-ring at various phase angles. Most E_ and GPHASE observations were made when the rings were viewed edge-on, on equatorial orbits, in order to increase the line-of-sight optical depth of these very diffuse structures.

c. Movies of the F-ring, intended to cover all (or most) co-moving longitudes of the ring in a single observation. This was done initially as VIMS-prime and later as ISS-riders, on non-equatorial orbits to resolve radial structure.

d. Riders on various ISS faint ring observations.



Cornell non-rings observations

In addition to observations of the rings, the Cornell group also took on responsibility for several categories of non-ring observations which used similar techniques or designs as some Rings observations.

> … VIMS proved to be an effective instrument for observing atmospheric occultations by Saturn and Titan.

Saturn and Titan stellar occultations

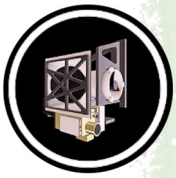
Using the same technique developed for ring stellar occultations, as discussed in the section entitled Saturn and Titan Stellar Occultations, VIMS proved to be an effective instrument for observing atmospheric occultations by Saturn and Titan. With sampling intervals of 20–40 msec, the altitude resolution is typically 100–400 m. The science obtained from such observations includes vertical profiles of temperature, atmospheric composition (chiefly methane) and aerosol abundance, as functions of latitude, as well as information on the shape of Saturn's geoid. Over the course of the mission ~70 stellar occultations by Saturn were planned, with all but 13 returning useful data. Another 35 were observed as bonuses at the end of ring occultations, but many of these were seen against a sunlit limb and suffer badly from background light from the planet. A total of 14 stellar occultations by Titan were observed, all but one successfully. Some of the latter show noticeable aerosol layers. An important limitation of such observations is atmospheric refraction, which eventually causes the star to leave the VIMS pixel. This limits the maximum depth of Saturn occultations to a pressure level of ~5 mbar.

Saturn and Titan solar occultations

Using the solar port originally designed for spectral calibrations, VIMS has observed 29 solar occultations by Saturn and 16 by Titan. Because the angular diameter of the sun exceeds the VIMS instantaneous field of view (IFOV) of 0.5 mrad, solar occultations were observed in IMAGE mode rather than in the special mode designed for stellar occultations, thus reducing the vertical resolution to10–30 km. All of these observations were done as riders on UVIS occultations. Analysis of several Titan solar occultations has led to vertical profiles of methane and CO, as well as characterization of the aerosol size distribution. All but one of the solar occultations attempted returned data, but in several cases the Titan observation were corrupted because the bright limb of Titan itself appeared in the main VIMS aperture while the sun was in the solarport.

Enceladus plume observations

VIMS made several important observations of the plumes of Enceladus, including both high-phase images that led to the discovery of the plumes' significant variations with orbital phase and a solar occultation from which the volume density of water ice particles could be measured directly.



STELLAR CALIBRATIONS

In addition to regular observations of standard stars for instrumental calibration purposes, VIMS also obtained near-IR spectra for ~40 of the brightest stars in the sky, many of which were published in an IR spectral atlas. Many of the stars are late-type variables that exhibit strong absorptions due to CO and water vapor.

SOLAR PORT CALIBRATIONS

Over the course of the mission, a substantial number of calibration observations of the Sun were made with the VIMS solar port. Some of these simply provide routine monitoring of the solar spectrum, as check on instrumental sensitivity drifts while others were used to map the spatial variations in its throughput.

EXOPLANET AND VENUS TRANSITS

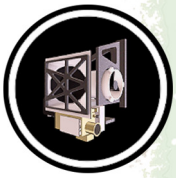
In 2010 and 2011 several attempts were made to observe stellar transits of the giant exoplanet, HD189533b. VIMS was used in 2 × 2 IMAGE mode in order to provide simultaneous background measurements and some insurance against pointing variations. Unfortunately the star was much fainter than normal VIMS point source targets and no transit was detected. Analysis of the data, however, demonstrated that VIMS sensitivity scaled with integration time as expected, even down to signal levels of order 0.1 DN. In December 2012 a very similar technique was used to monitor a predicted transit of Venus across the sun using the VIMS solar port. This observation, which involved a reduction in the solar flux of only 0.01% was successfully observed, though the signal-to-noise ratio was too low to detect the absorption signature of Venus' atmosphere in the transit spectra.

PRINCIPAL RESULTS

1. VIMS spectral observations at SOI revealed that the mysterious red coloring agent in the rings resides within the water ice grains that make up the regoliths on the ring particles [Nicholson et al. 2008].

2. Observations of ring occultations of o Ceti (aka Mira) in 2005 confirmed the existence of strong self-gravity wakes in the A-ring, leading to the first reliable estimates for the ring thickness of ~6 meters in this region [Hedman et al. 2007b].

3. Observations of multiple stellar and radio occultations in 2005–2009 led to the discovery that the amplitude of the radial perturbations at the outer edge of the B-ring (due to the Mimas 2:1 resonance) varies from ~70 km to < 5 km, and that these may also be indirectly responsible for the regular spacing of the multiple gaps within the Cassini Division [Hedman et al. 2010].



4. The observation of restrahlung bands of H_2O ice in a stellar occultation by the F-ring permitted discrimination between clumps of macroscopic source bodies and the background of micron-sized dust [Hedman et al. 2011].

5. A comparative analysis of VIS-IR spectral indicators (slopes and band depths) of rings, regular satellites and small moons has allowed VIMS to map the distribution of water ice and red contaminant materials across the Saturn system [Filacchione et al. 2012, 2013; Clark et al. 2012]. However, in the main rings, the abundance of the red coloring agent is lower and there is at present no way to distinguish definitively between the nano-iron model and more traditional carbon-tholin models. Recent modeling results obtained with Hapke theory indicate that both intimate and intraparticle mixing of water ice, amorphous carbon and organic material (Titan tholins) can reproduce the observed ring spectra [Ciarniello et al. 2019].

6. VIMS investigations of numerous, small-scale, wavelike structures in the C-ring have provided strong evidence that several of these are density waves driven by global oscillations within Saturn itself, opening up a new window on the planet's internal structure and rotation rate [Hedman and Nicholson 2013; Hedman and Nicholson 2014].

7. A pair of stellar occultations with turnaround radii in the inner A-ring yielded strong evidence for viscous over-stability in the denser parts of Saturn's rings, supporting previous work based on radio occultation data. [Hedman et al. 2014].

8. Together with occultation data from RSS and UVIS, VIMS data from more than 100 stellar occultations has led to the characterization of numerous non-circular features in the C-ring and Cassini Division, including the discovery of a large number of normal mode oscillations on the edges of both narrow gaps and their associated ringlets. [Nicholson et al. 2014a, 2014b; French et al. 2016].

9. Ring temperature maps have been built from VIMS spectra by using an indirect method based on the wavelength of the temperature-dependent reflectance peak at 3.6 μm [Filacchione et al. 2014].

10. Application of a new phase-sensitive wavelet analysis technique to selected VIMS stellar occultation profiles has led to the identification of several satellite-driven density waves in the optically-thick B-ring, resulting in the first estimates of surface mass density in this most opaque part of Saturn's rings. The results are unexpectedly low, and imply a total mass for the rings of ~40 percent that of Mimas [Hedman and Nicholson 2016].

EXAMPLES OF STELLAR OCCULTATION OBSERVATIONS

Figures VIMS-5 through VIMS-10 show examples of stellar occulation observations.

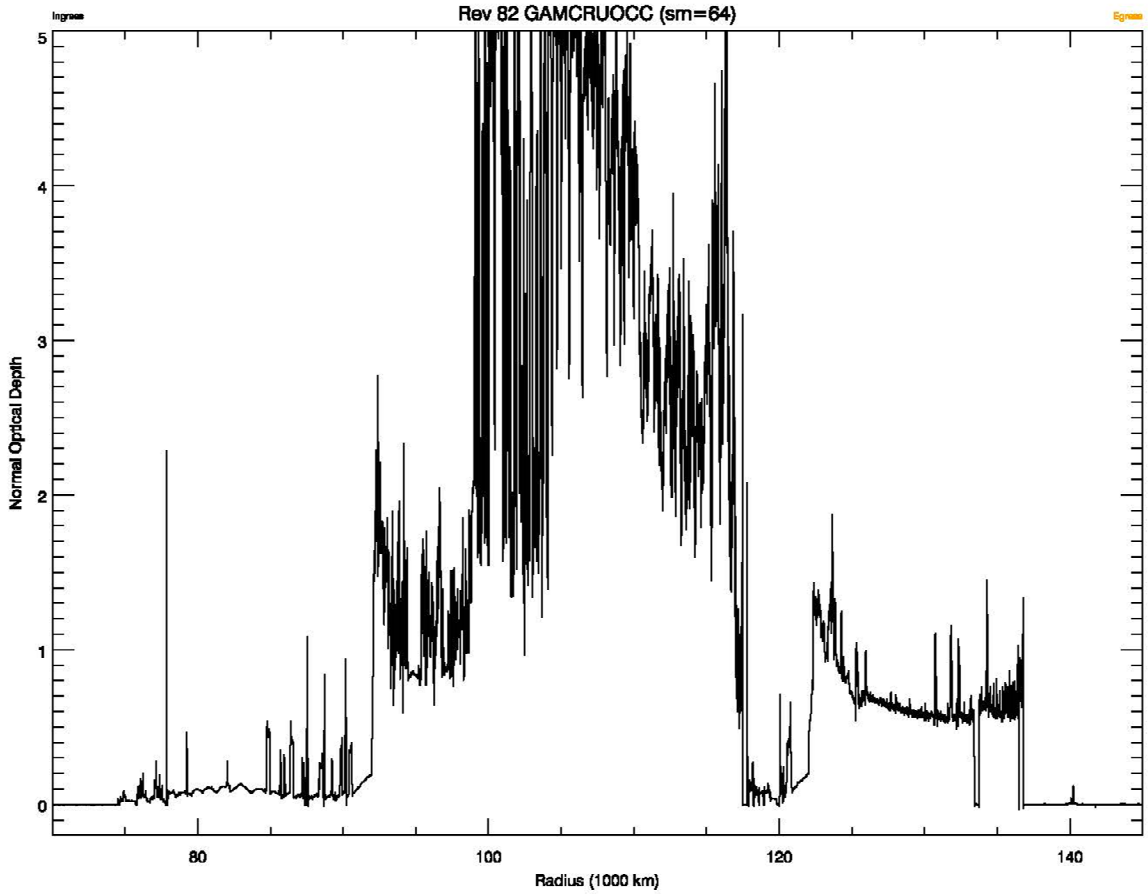


Figure VIMS-5. An optical depth profile of Saturn's rings at a wavelength of 2.92 microns, derived from a VIMS occultation of the star gamma Crucis on rev 82, obtained in August 2008. This is one of the highest-quality VIMS occultation observations, as evidenced by the very flat baselines exterior to the A-ring's edge at 136,770 km and interior to the C-ring at 74,500 km. Note that the optical depth exceeds 5 in some regions of the central B-ring.

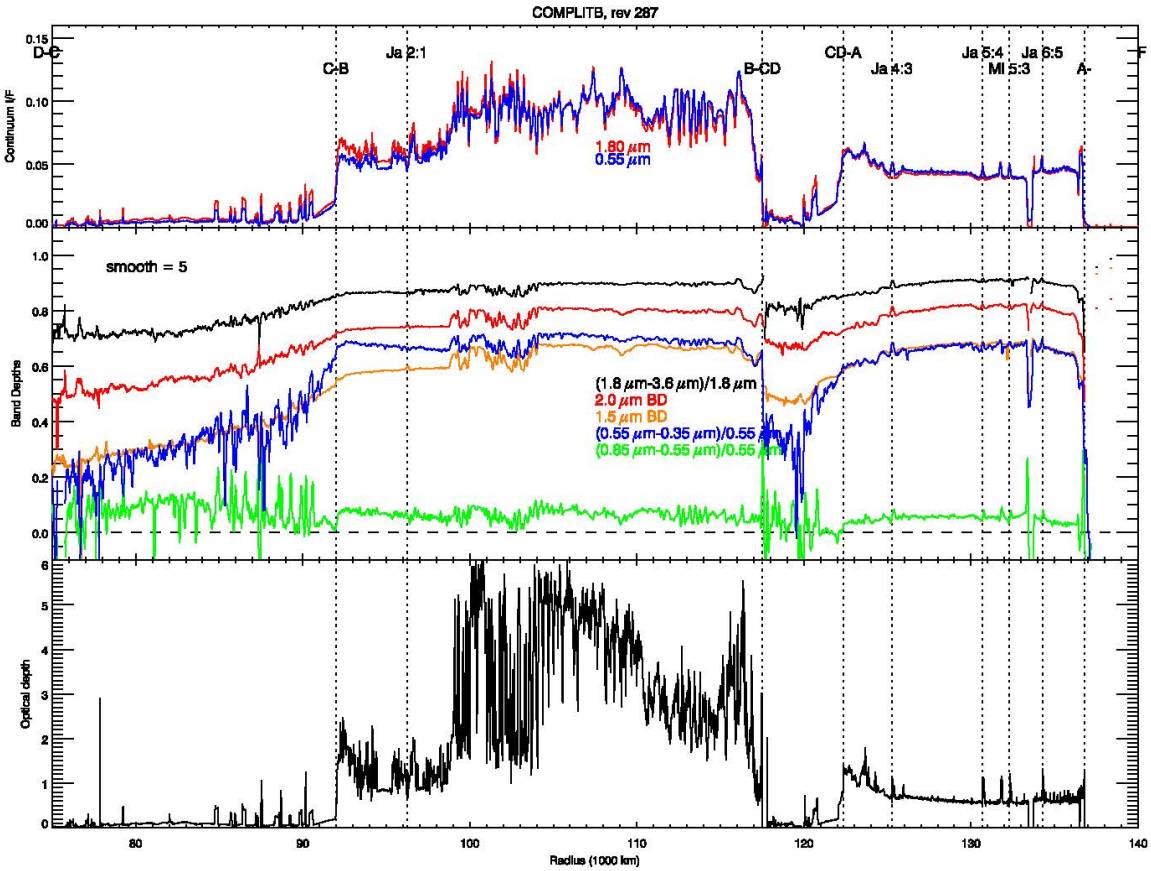

Figure VIMS-6. Radial profiles of IR spectral parameters derived from the final VIMS scan across the sunlit rings on rev 287, rebinned to a uniform sampling resolution of 20 km. *Upper panel*: shows the reflectivity of the rings at continuum wavelengths of 0.55 and 1.8 microns, with the locations of major ring boundaries and the strongest density waves identified by vertical dotted lines. *Middle panel*: shows the fractional depths of the IR water ice bands at 1.55, 2.0 and 3.6 microns, coded by line color, as well as the UV and red slopes measured with the visual channel, all smoothed to a resolution of 100 km. *Lower panel*: shows the optical depth profile of the rings obtained from a VIMS occultation of the star gamma Crucis on rev 82, binned to 10-km resolution, as context for the spectral scans.

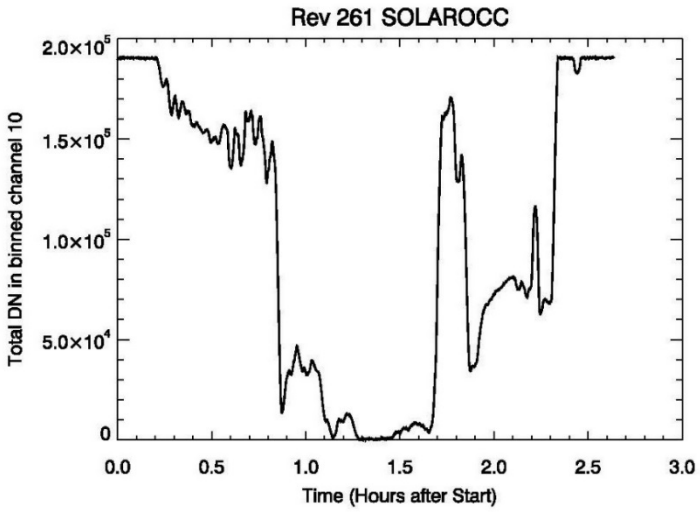

Figure VIMS-7. A transmission profile of the rings at a wavelength of 1.06 microns derived from a VIMS solar occultation on rev 261, obtained in February 2017. Note the lower spatial resolution compared to the stellar occultation in Figure VIMS-5, but the much higher signal-to-noise ratio.

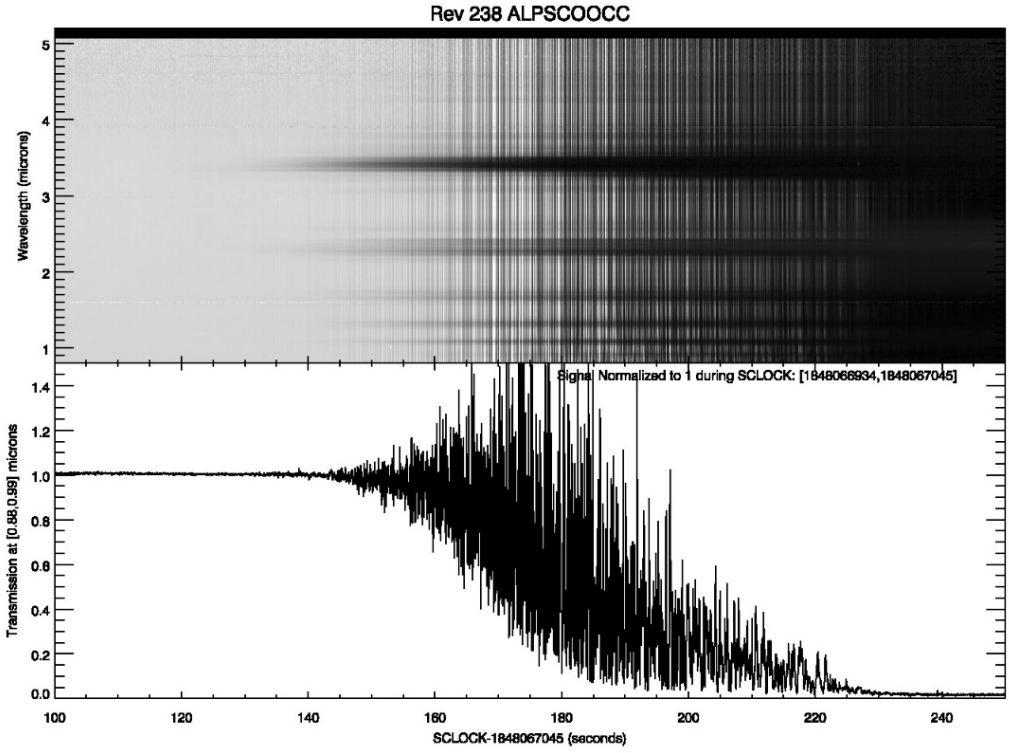

Figure VIMS-8. An ingress stellar occultation by Saturn's atmosphere at 63 deg south latitude on rev 238, obtained in July 2016. Time is shown on the abscissa, in seconds, with wavelength on the ordinate, from 0.85 to 5.1 microns. The greyscale indicates the measured stellar brightness, normalized to unity before the occultation began. In addition to a gradual loss of signal due to differential refraction, punctuated by rapid oscillations due to turbulent scintillation, one sees absorption at several discrete wavelengths (3.4, 2.3, 1.7 microns, etc.) due to stratospheric gasses, chiefly methane.

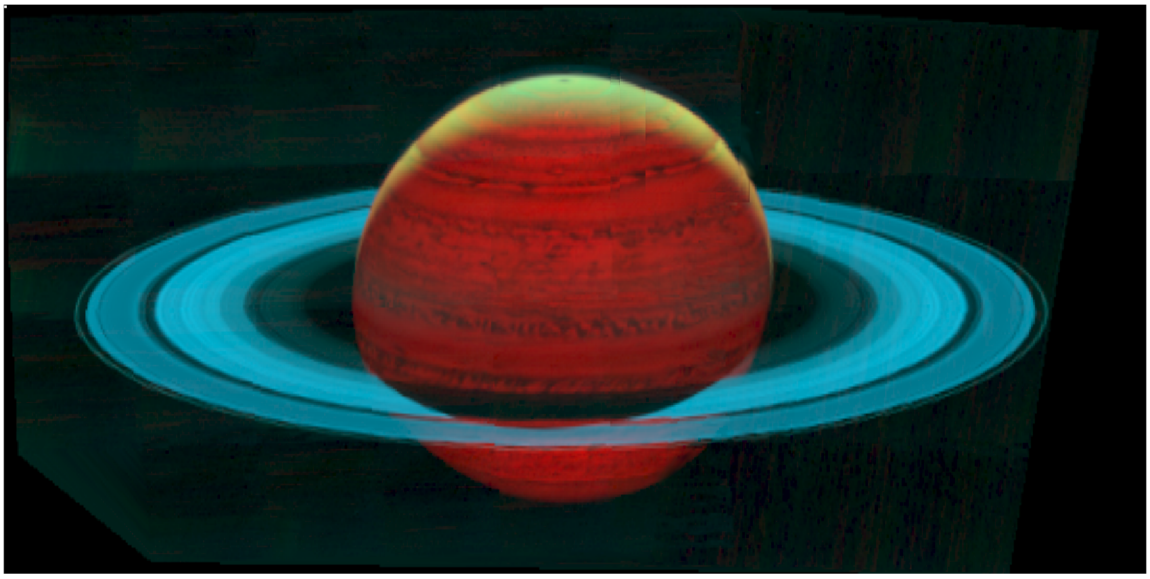

Figure VIMS-9. A mosaic of Saturn and its rings obtained by VIMS on revs 287/289, in August 2017. A total of 35 VIMS cubes were combined to produce this false-color image, with *Red* showing thermal emission from Saturn's deep atmosphere at 5 microns, *Green* showing reflected sunlight from the clouds at 3 microns, and *Blue* showing reflected sunlight from the icy rings at 1.8 microns. The view is at a phase angle of 140 degrees, with only a thin crescent in the north illuminated by sunlight. This close to summer solstice, the planet's shadow on the rings extends only just beyond the Cassini Division. Dark mottling on the planet is due to the variable thickness of clouds in the upper atmosphere. Saturn's oblateness is slightly exaggerated here by changes in the viewing geometry during the total observation period of almost 12 hours.

Open questions

A big unanswered question remains that of the nature of the non-icy component. We know that some of it is meteoritic (or cometary) debris, but the true nature of the UV-absorbing component(s) remains elusive. More sophisticated spectral modeling might eventually solve this problem, as we certainly have acquired plenty of spectra.

Titan

Before Cassini, Titan's surface was unknown territory because aerosols in its dense nitrogen and methane atmosphere hide the surface in the optical wavelengths. It was believed that only radar waves would be able to cross the atmosphere and provide images of the surface, thus it was not expected that the VIMS instrument would be able to image Titan's surface. During Cassini's cruise phase, telescopic observations hinted that Titan's surface may be observable by VIMS at 1.6 and 2.0 μm [Meier et al. 2000], providing impetus for VIMS prime time observations during the first Titan flyby (T00A). Since it had been added to solve the issue of the transmission between the Huygens probe and the Cassini spacecraft, this flyby had not yet been allocated to any instrument. During that first flyby, the VIMS instrument demonstrated its potential to observe Titan's surface in seven atmospheric windows [Sotin et al. 2005]. The 5-μm band in particular was shown to have very little

scattering from atmospheric aerosols, while the 2-μm band proved to be the best compromise between solar flux, atmospheric scattering, and detector sensitivity. That discovery propelled the VIMS instrument into a key mapping role for Titan, and provided information very complementary to radar images. Most of the VIMS images of Titan's surface were acquired during the extended mission because the flybys during the Prime Mission were already allocated.

As history has shown, VIMS made some fundamental observations of Titan's atmosphere with implications for both its composition and dynamics. A solar port, aligned with the UVIS solar port, was set up to allow for solar occultation as riding along with UVIS, and a dozen solar occultation observations of Titan were performed at different latitudes and seasons, providing key information on the aerosol content of the atmosphere. Finally, specular reflections from Titan's seas were observed at 5 μm and have provided key information on the presence and dynamics of Titan's seas. The following three sections provide the main scientific results obtained by the VIMS instrument.

TITAN'S SOLID SURFACE

The VIMS instrument can see Titan's surface through seven atmospheric windows in the near infrared between 0.9 and 5 μm [Sotin et al. 2005; Rodriguez et al. 2006]. Because atmospheric scattering decreases with wavelength, and observations of specular reflection (Figure VIMS-10) show that there is very little scattering at 5 μm, it was determined that optimum imaging occurred at 2 μm. RGB, synthetic color images can be constructed by choosing three out of the seven wavelengths from a VIMS image cube, enhancing the visibility of geological features, which can be

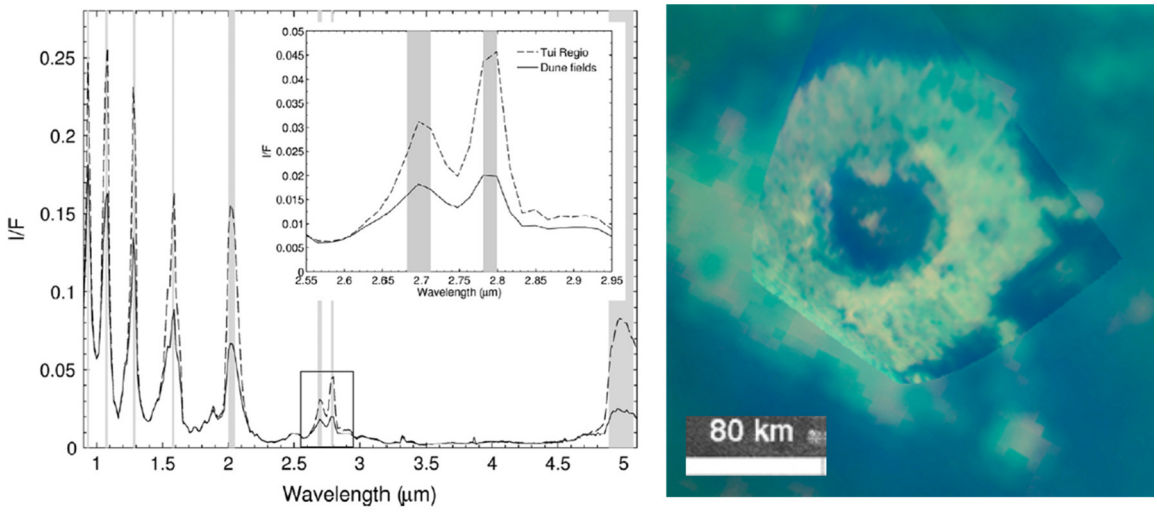

Figure VIMS-10. Titan's surface. *Left*: Typical spectrum of Titan's surface with the dark spectrum taken over dune fields and the bright spectrum taken on the bright feature known as Tui regio. *Right*: Sinlap crater is considered as the least altered impact crater on Titan [Neish et al. 2015]. Resolution ranges from 1 to 4 km. The RGB image was constructed with R=4.8–5.2 μm, G=2.00 μm, B=1.28 μm.

observed with pixel size as small as 500 m in a few spots. The resolution depends on the distance between the Cassini spacecraft and Titan's surface and the global maps are mosaics of images with very different pixel scales and viewing geometry. The VIMS images enable detailed comparisons to be carried out with Titan Radar Mapper (RADAR) images, for example, Soderblom et al. [2007a] demonstrated the very strong correlation of the dark brown VIMS units with the radar dune fields. They suggested that the bright areas surrounded by these dune fields are deposits of bright, fine, precipitating tholin-aerosol-dust, and hypothesized that chemical/mechanical processes may be converting the bright, fine-grained aerosol deposits into the dark, saltating, hydrocarbon and/or nitrile grains. Alternatively the dark dune materials may be derived from a different type of air aerosol photochemical product than Titan's bright materials.

VIMS mapped a few impact craters [Le Mouélic et al. 2008; Buratti et al. 2012; Neish et al. 2015]. These impact craters exhibit various degrees of degradation, with Sinlap being the least degraded. Buratti et al. [2012] studied the crater Paxsi, located in the dune field known as Senkyo. This crater's dark brown interior was attributed to infilling by dune material. The number density of impact craters on Titan is small suggesting a young surface.

At the end of the Cassini mission, it is not clear that Titan's surface displays cryovolcanic features. 5-µm-bright lobate features at Tui regio [Barnes et al. 2006] suggest an endogenic origin, but, other authors have attributed this 5-µm-bright feature to evaporitic material [MacKenzie et al. 2014], which suggests that Tui regio may be located in a depression near Titan's equator. Similarly, Hotei Regio, also located in the Xanadu area to the East of Hotei, exhibits a 5 µm bright feature also interpreted as evaporitic material. The interpretation that the 5-µm-bright feature is evaporitic material comes from the observation of such features at the North poles, next to the large hydrocarbons seas.

The composition of Titan's surface has stimulating much debate since the observation of the surface at seven infrared wavelengths, and one, important unsettled question is the presence or absence of convincing water ice deposits on Titan's surface. Water ice has a clear spectral signature in the 2.7-µm window, characterized by two peaks at 2.7 and 2.8 µm. Its spectrum shows a strong decrease in albedo between 2.7 and 2.8, suggesting that the 2.8-µm peak should be much less pronounced than the 2.7-µm peak. This is not what is observed, suggesting that Titan's surface is covered by organic material which masks the spectral signature of water ice. The composition of Titan's surface has been studied by Clark et al. [2010], using absorption bands in the 5-µm atmospheric window. They discovered a benzene absorption (5.05 µm), alkane absorptions (near 4.97 µm), and a component yet to be identified which has an absorption at 5.01 µm.

TITAN'S SEAS

Titan is the only place in the solar system, other than Earth, that has seas of liquids at its surface. That many very dark areas on Titan are bodies of liquid was confirmed by the solar glint (secular reflection) at 5 µm (Figure VIMS-11), first observed by Stephan et al. [2010d] over Jingpo Lacus.

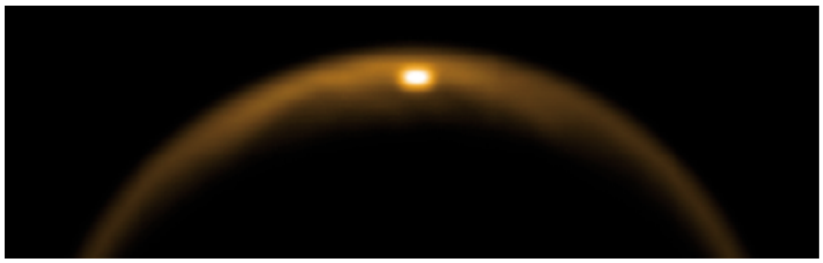

Figure VIMS-11. The 5 μm solar glint during the T58 flyby.

This glint demonstrated that the lake's surface is smooth and free of scatterers, at the observation wavelength of 5 μm. Just before Cassini arrived at Saturn, Lorenz and Lunine [2005] wrote:

> *"The glint may be observable at longer wavelengths by VIMS (although this will not be trivial, since the specular point moves across the surface as the sub-spacecraft point moves, and VIMS is a mapping spectrometer, not a framing camera, so its image is not built instantaneously)".*

Despite these difficulties, several observations of 5-μm specular reflections have been made. Measuring the intensity of specular reflections was employed by Barnes et al. [2011b], to demonstrate that the surfaces of many of Titan's lake and seas are very smooth, with waves which have slopes 2 orders of magnitude lower than those on Earthly lakes and seas.

Titan's lakes and seas are very dark in Titan's atmospheric windows, and their distribution correlates very well with the radar observations [Sotin et al. 2012]. Besides the specular points that provide information on the waves, VIMS observations also provide information on transport processes operating to move liquids between Kraken Mare and Ligeia Mare through a channel known as Trevize fretum [Sotin et al. 2015].

VIMS also determined that ethane is one of the components present in a large lake, Ontario lacus, located in the southern hemisphere [Brown et al. 2008]. The VIMS instrument cannot determine whether methane is present because of its abundance in the atmosphere. However, in the solid surface, liquid ethane/methane was detected by VIMS in some non-polar locations [Clark et al. 2010].

TITAN'S ATMOSPHERE

VIMS provided data important to understanding on Titan's climate by observing the appearance and evolution of clouds [Rodriguez et al. 2009, 2011], as well as determining their composition using solar occultation observations [Bellucci et al. 2009; Maltagliati et al. 2015]. Two types of clouds were detected during the period 2005–2009 during northern winter (Figure VIMS-12). Initially the north pole was covered by a polar hood, while later clouds with a short lifetime were detected at southern mid-latitudes.

The composition of Titan's atmosphere was derived from solar occultation observations by Bellucci et al. [2009], who determined the mixing ration of methane above an altitude of 200 km to

be between 1.4 and 1.7%, while the amount of CO was 33 ±10 ppm. Maltagliati et al. [2015] used solar occultation observations to refine measurement of the mixing ratio of CH_4, finding it be 1.28% ±0.08% and the CO abundance equal to 46 ±1 6 ppm, comparable with the previous measurements. Their work showed the presence of ethane, explaining many of the remaining, and previously unattributed absorption bands.

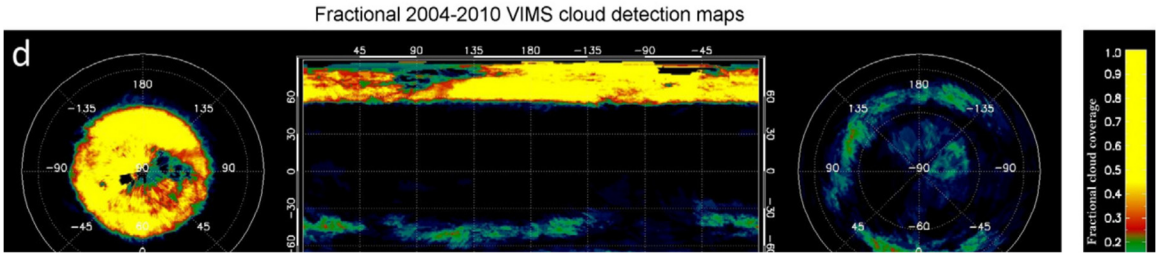

Figure VIMS-12. Fraction of cloud coverage on Titan during the period 2004–2010.

Conclusion

The VIMS instrument exceeded all expectations with regard to its studies of Titan, with major advances in understanding of Titan's surface and atmosphere. It made fundamental discoveries regarding the composition of Titan's surface and atmosphere, the dynamics of Titan's atmosphere, and the morphology of its surface. VIMS paved the way for the development of an infrared camera that may eventually enable us to obtain global maps of Titan's surface at 25-meter resolution (Huygens type resolution), providing important information on unanswered questions about Titan's geology, such as why is the surface so young; why are there geomorphological features that trace outgassing; is there fluvial erosion; what are the ages of any methane outbursts; are there tectonic features; is there aeolian transport of organics?

Open questions

Are there water ice outcrops on the surface?

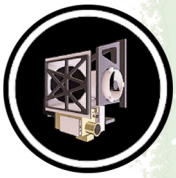
What is the composition of the river beds?

Where are located the ethane reservoirs?

Are there morphological features related to the release of methane in the atmosphere?

What is the nature of the organic material covering Titan's surface?

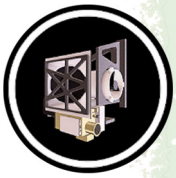
What is the nature of the very bright deposits?



ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AO	Announcement of Opportunity
CAPS	Cassini Plasma Spectrometer
CIRS	Composite Infrared Spectrometer
D/H	Deuterium to Hydrogen
FUV	far ultraviolet channel
HST	Hubble Space Telescope
IFOV	instantaneous field of view
IR	infrared
ISS	Imaging Science Subsystem
JWST	James Webb Space Telescope
mrad	microradians
NAC	narrow angle camera
NIMS	Near Infrared Mapping Spectrometer Subsystem
RADAR	Titan Radar Mapper
RPWS	Radio and Plasma Wave Spectrometer
RSS	Radio Science Subsystem
S-G	self-gravity
SNR	signal to noise ratio
SOI	Saturn Orbit Insertion
UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph
V	visible
VIMS	Visual and Infrared Mapping Spectrometer
VIS-IR	visible-infrared
WAC	wide angle camera



THE VIMS BIBLIOGRAPHY SUMMARY

The Cassini VIMS and its team contributed to 373 peer-reviewed articles, book chapters, and reviewed conference proceedings. The publications span 29 years (and counting) from 1990 to 2018.

This bibliography was compiled from the online databases Scopus, Science Direct, and the SAO/NASA Astrophysics Data System. Generally, the databases were searched for “Cassini VIMS” as a keyword, and the returned entries were evaluated to determine if VIMS data were the main driver of a publication or made significant contributions to its scientific conclusions. Publications were also considered for inclusion at the recommendation of VIMS Science Team members based on the above criteria. These entries were assembled in an EndNote Database (available on request), and further organized and analyzed (also available on request).

The contributions appeared in 54 different publications in at least 5 different countries. Icarus published 198 of the references (53%), and 48 (15%) appeared in Planetary & Space Science. Geophysical Research Letters had 17 articles, all other sources had 10 or less. Twenty journals had only a single paper. Also represented were the proceedings of three conferences, eight books, and four graduate dissertations.

The references were categorized based on their target, discipline of study, and technique. Almost the same number of publications was contributed on the study of Saturn and on the study of Titan, 164 & 167 respectively. Also represented were Venus (2), Earth & its moon (5), Mars (1), Jupiter (23), stars (7), and the hardware and software systems used by the instrument (10).

There are 3,272 author listings in the bibliography, representing over 720 individuals. Three hundred and ninty-six of them appear only once, while P.D. Nicholson is the most prolific with 129 entries (Appearing in 35% of the references, representing 4% of the total author listings). The largest number of authors on a single paper is 34. The median number of authors for a reference is 7, the mode is 3.

Almost 190 different people lead the publications, with M. M. Hedman appearing as first author most often (15 times).

Citation numbers were collected for all but two of the entries. The VIMS h-index as calculated from the 371 references with available data is 47. The highest number of reported citations is 248, and the average is 21.

Further details of analysis are available on request. Please direct any requests, additions, or corrections to ejoseph@lpl.arizona.edu.

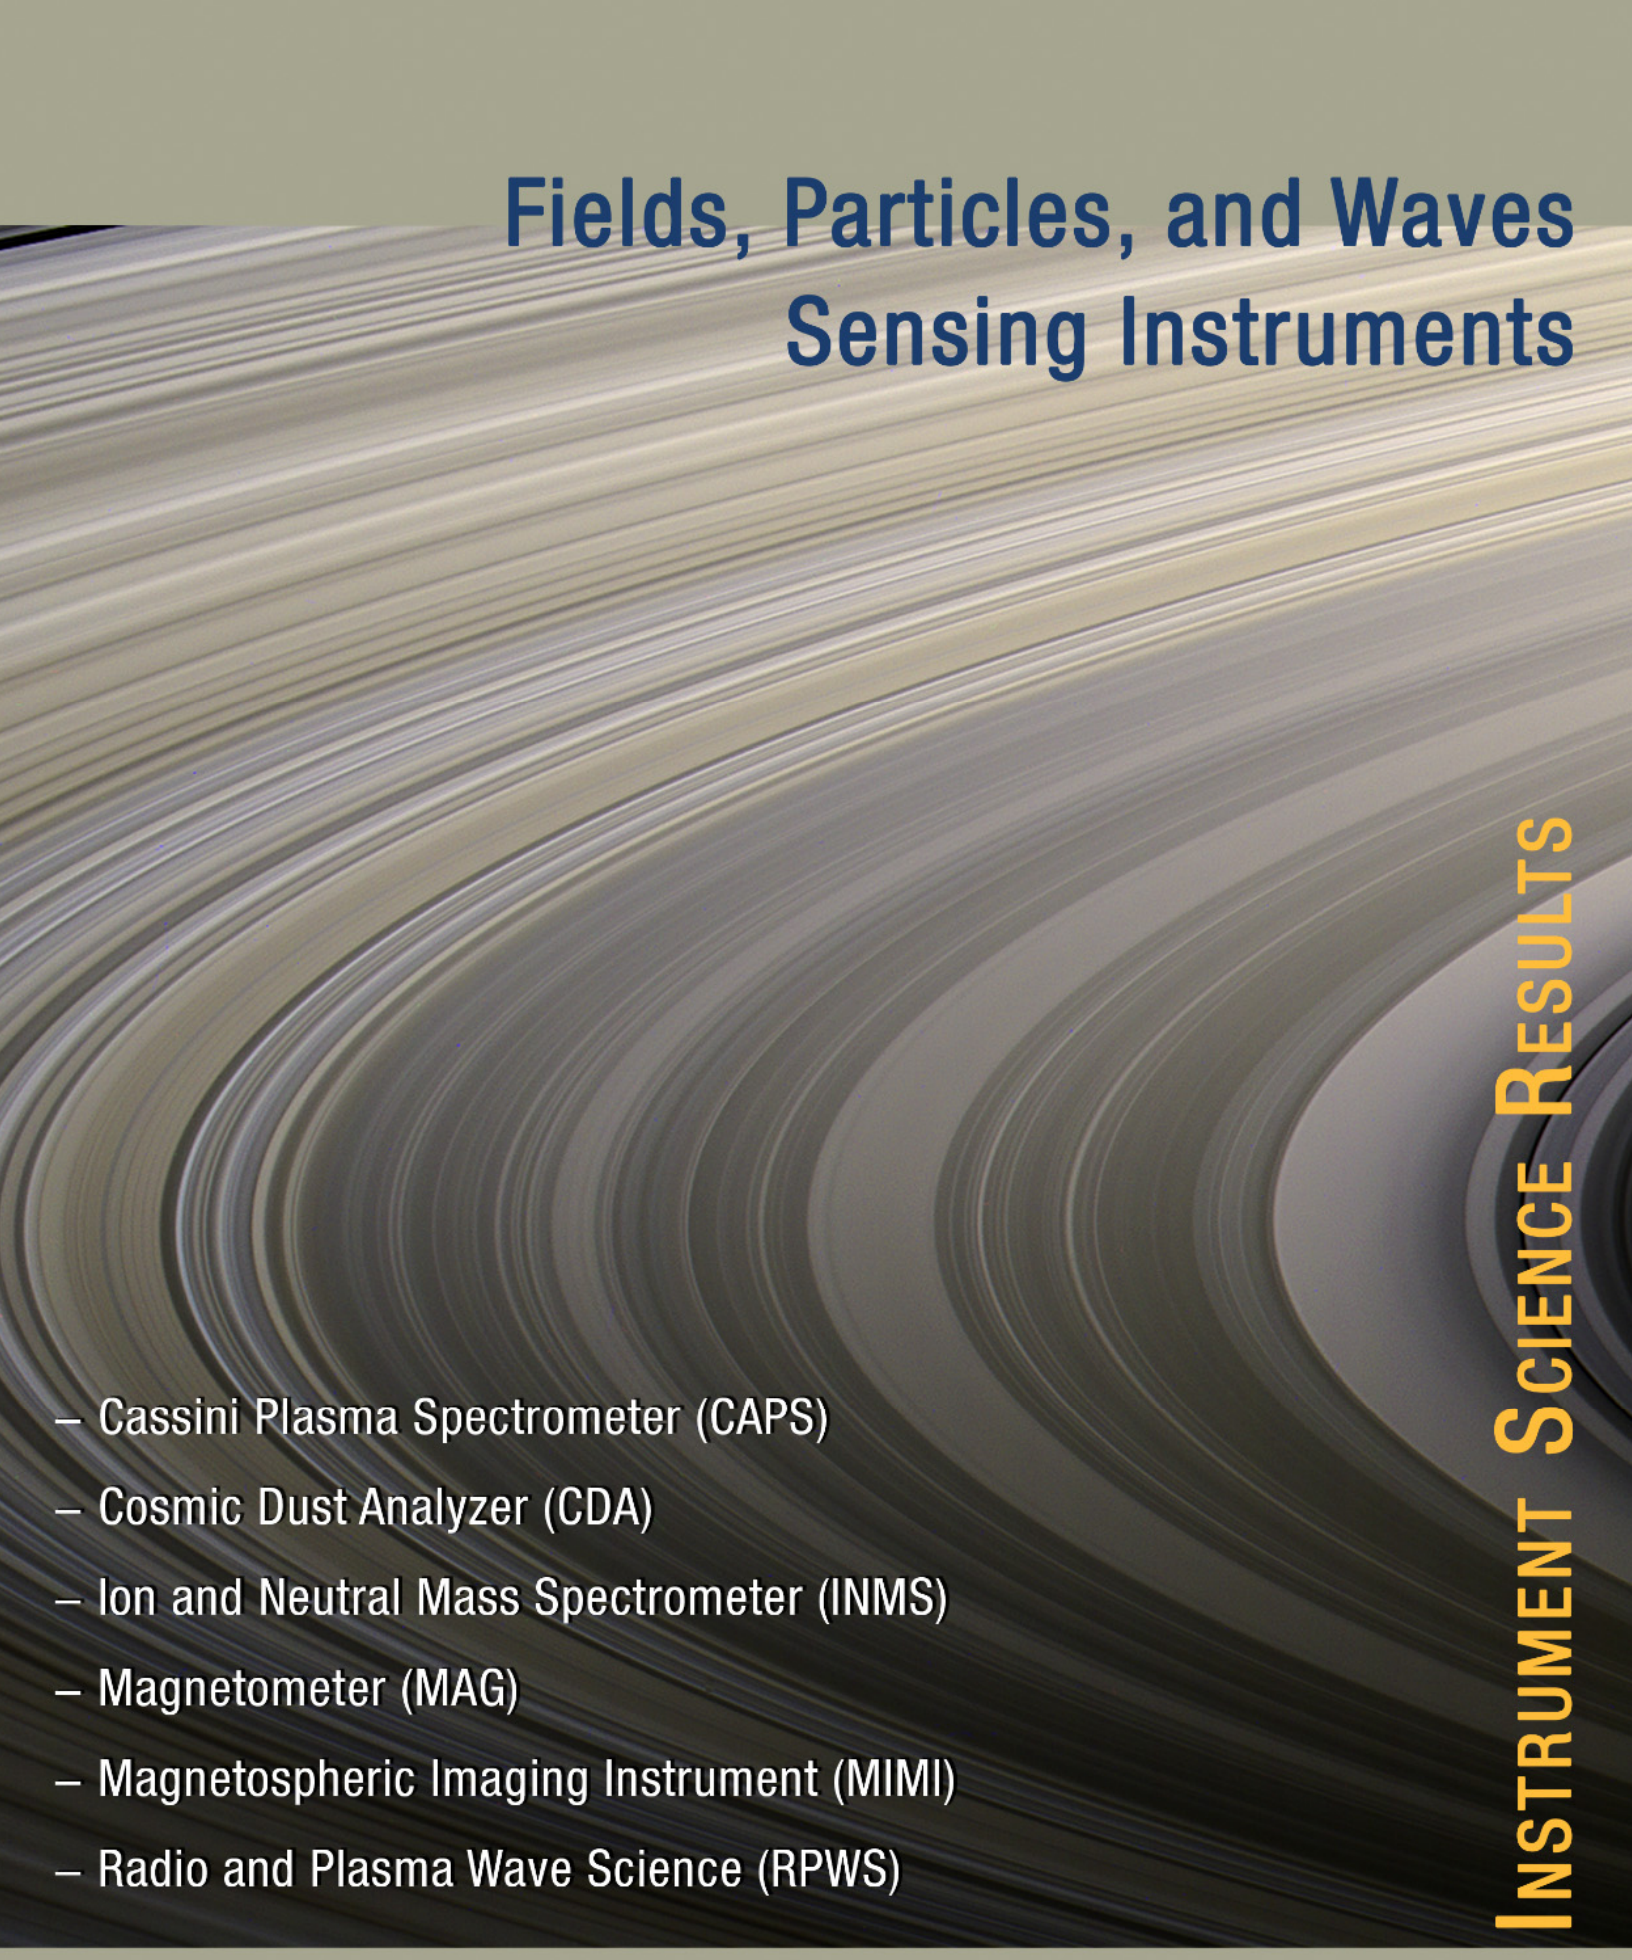
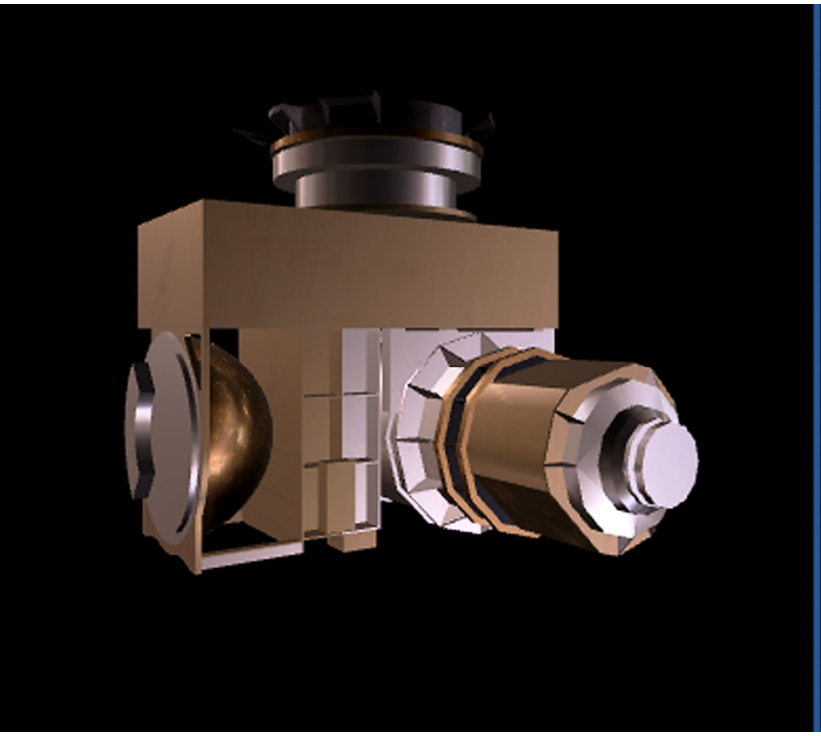
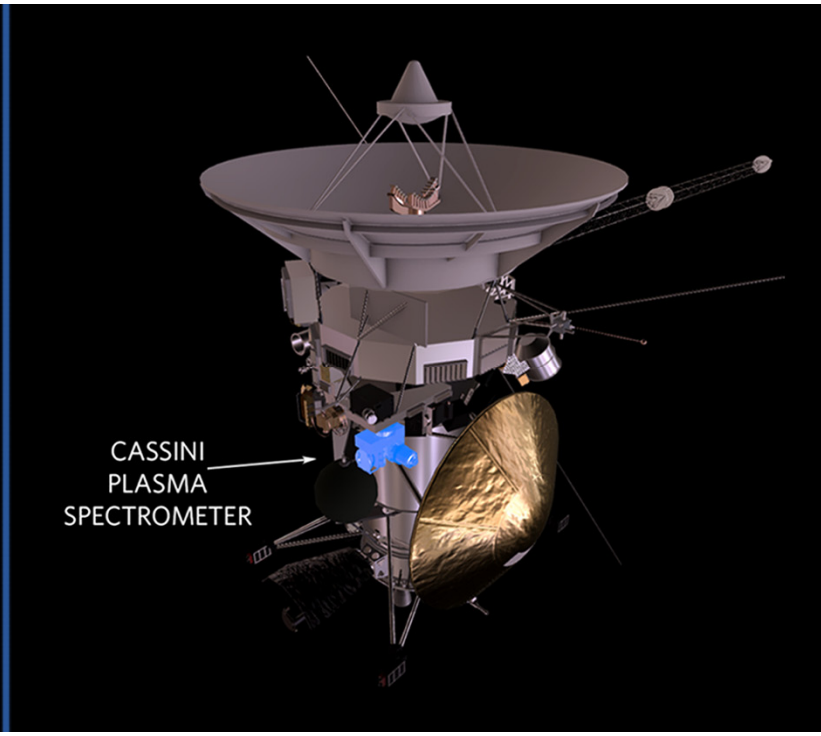
Fields, Particles, and Waves Sensing Instruments



- Cassini Plasma Spectrometer (CAPS)
- Cosmic Dust Analyzer (CDA)
- Ion and Neutral Mass Spectrometer (INMS)
- Magnetometer (MAG)
- Magnetospheric Imaging Instrument (MIMI)
- Radio and Plasma Wave Science (RPWS)

INSTRUMENT SCIENCE RESULTS





Cassini Plasma Spectrometer

The Cassini Plasma Spectrometer (CAPS) was an in situ instrument that investigated the plasma environment in and near Saturn's magnetosphere. CAPS made measurements of the plasma composition, density, flow velocity, and temperature. The **science objectives** of CAPS were to determine the sources of plasma in the magnetosphere, characterize dynamic magnetospheric processes, and study the interaction of plasma sources, including Enceladus, the rings, and Titan, with the magnetosphere.

CAPS comprised three sensors, a time-of-flight Ion Mass Spectrometer (IMS), an Electron Spectrometer (ELS), and an Ion Beam Spectrometer (IBS) that together measured the composition and velocity distributions of positively and negatively charged ions and electrons from approximately 1 eV to several tens of keV depending on the sensor. CAPS was mounted on an actuator platform that rotated the sensor fields-of-view parallel to the spacecraft Z-axis in order to compensate for 3-axis stabilization of the Cassini spacecraft.

EXECUTIVE SUMMARY

The CAPS instrument was designed to make comprehensive three-dimensional mass-resolved measurements of the full variety of plasma phenomena found in Saturn's magnetosphere. The CAPS science objectives can be broken into four general categories: 1) investigate the structure, composition, and boundaries of the magnetosphere; 2) identify plasma sources and sinks and the physical processes by which they are created and quenched; 3) understand dynamical processes of plasma acceleration, transport, and loss; and 4) study the interactions of plasma sources, including Enceladus, the rings, and Titan, with the magnetosphere.

> … CAPS made significant discoveries and contributions to our understanding of a wide range of phenomena including the unexpected composition and interactions of the ionospheres of Titan, Enceladus, and the rings, as well as the structure and dynamics of the magnetosphere.

By the end of CAPS operations, the investigation met all of the goals and objectives listed above, thereby fulfilling objectives laid out in the Announcement of Opportunity (AO) and Cassini Solstice Mission (CSM). In doing so CAPS made significant discoveries and contributions to our understanding of a wide range of phenomena including the unexpected composition and interactions of the ionospheres of Titan, Enceladus, and the rings, as well as the structure and dynamics of the magnetosphere. Examples of the former include discovery of massive negative and positive ions at Titan and Enceladus, while the latter include radial transport driven by centrifugal interchange instabilities and the massive co-rotating magnetodisk in the middle magnetosphere. CAPS also showed itself to be uniquely capable of measuring the composition and energy distributions of hot plasmas found in the magnetotail and outer magnetosphere. During cruise to Saturn CAPS made the first observations of interstellar pickup ions beyond the orbit of Jupiter as well as the sun's hydrogen shadow.

CAPS operated from checkout through the Cruise phase (1997 through 2004), the primary mission (2004 through June 2008), the extended mission (2008 through 2010) and well into the Solstice Mission (2010 through 2012). Due to an unfortunate and very unusual power anomaly (see National Electrical Safety Code (NESC) RP-12-00803) CAPS did not operate from June 2012 through the end of mission.

During cruise CAPS measured the plasma environments inside the Earth's magnetosphere, and the upstream solar wind, bow shock and magnetosheath conditions at Jupiter. Following the Jupiter swing-by, CAPS made its first major discovery when it captured the first direct, mass-resolved observations of heliospheric pickup ions (H^+, He^+, He^{++}, and O^+) beyond the orbit of Jupiter [McComas et al. 2004]. The neutral interstellar atoms corresponding to these ion species were ionized by solar ultraviolet (UV) and then picked up by the solar wind. The observations were made

between 6.4 and 8.2 astronomical unit (AU) consistent with gravitational focusing of the neutral atoms by the Sun.

During orbital insertion on July 1, 2004, CAPS discovered a completely unexpected atmosphere and ionosphere hovering over the main rings [Young et al. 2005]. The ring plasma is created by photon sputtering of ring ices, creating O_2 molecules that are ionized by solar UV, leading to an admixture of O^+, OH^+, H_2O^+ and O_2^+ ions between the F-ring and G-ring [Tokar et al. 2005].

CAPS contributions to understanding the complexity of the magnetosphere began with the ring plasma, followed by further discoveries of unusual plasma populations and phenomena with each new satellite encounter. During the initial flyby of Titan, the ELS, which was designed to measure electron velocity distributions, showed that in fact the high-altitude (~1000 km) ionosphere is rich in negatively charged ions with masses up to and greater than 13,800 amu/q. At the same time the IBS, designed primarily for solar wind and high Mach number flows, identified heavy positive ions with masses up to 350 amu/q and occasionally above 1000 amu/q [Coates et al. 2007a; Coates et al. 2010a] that were an extension of lower-mass (1 to 100 amu/q) ion spectra measured by Ion and Neutral Mass Spectrometer (INMS) [Coates 2005; Waite et al. 2005, 2007a]. Analysis of these data, combined with chemical modeling, suggests that the heavy ions are precursors of aerosols and tholins seen much lower in the atmosphere (~few hundreds of km). Estimates suggest that this process results in ~0.1 to ~1.0 metric tons per year of tholins added to the atmosphere. These discoveries, together with modeling of the atmosphere and its chemistry, reveal that Titan has what is easily the most complex atmosphere in the solar system.

Titan's ion wake is the most prominent example of Titan-magnetosphere interactions [Hartle et al. 2006b; Wellbrock et al. 2012]. It consists primarily of heavy (m/q ~16 and 28) and light (m/q = 1–2) ions stripped off by the co-rotating flow at a rate estimated to be ~0.3 to 4.0×10^{28} amu/q/s down Titan's wake (or tail as some prefer).

Extensive measurements of the distribution of ion density, temperature and flow velocity made over a period of 4.5 years have revealed the major structures and flow patterns in the magnetosphere [Thomsen et al. 2010]. From Voyager data it was expected that N^+ originating at Titan would be a major plasma component; however, Thomsen et al. [2010] established that water group ions (O^+, OH^+, H_2O^+ and H_3O^+ collectively referred to as W^+) are the dominant species, coming primarily from ion pickup near the orbit of Enceladus. Titan is a relatively weak source with most magnetospheric N^+ originating at Enceladus—yet another surprising feature of the chemical composition of Saturn's magnetosphere [Smith et al. 2008]. CAPS also found that the plumes of Enceladus contain large amounts of negative ions and heavy positive ions with a mass continuum that extends up into the tens of thousands of amu/q reaching into the realm of nano-grains at densities up to 10^3 particles/cm^3 [Hill et al. 2012]. It is thought that as plume gases are ionized they load and deflect the passing co-rotating magnetic flux tubes, leading to the addition of approximately 100 kg/s of fresh Enceladus plasma. This amount of mass loading was confirmed by an analysis of stresses in the distended magnetodisk located in the equatorial plane [Sergis et al. 2010]. Calculation of stress balance in the magnetodisk leads to estimates of a total mass

~10^6 kg for the closed portion of the magnetosphere. Extensive studies of magnetotail dynamics showed that the primary magnetospheric plasma sink is associated with plasmoid generation and subsequent losses down the magnetotail into the solar wind [Hill et al. 2008].

As the number of orbits piled up and their geometric relation to magnetosphere boundaries changed with local time and latitude, the structure of the magnetosphere became apparent. The distribution of plasma is highest near the orbit of Enceladus (3.95 R_S) with an average density ~100 ions/cm^3 and then drops by a factor of ~1000 near ~16 R_S [Thomsen et al. 2010]. Plasma structures in Saturn's magnetosphere do not appear to have strong long-term annual or seasonal variability although on scales of hours to days plasma structures created by interchange instabilities create marked variation in plasma properties [Hill et al. 2005].

From the very first orbits passing through the high-altitude magnetosphere, it was apparent that the magnetosphere is far more dynamic than previously thought. Hundreds of plasma injection events were observed in which hotter plasma from beyond ~10 R_S invaded cold plasma deeper in the magnetosphere. Detailed analysis revealed that the injections were the result of a centrifugal instability set up by forces generated by the co-rotating inner magnetosphere [Hill et al. 2005]. Transport driven by these instabilities is largely responsible for moving the hundreds of kilograms of plasma produced by Enceladus into the outer magnetosphere.

Many plasma observations and analyses featured data collected simultaneously by most if not all of the particles and fields instruments. Prior to the mission it was understood that collaboration by the entire Magnetospheres and Plasma Science (MAPS) suite (CAPS, INMS, MAG, MIMI, and RPWS) was essential to the success of Cassini, and would lead to synergistic science opportunities on many spatial and temporal scales. A glance at the references included with this report, and the complete CAPS publication list of papers in the refereed literature, shows that the goal was indeed achieved.

The CAPS investigation team met or exceeded all of the objectives of both the Primary and Cassini Solstice Missions.

CAPS operated for the first eight years of the Cassini mission before a power anomaly forced the instrument to be turned off in 2012 [NASA Engineering and Safety Center (NESC)-2013]. Understandably this left behind numerous science questions (see the section below on Top Open Questions). Thus there are many significant issues remaining, one in particular is the processes responsible for creating heavy negative and positive ions in the atmosphere of Titan and the plumes of Enceladus. Other important open questions about the magnetosphere include: how is plasma transported outward, and magnetic flux returned inward, in the region between 12 and ~20 to ~25 R_S? and where and how does the magnetosphere unload tons of cold, dense plasma?

As this cursory summary shows, the CAPS investigation met or exceeded all of the objectives of both the Primary and Cassini Solstice Missions. During the Primary Mission CAPS achieved all of its highest-priority goals and major objectives. Moreover, serendipity at Titan and Enceladus

allowed CAPS ELS to make the completely unanticipated discovery of negative ions in both ionospheres. This, and heavy positive ion measurements by IBS, have led to an entirely new understanding of the chemistry of planetary atmospheres with features that were not anticipated in the initial instrument objectives. CAPS measurements of the global composition of the magnetosphere, the surprisingly wide range of plasma sources and sinks, and the primary drivers of plasma transport all mark major contributions to our understanding of magnetospheric physics. Solstice Mission objectives were to enhance our knowledge of the general workings of the magnetosphere and to increase our understanding of long-term temporal variations in plasma sources and sinks from one solstice to the next.

Top Science Highlights

1. Discovered heavy negative ions with masses up to and greater than 13,800 amu/q, and heavy positive ions with masses up to and greater than 1000 amu/q in Titan's upper atmosphere.

2. Discovered that the newly found massive ions are precursors to the formation of atmospheric aerosols and tholins that form the haze components of Titan's upper atmosphere, and that may eventually settle to its surface.

3. Discovered that the plumes of Enceladus contain heavy negatively and positively charged water cluster ions and ice grains with masses extending well above 10,000 amu/q.

4. Discovered that the Enceladus plume emits ~100 kg/s of water-based ions (O^+, OH^+, H_2O^+ and H_3O^+) that become the dominant source of plasma in the magnetosphere.

5. Discovered that Enceladus, not Titan, is the primary source of nitrogen ions in the magnetosphere as was previously thought from Voyager data.

6. Discovered that the main rings of Saturn have an atmosphere consisting of molecular oxygen and water ion products.

7. Discovered that plasma found outside the edge of the A-ring is quenched by nanograins from the rings.

8. Discovered that the ring atmosphere changes with season because of changes in illumination by solar UV.

9. Discovered molecular oxygen exospheres around Dione and Rhea and a dust ring or halo at Rhea.

10. Discovered hydrogen ion outflows leaving Saturn's high latitude atmosphere along magnetic field lines.

11. Discovered hundreds of hot plasma injections in the middle magnetosphere. These result from centrifugal interchange instabilities that drive the radial transport of plasma out of the inner magnetosphere.

12. Discovered a massive heavy-ion co-rotating magnetodisk in the middle magnetosphere weighing ~1000 tons.

13. Discovered an unknown and unexplained plasma convection pattern in the inner magnetosphere that displaces plasma inward near local midnight and outward near noon.

14. Discovered plasmoids carrying water ions down the magnetotail at distances greater than 3 million km at a rate consistent with removal of plasma originating from Enceladus.

15. Discovered that both Dungey-style and Vasyliunas-style reconnection events, which propel plasma down the magnetotail, may occur depending on solar wind conditions.

16. Discovered heliospheric pickup ions (H^+, He^+, He^{++}, and O^+) beyond the orbit of Jupiter. This is the first evidence for interstellar helium atoms and is only the second observation of the Sun's hydrogen shadow.

17. Discovered that Jupiter's bow shock and magnetosheath extend as far as 700 Jupiter radii downstream from the planet.

Top Open Questions

1. What are the chemical and physical mechanisms that create and destroy large negative and positive ions at Titan, and what are their lifetimes?

2. Sunlight clearly plays a key role in determining the maximum negative ion masses found in Titan's atmosphere, but does it control production, loss, or the balance between the two?

3. What is the mechanism causing heavy ions in Titan's atmosphere to form aerosols? And do the aerosols then grow to form tholins? Or are they all the same thing?

4. Are heavy ions (above ~100 amu/q) at Titan picked up by co-rotating plasma, and negative ions picked up in a way that is analogous to positive ions? If so then what is their fate? Are they ejected or destroyed?

5. The loss mechanisms for some species such as N_2 and CH_4 are critical to understanding Titan's atmosphere. Can the daughter ion species be detected in the magnetosphere and the loss rates estimated?

6. What are the chemical and physical mechanisms that create and destroy large negative and positive water ions and neutrals in the Enceladus plume?

7. How are the nano-grain ice-particles in the Enceladus plume formed?

8. How is cold heavy plasma transported outward from the middle magnetosphere (~12 R_S) and magnetic flux returned from the outer magnetosphere (~25 R_S)?

9. Where and how does the magnetosphere unload its cold, dense plasma?

10. How do the sources of magnetospheric plasma (Enceladus plumes, Titan's ionosphere, Saturn, solar wind) match up with the sinks removing plasma (solid surface adsorption, reconnection and plasmoids) to keep the mass budget of the magnetosphere in equilibrium? Does this change with season?

11. What role does the ring atmosphere play in determining the composition of Saturn's upper atmosphere?

12. What causes the inner magnetosphere's dawn-ward convection that drives the noon-midnight asymmetry in plasma temperature, plasma density, energetic particle intensity, etc.?

13. What determines the scale size and inflow speed of interchange injections, and what determines the apparently variable rate and depth of such injections?

14. What is the relationship between large-scale, tail-reconnection-driven plasma injections and small-scale interchange injections?

15. Jupiter's magnetosheath was observed as far as 700 R_J downstream—how far does it extend?

Instrument Summary

The CAPS instrument was a novel design comprising three high-performance sensors that together measured the velocity distributions of electrons and ions from approximately one electron volt (eV) to several tens of kiloelectron volts (keVs) [Young et al. 2004]. The CAPS sensors exceeded their design goals, leading to discoveries of new charged particle populations that reveal the magnetosphere and Saturn's satellites to be a far richer and more complex environment than earlier Voyager data and scientific modeling would have led us to believe. In particular, the discovery at Titan of heavy and ultra-heavy negatively and positively charged ions will lead the way to an understanding of the origin and growth of tholins in Titan's atmosphere. The discovery at Enceladus of a broad range of charged particles including heavy and ultra-heavy negatively and positively charged ions, charged water cluster ions, and charged nano-grains, has helped establish the unique characteristics of the plumes as well as chemical and ionization processes in dusty plasmas.

The photograph in Figure CAPS-1 shows the location and orientation of the three sensors (arrows point to their apertures), and the data processing unit (DPU) which contains command and control electronics, data processors, spacecraft interfaces, and most of the low- and high-voltage power supplies. The entire instrument including the DPU is mounted on an actuator capable of rotating the CAPS sensors through a range of 160º parallel to the spacecraft z-axis at a nominal rate of 1°/s. This compensates in part for the three-axis stabilization of the Cassini spacecraft. Figure CAPS-2 is a cross-section of the optical design of the three sensors in simplified form.

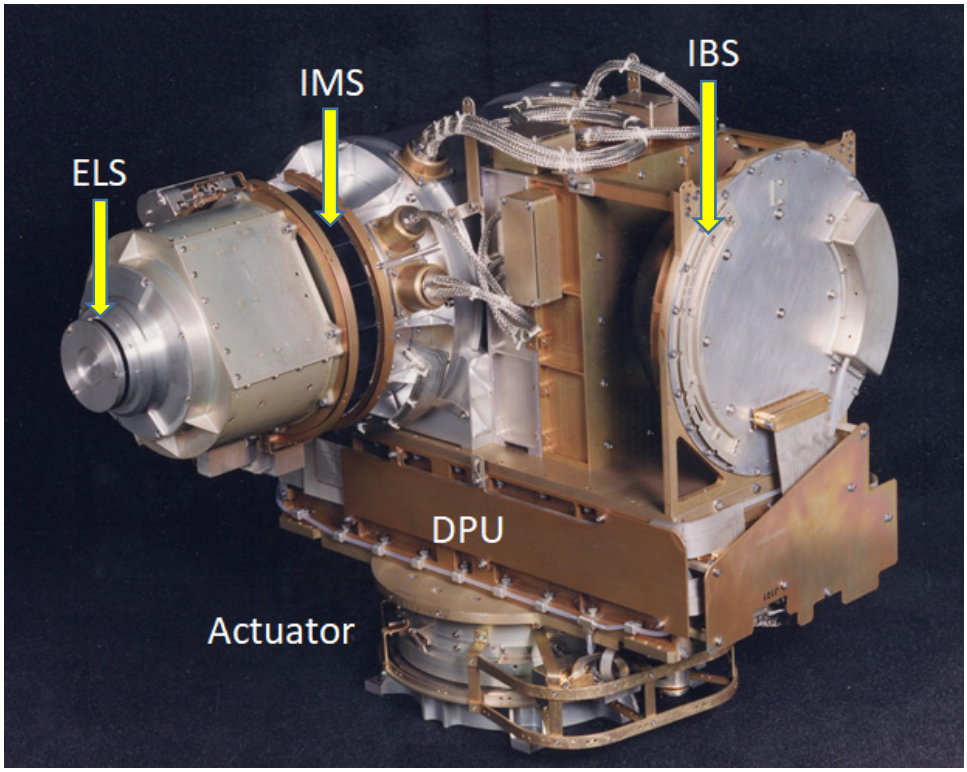

Figure CAPS-1. The CAPS flight unit prior to integration on the Cassini spacecraft late in 1997.

The ELS is an electrostatic energy-angle analyzer that measures electron velocity distributions with medium energy resolution ($\Delta E/E = 0.17$) and azimuthal resolution $\Delta\alpha = 5.2º$ (the angle α is in the plane of the drawing). ELS covers an elevation range of 160° in elevation with a resolution of $\Delta\beta = 20°$ corresponding to eight sectors on the microchannel plate detector. (These response characteristics were chosen to match those of the IMS.) As for all three CAPS sensors the azimuthal range of coverage when the instrument is scanned is ~160° corresponding to the actuator rotation range (the actuator axis of rotation is perpendicular to the plane of the paper). The energy range of 1 eV to 28 keV is sufficient to cover thermal energy electrons found near the icy satellites and rings and all but the most energetic trapped populations found in the outer magnetosphere. A scan over the energy range requires 2.0 s.

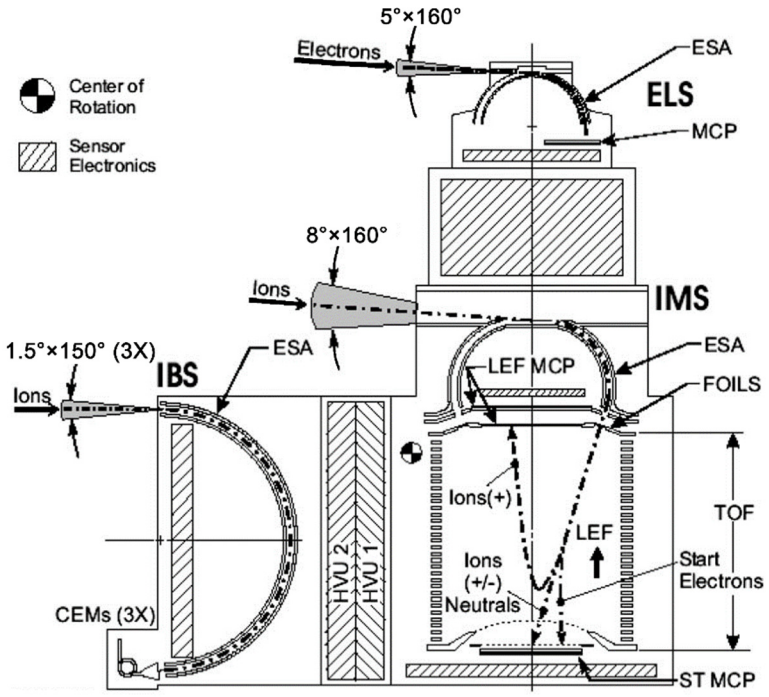

Figure CAPS-2. Cross-section of the three CAPS sensors showing schematic optical paths.

An important feature of the ELS that was not anticipated prior to arrival at Saturn was its ability to measure negative ions as well as electrons. Some scientists miss the point that an energy/charge analyzer is insensitive to the mass/charge of particles passing through its electric field and reaching the detector. It is easy to see why this is the case. The centrifugal force on a charged particle is $F = mv^2/qR_0$, where R_0 is the central radius of the analyzer and the velocity squared of the same particle is $v^2 = (2\ E/q)/(m/q)$, E/q is ion energy/charge, and m/q is its mass/charge. If we substitute the second equation into the first, then m/q cancels out and the force bending the particle through the analyzer is dependent only on energy per charge: $F = 2\ E/qR_0$. The ELS energy distribution can then be converted from E/q to $m/q = 2\ E/qV_{SC}^2$ where V_{SC} is the spacecraft ram velocity (this equation is conceptual—the actual conversion from ion energy to mass/charge must account for both the ELS passbands and the thermal velocity of the measured distribution).

ELS sensitivity, like those of the other two CAPS sensors, is proportional to its geometric factor G, which is defined such that:

$$C = J\ G\ \Delta t,$$

where C is the detector counting rate in counts/s, J is the differential particle energy flux in eV/cm^2 s sr eV, and Δt is the sampling interval in seconds. The geometric factor is made up of several elements and in its approximate (conceptual) form is given by:

$$G \sim A\ \varepsilon\ \tau\ \Delta\alpha\ \Delta\beta\ \Delta E/E,$$

where A is the effective analyzer sensitive area in cm^2, ε is the detector efficiency in counts/ion, τ is the transmission of any grids in the optical path (dimensionless), Δα and Δβ (radians) are the angle passbands introduced above, and ΔE/E is the energy passband (in units of eV/eV). The geometric factor of ELS is calibrated to be $G = 1.4 \times 10^{-2}$ cm^2 sr eV/eV.

The IBS is also an electrostatic energy-angle analyzer, but with the very high resolution required to resolve high Mach number ion flows (~10 or greater) found in the solar wind in the outer solar system, and during flybys through the cold ionospheres of Titan and Enceladus. An advantage of this design that turned out to be far more important than anticipated, is that the high spacecraft flyby velocities (~7 km/s at Titan) and low ion thermal speeds (<100 m/s) yielded very high Mach number flows in the spacecraft frame of reference that allowed IBS to effectively resolve ion velocity distributions into mass spectra.

IBS energy resolution is ΔE/E = 0.014 with an angle resolution in azimuth x elevation of Δα × Δβ = 1.4° × 1.5°. Although the range in azimuth is very limited by its high resolution, IBS has an unresolved elevation response of 160° for a single detector (out of three). IBS energy range is 1 eV to 50 keV which is covered in 2.0 s. The very high resolution makes the IBS sensitivity of 4.7×10^{-5} about two orders of magnitude smaller than that of the other two sensors.

The IMS is a time-of-flight (TOF) ion mass spectrometer that has certain advantages in terms of sensitivity, energy range and mass resolution in comparison to other types of mass spectrometers flown on space missions [Young et al. 2004]. Figure CAPS-2 shows a cross-section schematic of the IMS optics.

The IMS measures ion energy and angle distributions with a resolution similar to ELS (ΔE/E = 0.17 and Δα = 8.3°). Its elevation range, and resolution is the same as ELS: Δβ = 20° in eight sectors covering 160°. The IMS energy range is 1 to 50,000 eV which is covered in 4.0 seconds.

Ions enter the IMS via an electrostatic energy analyzer (ESA) operating on the same principle as the ELS and IBS sensors. After leaving the ESA ions are accelerated by 15 kV before striking one of eight ultra-thin carbon foils (~1 $\mu g/cm^2$) and entering the TOF analyzer. As ions leave the foils they emit secondary electrons that strike the Straight Through (ST) microchannel plate (MCP) detector, initiating timing electronics. When ions (which may be positive, negative, or neutral) strike either the ST or LEF detectors (Figure CAPS-2) the event stops the timing and the ion TOF is recorded together with ion energy and angle of arrival.

IMS makes two independent TOF measurements, medium and high resolution. Medium resolution measurements are made with ST optics (Figure CAPS-2) at M/ΔM ~8 with a range M/q 1 to ~400 amu/q. The sensitivity in this mode is typically ~5×10^{-3} cm^2 sr eV/eV depending on ion species and energy. High resolution measurements are made with time-focusing linear electric field (LEF) reflectron optics at resolutions M/ΔM ~60 depending on ion energy and species. The mass range in this mode is 1 to ~100 amu/q.

Ion mass/charge is given approximately by the simple equation $M/q \approx 2E/q\ (T/L)^2$ where E/q is ion energy/charge, T is the time-of-flight, and L is the effective distance the ion travels from carbon foil to detector about 18 cm. However, this equation is only approximate because energy lost in the foils and optics has to be considered and the flight distance depends on the angle at which the ion leaves the foil.

This abbreviated description of the IMS optics makes clear that there are several factors dependent on averages over random processes that affect TOF measurements. The width of the TOF peaks, and therefore mass resolution, are affected by ESA energy resolution, by scattering in the carbon foils and the effect that that has on trajectories. Sensitivity depends on ion species, transmission through the foils, and the secondary electron yield of the foils and the two detectors. In addition, "ghost" peaks caused by scattering may appear, further complicating TOF spectra. The complexity of IMS optics and electronics, and its dependence on random atomic processes that are essential to its functioning, were addressed by extensive pre-flight calibration as well as post-flight calibration of a high-precision ion optical model, and extensive numerical simulations. In the end these post-flight efforts allowed accurate determinations of even minor ion species. Prominent examples are measurements of very small amounts of nitrogen and nitrogen-bearing compounds in the outer magnetosphere [Smith et al. 2005, 2007, 2008].

> The complexity of IMS optics and the multiple random processes that contribute to CAPS measurements of mass spectra were addressed by extensive post-flight calibration of a high precision model of the optics, and literally years of numerical simulations.

CAPS collects data based on two measurement cycles. During the shorter A-Cycle (32 seconds) CAPS acquires ion and electron count rate distributions consisting of energy × eight elevation-angle "pixels" × TOF (in the case of IMS). The longer B-Cycle (256 seconds) consists of 8 A-Cycles and corresponds very roughly to the amount of time needed for the CAPS turntable, which moves approximately 1°/s, to rotate through an azimuth range of ~160°. Data are acquired and buffered for one B-Cycle in one side of a ping-pong memory while a second B-Cycle is acquired in the other side. The first side is then read out to telemetry and the next cycle of data acquired.

A critically important aspect of the CAPS instrument that greatly affected scientific aspects of the investigation was that because CAPS was mounted on the Particles and Fields Pallet, which is fixed to the spacecraft (Figure CAPS-3), it was not possible to view the full sky (4π sr) at any one time. Being able to scan the entire sky is critical to plasma observations because plasma distributions are seldom isotropic and are typically distorted in many ways (e.g., field-aligned, pancaked, rammed), all of which are key to understanding the phenomena causing the anisotropy in the first place.

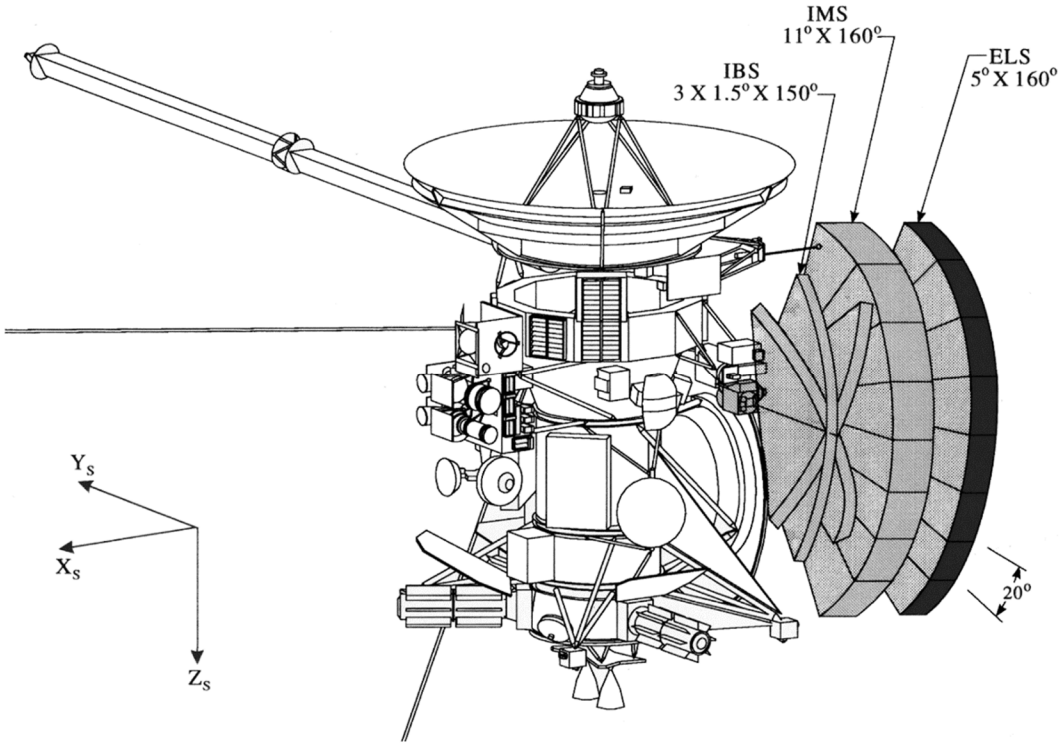

Figure CAPS-3. Location of CAPS on the Fields and Particles Platform showing the sense of CAPS rotation and location of the fields-of-view.

To address the problem of a limited field-of-view (FOV) the design team began by mounting the entire complement of CAPS sensors and the DPU on an actuator (ACT) capable of scanning the sensor FOVs around an axis parallel to the spacecraft Z-axis over a range of ±104° centered on the spacecraft −Y axis. After launch there was an indication that CAPS rotation caused it to snag on a piece of multi-layer insulation (MLI) thermal protection blanket. Out of caution that CAPS might get stuck in one position for the remainder of the mission the ACT scan was limited to +104° (the direction along the spacecraft +X axis) and −80°.

Limited to a scan range of 184° about the Z-axis, the ACT solved only part of the FOV access problem and only in the azimuthal direction. When combined with the elevation acceptance angle of 160° and protrusions of portions of the spacecraft into the FOV (i.e., the high gain antenna, Radioisotope Thermoelectric Generator (RTG) shielding, and other instruments on the pallet—see Young et al. [2004] and Figure CAPS-5) the solid angle commanded by CAPS was limited to approximately 5.8 sr or about 45% of the full sky.

The solution to these limitations was to rotate or otherwise re-orient the spacecraft to enable CAPS (as well as other MAPS particle instruments) to observe a region of the sky closer to 4π sr, albeit slowly. This made operations more difficult for CAPS, MAPS, remote sensing instruments, and indeed the entire spacecraft operations team (see Cassini Final Mission Report Volume 5: Mission Operations System Performance Assessment).

Calibration of ELS and IBS, which are conventional plasma energy-angle analyzers, was relatively straightforward. Calibration of IMS was an entirely different, and far more complex, matter. Figure CAPS-4 shows an example of IMS calibration data taken in an ion beam of m/q = 16 ions. The mass separation optics used to form the calibration ion beam did not have resolution sufficient to separate ion species with virtually the same m/q, it was possible to form beam containing O^+, NH_2^+ and CH_4^+ simultaneously and use it to probe the ability of IMS to separate these species using TOF.

Figure CAPS-4 shows a sample of IMS straight-through (ST) and LEF calibration data from a beam containing O^+, NH_2^+ and CH_4^+at 1024 eV, one of the standard IMS calibration energies. The LEF spectrum shows H^+ and C^+ from the breakup of CH_4^+ in the foils, H^+ and N^+ from the breakup of NH_2^+, and O^+ and O^{++} from oxygen ions in the beam. This spectrum demonstrates the ability of the IMS TOF system to separate three ion species with nearly identical mass/charge ratios that could not otherwise be separated by conventional magnetic or quadrupole spectrometers flown on space missions. The ST spectrum shows H^- ions from the breakup of NH_2^+ and CH_4^+ together with C^- from the latter and O^- from oxygen. All three species in the calibration beam produce neutral atoms that show up as a single peak. There are two ghost peaks centered at 250 and 270 channels caused by electrons leaving structures around the LEF detector and reaching the ST detector. These can be identified and calibrated out.

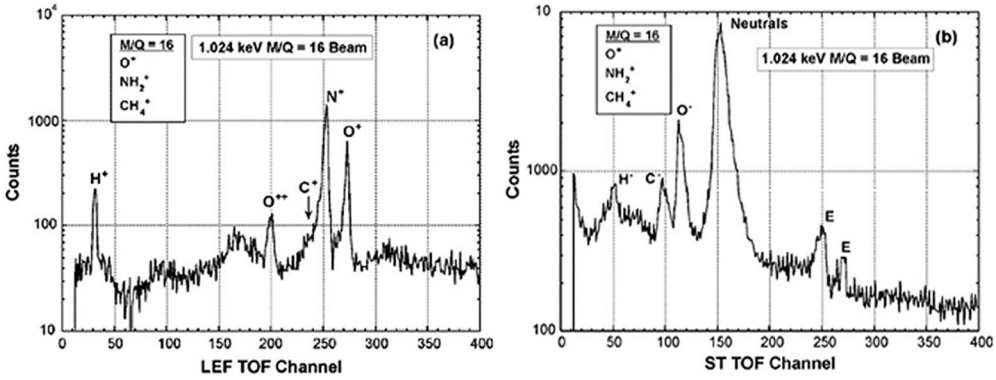

Figure CAPS-4. IMS TOF calibration data for an input beam of M/q = 16⁺ ions at 1024 eV.

Key Goals and Objectives of the CAPS Investigation

The overarching scientific objectives of the CAPS investigation spelled out in the AO were to perform the highest quality measurements that would allow the CAPS team to understand the physical, compositional, and temporal characteristics of Titan's ionosphere, the icy satellites, the rings, and Saturn and their interactions with Saturn's magnetosphere. A second goal was to achieve those measurements with a quality that was at least ten times better than that of Voyager since their measurements and analysis had been considered the gold standard for studies of Saturn's magnetosphere. In fact, it was data from the Voyager mission that were used to develop the CAPS science objectives, performance guidelines, and sensor requirements. In the following section we briefly summarize the specific objectives of the CAPS investigation.

Note: In the short discussion of AO and CSM objectives given below there are several sections in which we hybridized goals by combining objectives such as Titan-Magnetosphere Interactions, Rings-Magnetosphere Interactions, etc. In those sections we list and discuss objectives from both disciplines, e.g., Titan-Magnetosphere Interactions contains both Titan and Magnetosphere AO and CSM Objectives in order to capture the full breadth of the science objective.

Titan

Because of its mass-resolving capabilities, the CAPS investigation was expected to contribute to measurements of the overall composition and abundances of complex and trace ions in the upper atmosphere (**T_AO1, T_AO2, T_AO5, TN1c**), and explore their vertical and horizontal distributions (**T_AO2**) as well as seasonal dependence (**TC1a**) in order to help determine the evolution of Titan's atmosphere. CAPS contributed also to understanding the magnetosphere as a source of ionization at Titan, and the contribution made by Titan to the outer magnetosphere (**T_AO5**).

Titan AO objectives

- **Titan Atmospheric Formation and Evolution (T_AO1):** Determine abundances of atmospheric constituents (including any noble gases), establish isotope ratios for abundant elements, constrain scenarios of formation and evolution of Titan and its atmosphere.
- **Titan Atmospheric Composition and Distribution (T_AO2):** Observe vertical and horizontal distributions of trace gases, search for more complex organic molecules, investigate energy sources for atmospheric chemistry, model the photochemistry of the stratosphere, study formation and composition of aerosols.
- **Titan Upper Atmosphere (T_AO5):** Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.

Titan CSM objectives

- **Titan's Great Seas (TC1a):** Determine seasonal changes in the methane-hydrocarbon hydrological cycle of lakes, clouds, aerosols, and their seasonal transport.
- **Determine intrinsic and/or internal induced magnetic field (TN1b):** Characterize possible inducing magnetic fields by measuring the draping of the magnetic field. Study the decay of ionospheric magnetic fields.
- **Measure aerosol and heavy molecule layers and properties (TN1c).**

Titan-Magnetosphere Interactions

- With sensors that functioned as both energy and mass analyzers CAPS was uniquely positioned to study the interactions between Titan and the magnetosphere (**M_AO4**), and the reverse situation (**M_AO5**), including specifically contributions to the magnetodisk (**TC2a**) which, it turns out, was very little. Measurements of heavy ion layers (**TN1c**) were a continuation of the (**T_AO1**) objective to study atmosphere/ionosphere composition. Plasma flow past Titan drags magnetospheric magnetic field lines across Titan's ionosphere inducing magnetic fields that may affect the ability to observe intrinsic fields (**TN1b**).

Titan-magnetosphere AO objectives

- **Titan Atmospheric Formation and Evolution (T_AO1):** Determine abundances of atmospheric constituents (including any noble gases), establish isotope ratios for abundant elements, constrain scenarios of formation and evolution of Titan and its atmosphere.
- **Magnetosphere and Solar Wind Interactions with Titan (M_AO4):** Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.
- **Plasma Interactions with Titan's Atmosphere and Ionosphere (M_AO5):** Investigate interactions of the surrounding magnetospheric plasma with Titan's atmosphere and exosphere.

Titan-magnetosphere CSM objectives

- **Titan-Magnetosphere Interaction (TC2a):** Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.
- **Titan Atmospheric Composition (TN1c):** Measure aerosol and heavy molecule layers and properties.

Enceladus

CAPS was uniquely able to measure both negative and heavy positive ions from Enceladus plumes (**M_AO2**) together with charged nano-grains over a long period of time, thus contributing to our understanding of plume composition and variability (**MC1a**) as well as surface composition from material falling back to the surface (**I_AO3**). Enceladus water-based plasma turned out to completely dominate the composition of the magnetosphere and, through mass loading, much of its dynamics (**I_AO5**).

Icy satellites AO objectives

- **Icy Satellite Surface Composition (I_AO3):** Investigate the composition and distribution of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles.
- **Icy Satellite Magnetosphere and Ring Interactions (I_AO5):** Investigate satellite interactions with the magnetosphere and ring systems and possible satellite gas injections into the magnetosphere.
- **Magnetosphere Charged Particles (M_AO2):** Determine current systems, composition, sources, and sinks of magnetospheric charged particles.

Icy satellites CSM objectives

- **Enceladus Plume Variability (MC1a):** Determine the temporal variability of Enceladus' plumes.

Icy Satellite Science

In addition to contributing in major ways to determining composition and sources and sinks of plasma (**M_AO2**), CAPS was able to identify and measure small amounts of plasma surrounding Dione, Rhea, and Tethys (**IN1c, IN2a, IN2b**), which went on to interact with the magnetosphere (**I_AO5**). Measurements of material returning from the magnetosphere to the satellite could be used to infer origins of surface coatings (**I_AO3**).

Icy satellites AO objectives

- **Icy Satellite Surface Composition (I_AO3):** Investigate the compositions and distributions of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles.
- **Icy Satellite Magnetosphere and Ring Interactions (I_AO5):** Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.
- **Magnetosphere Charged Particles (M_AO2):** Determine current systems, composition, sources, and sinks of magnetospheric charged particles.

Icy satellites CSM objectives

- **Dione (IN1c):** Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time. Investigate Dione's current level of activity.

- **Rhea (IN2a):** Determine whether there is ring material orbiting Rhea, and if so, what its spatial and particle size distribution is. Investigate the interaction of Rhea material with Saturn's magnetosphere.
- **Tethys (IN2b):** Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral populations.

Rings

Although CAPS could not participate in the final Cassini orbits over the rings, it did establish that there is an atmosphere and ionosphere formed by UV photolysis hovering over the main rings (**R_AO2**) with the resulting plasma moving along field lines connected to Saturn's ionosphere (**R_AO1, RAO_5**). An unexpected finding is that very clean O_2^+ and O^+ peaks in mass spectra indicate the dearth of contaminants in surface ices of ring particles (**RN1a**). The origin of locally formed negative ions is likely nano-grain particles ejected from the rings themselves (**R_AO4, RN1a**) which likely extend beyond the edge of the A-ring. Observed changes in the plasma composition outside the rings over time are caused by changes in solar UV illumination of the ring particles (**RC1a**).

Rings AO objectives

- **Ring Structure and Dynamics (R_AO1):** Study configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.
- **Ring Particle Composition and Size (R_AO2):** Map composition and size distribution of ring material.
- **Dust and Meteoroid Distribution (R_AO4):** Determine dust and meteoroid distributions both in the vicinity of the rings and in interplanetary space.
- **Ring Magnetosphere-Ionosphere Interactions (R_AO5):** Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.

Rings CSM objectives

- **Changing Rings (RC1a):** Determine the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near Solstice.
- **Ring Age and Origin (RN1a):** Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejecta trapped on field lines.

Rings-Magnetosphere Interactions

Material from the outer rings is found in the inner magnetosphere (**R_AO5**) while the rings are the major supplier of neutral H_2 ionized to form H_2^+ farther out in the magnetosphere and a highly seasonal supplier of neutral O_2 (**M_AO2**).

Rings-magnetosphere AO objectives

- **Ring Magnetosphere-Ionosphere Interactions (R_AO5):** Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.
- **Magnetosphere Charged Particles (M_AO2):** Determine current systems, composition, sources, and sinks of magnetospheric charged particles.

Magnetosphere Composition, Sources, Transport, and Losses

CAPS explored the structure of Saturn’s magnetosphere, which shares some features with Earth’s, whereas its composition is dominated by water-group ions produced by the plumes of Enceladus (**M_AO2, SC2a**). Many phenomena exhibit diurnal periodicities associated with the plasma sheet, but little in the way of seasonal variability except near the rings due to changes in UV illumination (**MC1b, SC2a**). Rather surprisingly, N^+ was shown to originate primarily at Enceladus and not Titan (**M_AO2, M_AO4, M_AO5**). Plasma outflows from Saturn’s ionosphere carry tens of kg/s of ions and field-aligned currents connecting Enceladus to its auroral footprint (**MN1b, SC2a**).

MAPS AO objectives

- **Magnetosphere Charged Particles (M_AO2):** Determine current systems, composition, sources, and sinks of magnetosphere charged particles.
- **Magnetosphere and Solar Interactions with Titan (M_AO4):** Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.
- **Plasma Interactions with Titan’s Atmosphere and Ionosphere (M_AO5):** Investigate interactions of Titan's atmosphere and exosphere with the surrounding plasma.

MAPS CSM objectives

- **Seasonal and Solar Cycle Variations (MC1b):** Observe Saturn’s magnetosphere over a solar cycle, from one solar minimum to the next.
- **Saturn’s Ionosphere and Radiation Belts (MN1b):** Investigate the temporal dependence and effects of solar wind coupling on the aurora, ionosphere, and magnetosphere. Probe for UV satellite footprints on Saturn.

- **Aurorae, Chemistry, and Upper Atmosphere (SC2a):** Observe the magnetosphere, ionosphere, and aurora as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.

Magnetosphere Dynamics

Plasma created in the Enceladus plume at a rate of 100 kg/s deep in Saturn's magnetosphere (**M_AO2**) is transported inward by scattering and outward by the centrifugal interchange instability (**M_AO3**) and eventually, primarily through plasmoid formation, is ejected down the magnetotail (**MN1a**). Dynamical processes (not yet understood) lead to periodicities in plasma characteristics near Saturn's rotation period that are associated with motion of the plasma sheet and possibly a plasma cam structure (**MN1a, MN1c**).

MAPS AO objectives

- **Magnetosphere Charged Particles (M_AO2):** Determine current systems, composition, sources, and sinks of magnetospheric charged particles.
- **Magnetosphere Wave-Particle Interactions (M_AO3):** Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.

MAPS CSM objectives

- **Magnetotail (MN1a):** Determine the dynamics of Saturn's magnetotail.
- **Magnetosphere Periodicities (MN1c):** Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the Saturn Kilometric Radiation (SKR) periods are imposed from close to the planet (3–5 R_S) out to the deep tail.

Shock, Magnetopause, Outer Magnetosphere

Cassini crossed Saturn's bow shock on numerous occasions as it and the magnetopause (average standoff 21 to 27 R_S) swept back and forth over the spacecraft (**M_AO3**). The magnetosheath flow carries both solar wind and W^+ ions, but there is little evidence for N^+ from Titan in part because its orbit lies just inside the average magnetopause distance from Saturn (**M_AO4**).

MAPS AO objectives

- **Magnetosphere Wave-Particle Interactions (M_AO3):** Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.

- **Magnetosphere and Solar Interactions with Titan (M_AO4):** Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.

Saturn

Both the aurora and SKR are dynamic phenomena controlled to varying degrees by both the solar wind and internal rotation of the magnetosphere. These dynamic phenomena have been observed to vary on all timescales from minutes up to the rotation period (~10 hours). They can be expected to vary on seasonal time scales because of the connection of the magnetosphere with the solar wind, which varies with solar activity (**SC2a**).

Saturn CSM objectives

- **Magnetosphere, Ionosphere and Aurora (SC2a):** Observe the magnetosphere and ionosphere as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.

Solar Wind

Measurements of the solar wind were carried out at intervals during cruise primarily to study the evolution of solar wind transients propagating through the solar system (**C_AO2**). CAPS also served as an upstream solar wind monitor during studies of Jupiter's magnetosphere (**J_AO3**) and helped show that Saturn's aurora is controlled by solar wind dynamic pressure (**SC2a**).

Cruise AO objectives

- **Cruise Solar Wind Investigations (C_AO2):** Investigate the behavior of the solar wind during solar minimum for comparison with earlier Galileo and Ulysses measurements.
- **Jupiter Magnetospheric Studies (J_AO3):** Explore the dusk side of the magnetosphere and intermediate regions of the magnetotail unvisited by previous spacecraft.

Venus

CAPS was not operating during the two Venus encounters.

Earth's Magnetosphere

Earth's magnetosphere was a target-of-opportunity with no specific objectives. CAPS operated for 10 hours upstream of Earth in the solar wind and then spent nine hours as Cassini flew through

virtually every major plasma structure in the magnetosphere. This gave an unusual cross-section freeze-frame snapshot including two substorms that took place during the fly-through.

Jupiter's Magnetosphere

Cassini flew down the Jovian magnetosheath in early 2001. The shock and sheath passed over the spacecraft about 40 times allowing observations that were shown to be consistent with a slow mode shock (**J_AO3**).

Jupiter flyby AO objectives

- **Jupiter Magnetospheric Studies (J_AO3):** Explore the dusk side of the magnetosphere and intermediate regions of the magnetotail unvisited by previous spacecraft.

Heliosphere

During cruise phase between Jupiter and Saturn, CAPS made the first observations of interstellar hydrogen, helium and oxygen as pickup ions (**C_AO1**). Modeling of the data also showed that Cassini was in the interstellar hydrogen shadow.

Cruise AO objectives

- **Interstellar Ion Composition (C_AO1):** Extend the sensitivity of composition measurements of interstellar ions by approximately three orders of magnitude.

CAPS Science Assessment

Table CAPS-1 shows the CAPS, AO, and Traceability Matrix (TM)/CSM Science objectives and the CAPS assessment.

Table CAPS-1 CAPS Science Assessment.

CAPS Objectives	AO and TM/CSM Science Objectives	CAPS Assessment
TITAN		
Atmospheric and ionosphere composition	T_AO1, TC1a, TN1c	
Ionospheric structure	T_AO2	
Magnetosphere interactions	T_AO5, T_AO6, M_AO5, TC2a, TN1b	
Seasonal variations	MC2a, TC1a

Detailed Magnetospheric Science Results

Composition of Titan's Atmosphere and Ionosphere

Discovery of heavy positive and negative ions

Before proceeding with this section, it should be understood that ELS and IBS, which are electrostatic energy/charge analyzers, have no intrinsic capabilities as mass spectrometers. Rather the detection of negative ions and very heavy positive ions, discovered by CAPS and discussed in detail below, is made possible because the ram velocity of the spacecraft in the Titan rest frame is far higher (at 6 to 6.4 km/s) than ion thermal speeds of at most a few hundred meters/s. Using the relationship $m/q = 2E/qV_{ram}^2$, where E is the ion energy and V_{ram} is the spacecraft velocity, the energy spectra of ions entering ELS or IBS (or for that matter IMS) can be treated as mass spectra albeit with relatively low mass resolution. Since ELS is designed to detect electrons, its measurements can be interpreted as negative ion mass spectra.

Measurements made by CAPS sensors between altitudes of 950 to 1400 km were responsible, along with those of INMS, for one of the major surprises of the Cassini mission—the high level of chemical complexity observed in Titan's ionosphere. From the earliest close encounters ELS detected heavy negatively charged ions with mass/charge up to 13,800 amu/q (Figure CAPS-5 and Fgiure CAPS-6). In addition, heavy positive ions up to ~350 amu/q [Crary et al. 2009] and as high as 1000 amu/q [Coates et al. 2010a] were detected by IBS. An unexpected level of chemical complexity was seen in the neutrals as well [Waite et al. 2007]. Before Cassini, models of Titan's chemistry had shown some complexity in the interaction of the neutral atmosphere with positive ions [Wilson and Atreya 2004]. The observations from Cassini necessitated more sophisticated modelling of the positive ion composition [Cravens et al. 2006, 2009]. The negative ion observations by ELS were completely unexpected at the altitudes sampled by Cassini, opening a whole new field for modeling and understanding the complex chemistry of Titan's atmosphere.

With these discoveries, Titan's ionosphere is now known to be the most chemically complex in the solar system. This complexity extends to altitudes sampled by Cassini and, based on models, even deeper in the atmosphere. Much of this complexity relative to other terrestrial planets, including Earth, is due to the cold, dense nitrogen-methane atmosphere and Titan's relatively low gravity compared to the other planets. CAPS pioneering discovery of large negative ions has been followed up by further studies of the spatial distribution and density of these ions on altitude and solar zenith angle [Ali et al. 2013; Wellbrock et al. 2013; Desai et al. 2017].

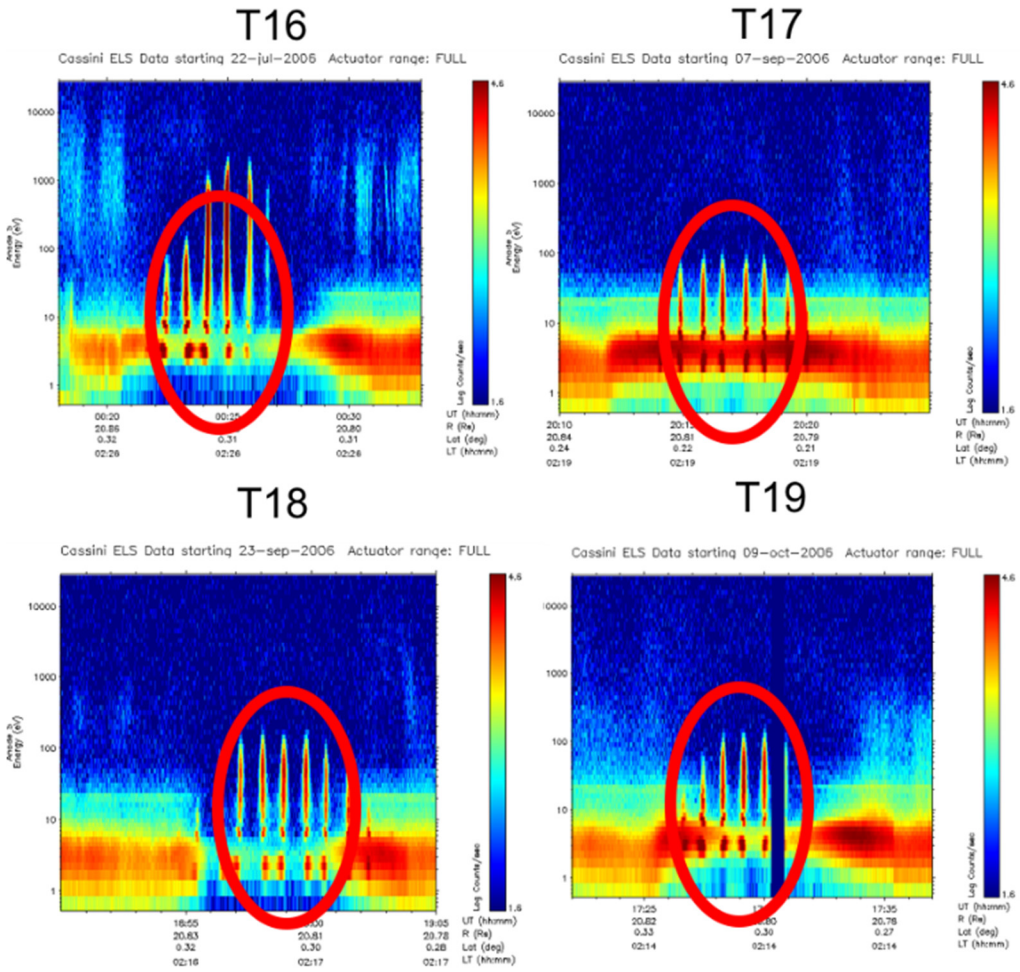

Figure CAPS-5. Energy-time spectrograms of negative ions taken over 15-minute intervals by CAPS ELS during successive Titan encounters T16, T17, T18, and T19. The sharp spikes encircled in red are compressed spectra measured each time the CAPS turntable swept the ELS field-of-view across the ram direction. Figure from Coates et al. [2007a].

Wellbrock et al. [2013] have shown that the highest densities of negative ions are found at lower altitudes. Moreover, the average altitudes where peak ion densities occur decrease with increasing ion mass. In addition, the maximum altitudes at which ions from a specific mass group are observed (the reference altitude) decrease with increasing mass group. This study provides the first step in investigating conditions which affect the densities of different negative ion mass groups.

The highest mass negative ions were observed during the T16 encounter (Figure CAPS-6). A recent analysis of this data shows that polar winter is where the heaviest negative ions are seen [Wellbrock et al. 2018]. This helps to constrain the chemical processes that produce these large ions.

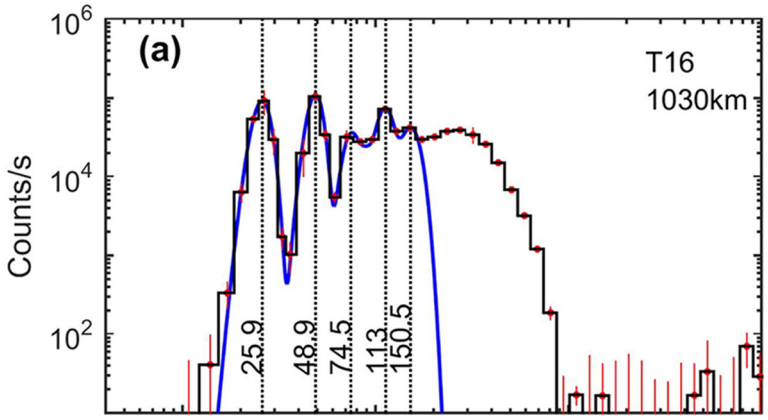

Figure CAPS-6. Fitting negative ion spectra using the instrument response function reveals that intermediate mass negative ions provide a steppingstone in producing the spectacularly heavy ions up to 13,800 amu/q [Desai et al. 2017]. The existence of negative ions was confirmed using RPWS Langmuir probe data, initially using observations at the lowest altitude encounter T70 [Ågren et al. 2012], where CAPS was not oriented in the ram direction for safety reasons, and subsequently at other encounters [Shebanits et al. 2016].

Chemical source of heavy ions

The relatively low-mass negative ions were identified as CN^-, C_3N^- and C_5N^- in the first chemical models used to describe the negative ions seen at these altitudes [Vuitton et al. 2009]. Considering several processes and estimating chemical reaction rates, they suggested that the most likely production process is dissociative electron attachment. They also suggested the most likely loss processes to be associative detachment supplemented by photo-detachment.

While some progress has been made on formation of higher mass ions, this topic is still under study. The geometric configuration of heavy ions is relatively unconstrained, and chains, rings or even fullerenes may be possible. Sittler et al. [2009a] have suggested that the latter may trap and transport oxygen [de Kok et al. 2007] to the surface although there are no observations that confirm this hypothesis. Agglomeration of large molecules caused by charging [Michael et al. 2011] or chemical processes [Lavvas et al. 2013] have been suggested as potential mechanisms to produce the large negative ions. However recent work by Desai et al. [2017] shows that chains of negative ions at intermediate masses may provide another pathway for heavy ion formation (Figure CAPS-7). Heavy negative and positive ions may also link up to form embryo aerosols of both negative and positive charge [Coates et al. 2007a; Crary et al. 2009].

Desai et al. [2017] use observations of negative ions by CAPS/ELS to show mass peaks where unsaturated carbon-chain negative ions such as CN^-/C_2H^-, C_3N^-/C_4H^-, C_5N^-/C_6H^-, etc., might exist (see also the comprehensive review by Millar et al. [2017]). Higher mass ions ~117 ±3 amu/q and 154 ±8 amu/q could be longer negatively charged carbon chains with 10 or 12 or more carbon atoms in saturated aromatic versions. Thus, negative ions exist at masses where INMS cannot measure positive ions. This makes the two instruments not only complementary in their measurements but also makes them highly dependent on each other if we are going to achieve

deeper insights into the composition of Titan's ionosphere. A second example of INMS/CAPS interdependence are IBS observations of heavy positive ions above 1000 amu/q [Crary et al. 2009] which complements INMS measurements that are limited to m/q ≤ 100 amu/q (Figure CAPS-7).

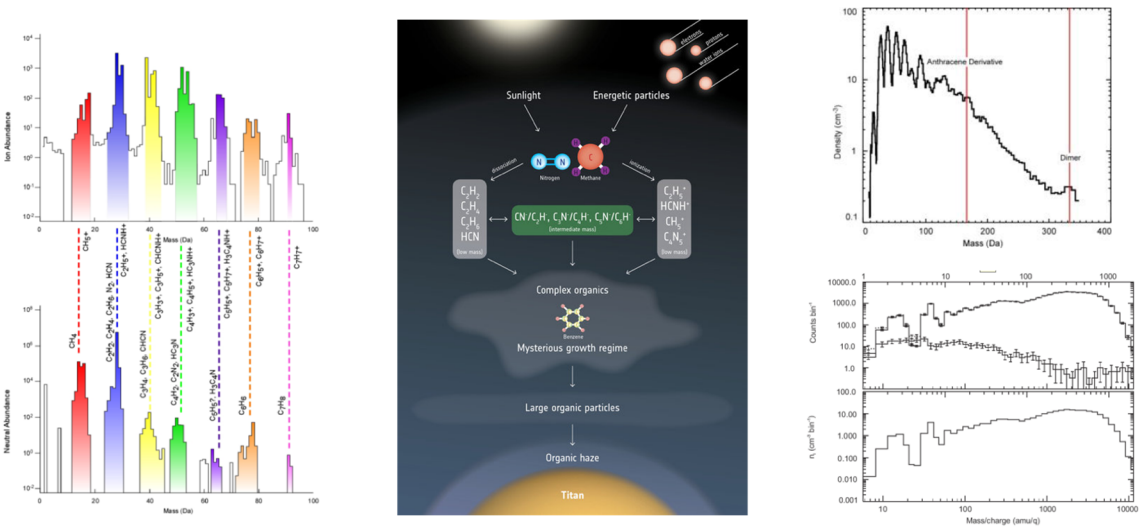

Figure CAPS-7. Observations of negative ions by CAPS/ELS show mass peaks where unsaturated carbon-chain negative ions might exist. The combination of the *Left panel:* INMS neutrals [Waite et al. 2007], *Middle panel:* IBS positive ions [Crary et al. 2009], and *Right panel:* ELS negative ions [Coates. et al. 2007] with a schematic illustrating the process of large ion formation. Figure from Desai et al. [2017].

Tholin formation

The maximum mass of negative ions increases with decreasing altitude [Coates et al. 2009]. Additionally, the number density of the higher mass group increases there [Wellbrock et al. 2013]. Furthermore, a depletion of the low mass (<150 amu/q) negative ions at a rate proportional to the increase of higher mass ions has been observed at the lowest altitudes (950 km) sampled by CAPS [Desai et al. 2017]. Additionally, non-mass-resolved negative ions were inferred from Langmuir probe data at 870 km [Ågren et al. 2012]. Taken together, the CAPS data provide evidence that the space plasma environment in the ionosphere produces these larger ions, while the RPWS data provide in situ evidence that they reach the lowest altitudes ever sampled by Cassini. The large ions then provide the source for aerosols and tholins that float down through Titan's atmosphere, forming the well-known haze layers. This idea is supported by UV occultation measurements—for example, Liang et al. [2007], which show that the density of tholins is measurable at 950 km and increases in density at lower altitudes, possibly all the way to the surface. Based on a combination of RPWS and CAPS data it is estimated that 10^5 to 10^6 metric tons per year of heavy organic aerosol compounds are added to the atmosphere from the ionosphere.

At the surface, the heaviest constituents of the haze could contribute hydrocarbons and nitriles to the dunes seen by the radar and could also provide material that would sink to the bottom of Titan's lakes. However, this process has not been observed directly in situ which leaves several

open questions for future Titan exploration [Tobie et al. 2014]. Several mission concepts have been proposed which could follow this process. These include the ESA-NASA TANDEM mission [Coustenis et al. 2009] and the NASA Dragonfly rotorcraft lander mission [Turtle et al. 2017].

Titan – Magnetosphere Interactions

The main themes of CAPS studies of the Titan-magnetosphere interaction are summarized in Figure CAPS-8. The particular goals were to: 1) measure the kinetic interaction between Titan's upper atmosphere and ionosphere with Saturn's magnetosphere where ion gyro-radii can be larger than Titan itself; 2) measure the composition of the plasma environment around Titan including its exosphere and ionosphere; 3) contribute to our understanding of the surface composition and its organic chemistry; and 4) contribute to our understanding of atmospheric loss and the required

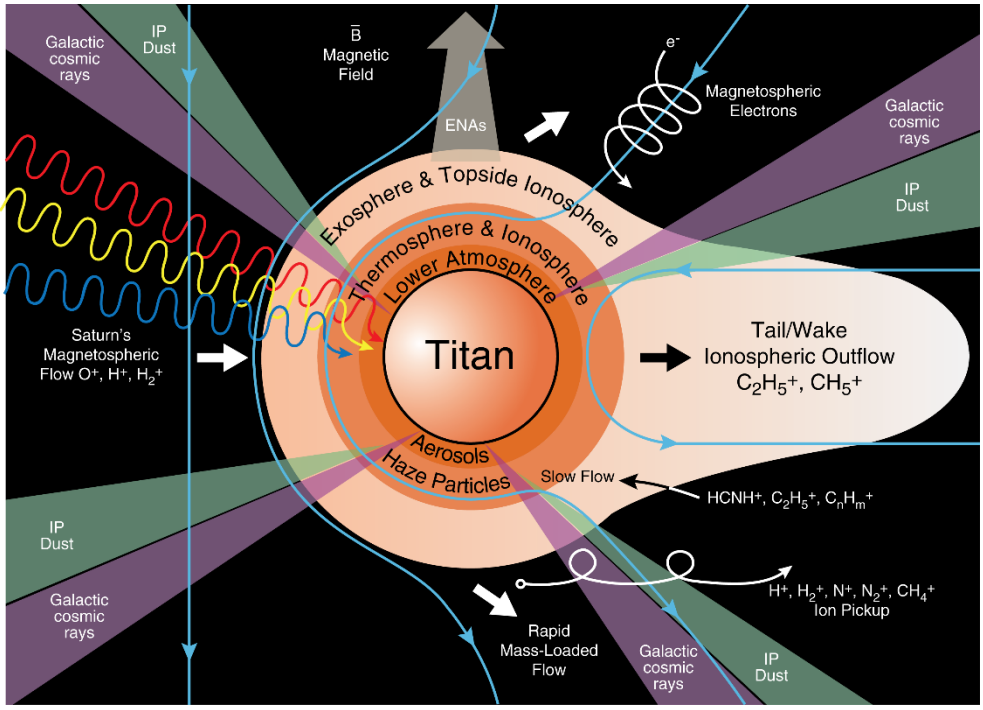

Figure CAPS-8. The main themes of CAPS studies of the Titan-magnetosphere interaction. Colorized figure of Titan includes: various atmospheric layers; surface and incoming photons, plasma, dust, energetic neutral atoms; and energetic charged particles, as well as other processes related to the interaction with the magnetosphere.

replacement timescales from the sub-surface of Titan for the content of methane within Titan's atmosphere, lakes, and surfaces. Lunine et al. [2009] have estimated the lifetime of methane due to photochemical reactions alone to be < 10 million years. Ultimately CAPS may contribute to the larger theme of understanding Titan's origins and the nebula from which the Saturn system was born—see Lunine [2009] and references within.

Kinetic interactions

CAPS discovered pickup ions in the form of beams of CH_4^+ and N_2^+ that can be explained theoretically as the result of kinetic interactions between Titan and the magnetosphere [Hartle and Killen 2006; Hartle and Sittler 2007; Hartle et al. 2011]. It is no surprise that beam composition is consistent with the composition of Titan's exosphere and atmosphere which are dominated by N_2 (98.4%) and CH_4 (1.4%)—cf. Waite et al. [2005].

Sittler et al. [2010] observed nearly field-aligned outflows from the topside ionosphere during the T9 flyby and estimated the loss of methane ions due to pick up from the exosphere at ~5×10^{22} molecules/s [Sittler et al. 2009b]. The outflows serve ultimately as a sink from Titan's atmosphere of roughly ~5×10^{24} molecules/s. Later, Coates et al. [2007b, 2012] observed similar amounts of ionospheric outflows during the T9, T63 and T75 flybys. The theoretical cause of these outflows was originally discussed in Hartle et al. [2008]. They are produced by a field-aligned polarization electric field $E_{pol} \sim -1/ne\nabla_{||}P_e$ so that above the ionospheric density peak the outward acceleration is > 10 times the force of gravity for m/q ~28 amu/q ions (note that the ionospheric electron temperature T_e ~1000° K is much greater than the ionospheric ion temperature T_{ION} < 180° K, which gives rise to charge separation and hence the dipolar electric field). Sittler et al. [2010] found that the resulting ion outflow speeds were ~7 km/s with T_{ION} ~50,000° K. Therefore, both significant acceleration and heating must have occurred at altitudes above 5000 km. Later, using electron observations, Coates et al. [2007b; 2015] measured the total potential drop of this electric field to be ~0.2 μV/m up to heights ~15,000 km, which is sufficient to accelerate methane ions to the observed speeds ~5–6 km/s. Future 3-D hybrid simulations similar to that done by Lipatov et al. [2011, 2012, 2014] will be required to understand the heating (e.g., due to wave-particle interactions) of ions to the observed high temperatures. In addition to the outflows, Sittler et al. [2010] also found evidence of Alfven waves during the T9 flyby with transverse velocity and magnetic field fluctuations that were anti-correlated with time and thus consistent with field-aligned propagation.

One other surprising observation that affects Titan atmospheric chemistry was CAPS discovery of kilovolt oxygen ions with inflows arriving from the magnetosphere at the exobase of Titan's atmosphere ranging up to ~10^{23} O^+/s [Hartle et al. 2006a, 2006b]. Its likely origins are Enceladus and the rings—see Johnson et al. [2005]; Cassidy and Johnson [2010]. Oxygen combined with the complex chemical makeup of the ionosphere is most likely the source of CO in the atmosphere [Hörst et al. 2008; Krasnopolsky 2012]. The influx of O^+ into the atmosphere, where it undoubtedly affects Titan's already complex chemistry, is one more unusual and interesting aspect of Saturn's magnetosphere in which it acts as a conduit for the chemistry of one moon (Enceladus plumes) to affect the chemistry of another.

Aerosol formation and surface composition

Heavy negative ions with m/q > 10,000 amu/q [Coates et al. 2007a; Wahlund et al. 2009], and positive ions with m/q > 1000 amu/q [Crary et al. 2009], can combine to form embryo aerosol particles which can then settle to lower altitudes [Waite et al. 2008]. As they drift down, they grow

to larger sizes to form tholins that make up the well-known smog haze layers extending down to ~400 km altitude. Eventually the particles settle to the surface [Lavvas et al. 2008; Sittler et al. 2009a, 2009b). In the Lavvas et al. [2008] model, more saturated versions of hydrocarbons and nitriles are assumed to form the aerosols, while Sittler et al. [2009a, 2009b] argue for the formation of large negatively charged carbon chains that eventually fold into fullerenes [Kroto et al. 1985; Kroto et al. 1991]. In an interesting connection to Titan chemistry, fullerenes are also thought to exist in interstellar molecular clouds and planetary nebula [Herbst 1981; McCarthy et al. 2006; Millar et al. 2007; Brünken et al. 2007; Remijan et al. 2007; Sakai et al. 2007, 2008; Thaddeus et al. 2008; Herbst and Osamura 2008].

Desai et al. [2017] present clear observational evidence that long-chain negative carbon ions can form and eventually grow into larger embryo aerosols. Vuitton et al. [2007, 2009], reporting on negative ion chemistry at Titan, also argue in favor of negative ion carbon chains, but with nitrogen appendages such as CN^-, C_3N^- and C_5N^-. Desai et al. [2017] also noted that stable multiply-charged heavier fullerenes might also be present within the ELS mass spectrum at m/q ~360 amu/q for C_{60}^{-2} or 420 amu/q for C_{70}^{-2} (see spectra in Figure CAPS-2 and Figure CAPS-3). When heavier negative ions above 150 amu/q are present at altitudes below the main ionospheric peak, broad mass peaks between 300 amu/q to 800 amu/q are present. This suggests that multiple charge state negatively charged fullerenes may exist in Titan's ionosphere—see Wang et al. [2009]; Shebanits et al. [2016]. Sittler et al. [2009a, 2009b] made the argument that the keV O^+ ions reported by Hartle et al. [2006a, 2006b] can penetrate to lower altitudes [Cravens et al. 2008], and become trapped inside the fullerenes—a condition known to occur with noble gasses such as ^{40}Ar, and nitrogen atoms [Pietzak et al. 1997]. Once trapped inside the fullerenes, the latter can condense into embryonic aerosols within the ionosphere. This process isolates the oxygen atom from reactions with Titan's reducing atmosphere. The oxygen ions will then ultimately end up on the surface of Titan where further chemical processing, driven by highly energetic galactic cosmic rays that penetrate to the surface, could lead to still more complex exobiological molecules [Sittler et al. 2009a, 2009b].

Atmospheric loss

Both CAPS and the INMS have provided crucial data for estimating processes that contribute to atmospheric loss. The review article by Johnson et al. [2009] highlights mechanisms and estimates of loss. They are primarily H_2 thermal (Jeans) escape, CH_4 destruction/precipitation, N_2/CH_4 sputtering, and ion pickup causing ionospheric outflows. Loss of CH_4 by hydrodynamic outflow [Yelle et al. 2008; Strobel 2008] thought to also contribute, was later shown not to be the case.

Waite et al. [2005] presented the first observations of H_2, CH_4 and N_2 altitude profiles extending above the exobase to ~1400 km. There is a break in the altitude profiles above the exobase that is consistent with atmospheric escape. Cui et al. [2008] and Bell et al. [2009] estimated H_2 escape to be ~10^{10} amu/q/cm^2/s locally, and ~1.6×10^{28} amu/q/s globally (integrated over the surface area of the atmosphere). Sittler et al. [2010] reported that during the T9 and T18 flybys H^+ and H_2^+ ions were present in the flow of plasma moving towards Titan. The ions also

happened to be moving perpendicular to the local magnetic field, leading Sittler et al. [2010] to conclude that they were seeing pickup ions from Titan's hydrogen corona which can extend to ~20 Titan radii (i.e., out to the Hill sphere).

Primary chemical losses occur when methane is dissociated and ionized by photochemical reactions initiated by solar UV and particle impact. Further reactions with neutrals and ions then make heavier hydrocarbons and nitriles, which can eventually grow into aerosols that precipitate to Titan's surface. Sittler et al. [2009a], using an analogy to molecular clouds and planetary nebulas, suggested that negative chains of carbon atoms form and eventually fold into fullerenes, implying that the same might be going on at Titan. They estimated precipitation to the surface to be ~2.7 × 10^{-14} kg/m^2/s at 950 km altitude and a global rate of ~4 × 10^{27} amu/q/s. This mass loss rate appears to dominate all other present-day atmospheric loss mechanisms—for example, Johnson et al. [2009]. Because the rate is large, in order to maintain a steady state methane concentration an upward diffusion of methane would be required, presumably from a source of methane on Titan's surface.

Sittler et al. [2009b] estimated the loss rate due to pick up ions to be between ~5 × 10^{22} ions/s and ~10^{24} amu/q/s, which is much smaller than the lower bound given by Johnson et al. [2009] of ~10^{26} amu/q/s, possibly due to the inclusion of scavenging down Titan's ion tail—see Sillanpaa et al. [2006]; Hartle et al. [2006b]. Woodson et al. [2015] showed the ion outflow detected between ~1 and 5 Titan radii consisted of H^+, H_2^+ and H_3^+ as well as two hydrocarbon groups with mass ranges between 12–19 amu and 24–32 amu. The net escape caused by ionospheric outflows is ~5 × 10^{24} mol/s or ~10^{26} amu/q/s [Sittler et al. 2010; Coates et al. 2012] which should be included in the Johnson et al. [2009] estimate. The escape fluxes caused by sputtering, hot atomic recoils and charge transfer by energetic neutral atoms also cause heating of the thermosphere and corona [De La Haye et al. 2007a, 2007b]. Adding all these terms Johnson et al. [2009] find a total escape rate of ~0.32 to ~3.8 x 10^{28} amu/q/s.

Recent work highlights the need to reanalyze INMS data … in order to understand the energy distribution of neutral molecules in the exosphere region.

Recent work highlights the need to reanalyze INMS data using detailed models of sputtering and energy deposition in the upper atmosphere in order to understand the energy distribution of neutral molecules in the exosphere region. Snowden and Yelle [2014] used Fourier's Law to extract energy deposition rates in the upper atmosphere from INMS data. They suggested that precipitation of magnetospheric ions observed by CAPS is likely too small to explain the observed temperature variations [Snowden et al. 2013] and escape rates. They also suggest that gravity waves produced in the lower atmosphere could cause the variability, but a source for the waves has not been identified, and it has recently been shown that the means of estimating the local temperature in an atmosphere with significant density structure might be problematic.

Tucker et al. [2016] showed that using the Louisville Theorem approach, with a non-thermal energy distribution at the exobase, can lead to incorrect estimations of the upper atmospheric thermal structure and, consequently, escape rates due to collisions in the transitional region. Furthermore, such corona fits obtain different exobase energy distributions for N_2 and CH_4 density distributions, which is suggestive of different heating mechanisms occurring between species. Therefore, ion/pickup fluxes and spectra extracted from CAPS data and model development of gas-kinetic models are needed for detailed simulations of the ion-neutral interaction. Such models can consider the ion-neutral interaction at the microscopic level and include the production of hot recoil molecules. This has led to a re-evaluation of an earlier Titan atmosphere model investigated by Johnson et al. [2016].

The final topic is hydrodynamic loss proposed by Yelle et al. [2008] and Strobel [2008]. By using CH_4 and N_2 ingress altitude profiles with methane diffusing through atmospheric N_2, and then using the ^{40}Ar density profiles, they were able to separate the molecular and eddy diffusivities, which then required an upward methane flux ~4–5 × 10^{10} amu/q/cm^2/s and globally ~4.5 × 10^{28} amu/q/s. This estimate is close to the chemical destruction/precipitation of methane to heavier molecules and aerosols. The model by Strobel [2008] called slow wind ague that solar UV penetrates below the ionosphere where it is deposited. This excess heat is then conducted upward to higher altitudes to drive the hydrodynamic slow wind. But, in order to meet the upward flux required by Yelle et al. [2008] this heat must be transported above the exobase where there are no collisions to conduct the heat, which is its major weakness. Direct Simulation Monte Carlo (DSMC) simulations by Tucker and Johnson [2009] did not show any enhancement of the methane escape rate significantly greater than the Jeans escape rate ~3 × 10^{22} amu/q/s. Therefore, it is highly unlikely that hydrodynamic escape of $CH_4$is currently occurring at Titan. Tucker et al. [2013] showed that H_2 escape cools the background gas resulting in non-isothermal density profiles without requiring a significant escape rate. Volkov et al. [2011] examined the hydrodynamic escape problem in detail using DSMC simulations. They found that above a Jeans parameter of 6 at the exobase the thermal escape rate is enhanced towards the analytical Jeans rate only by a factor of 1.4–1.7. This contrasts with Strobel [2008] who predicts a CH_4 escape rate orders of magnitude larger than the Jeans rates, possibly due to an overestimation of heat conduction in the transitional region.

Enceladus

In 2005, and far from Enceladus, IMS measured pick-up water group ions (O^+, OH^+, H_2O^+ and H_3O^+ or, collectively, W^+) throughout Saturn's inner magnetosphere [Young et al. 2005; Sittler et al. 2005; 2006; Tokar et al. 2008]. The source of these ions is charge-exchange collisions that scatter water group neutrals, replacing a fraction of the co-rotating core distribution with a new and slower-moving ion population without changing the total ion content. The newly created ions are moving near the local Keplerian speed, which is slower than the co-rotation speed, and hence are picked-up by Saturn's magnetic field. IMS detected these water-group ions within their source region, the Enceladus torus, thus providing the first measurements of W^+ ions throughout their toroidal source region and far from Enceladus. High ion count rates in IMS were observed at the

ion pick-up energies as shown in Figure CAPS-9 with largest signals near the Enceladus and Dione orbits. Another surprising measurement was the discovery of negative ions in the Enceladus plume, a result as surprising for Enceladus as it was for Titan [Coates et al. 2010a, 2010b].

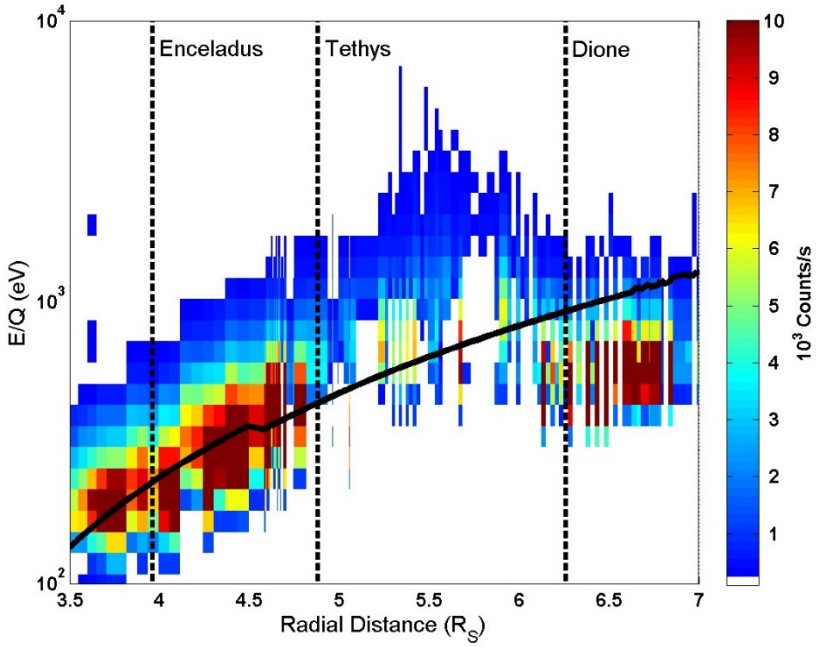

Figure CAPS-9. Energy charge of detected ions versus radial distance from Saturn in Saturn radii (1Rs = 6.03x10^5 km). Figure from Tokar et al. [2008].

Striking observations were also obtained with IMS during the close encounters of Cassini with Enceladus. Early in the Cassini mission, on July 14, 2005, the spacecraft flew within 175 km of Enceladus, passing through its surrounding cloud of neutrals and plasma. Although encounters with Enceladus later in the mission would be at much closer distances, CAPS was still able to detect indications of a strong interaction between Enceladus and magnetospheric plasma [Tokar et al. 2006]. Originally detected by the Hubble space telescope, Enceladus was known to sit in a cloud of neutral OH forming a torus around Saturn. The cloud detected by CAPS extends from about 3 to 8 R_S with maximum concentration of ~10^3 cm^{-3} inferred to exist near the orbit of Enceladus (3.95 R_S). The OH cloud is produced by dissociation of H_2O, and although the peak concentration suggested that the largest source of water molecules was in the region near the orbit of Enceladus, the nature of this source was unknown. IMS measurements during the 2005 encounter established a strong perturbation of the plasma flow caused by Enceladus, and perhaps most importantly, the presence of W^+ ions (Figure CAPS-10). This population had been detected earlier during Saturn orbit insertion [Young et al. 2005].

Later in the mission, during closer encounters with Enceladus, CAPS obtained in situ measurements of W^+ ions freshly produced in the dense Enceladus plume. The dominant species there are light ions (H^+, H_2^+), W^+ ions, and single water cluster ions, ($H_2O^*H_2O^+$). All were observed close to, and nearly due south, of Enceladus. The ions have kinetic energies in the IMS frame

roughly equal to ions that are at rest with respect to Enceladus and rammed into the CAPS sensors at the spacecraft speed. This is the signature of freshly produced ions in the plume due, e.g., to charge exchange interactions of incoming magnetospheric ions with neutral plume gas. Figure CAPS-11 shows an example of these ions detected by IMS during the E3 encounter only 52 km from Enceladus. The high counting rates close to the ion ram energies (denoted by vertical arrows) are clearly visible. Further details of these data are discussed in Tokar et al. [2009].

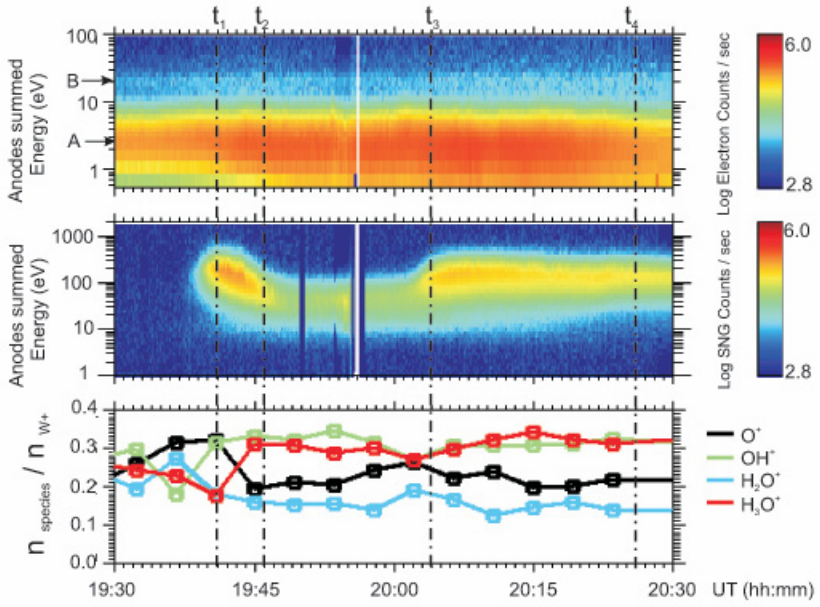

Figure CAPS-10. Data from CAPS on July 14, 2005. *Upper panel:* ELS electron counting rates summed over all direction anodes. Cold and hot electron components were detected with peak counts near A and B. *Middle panel:* Ion counting rates from IMS, with the slowing of the of the ion flow evident between t_1 and t_2. *Bottom panel:* Individual water group (W^+) ion densities divided by the total water group ion density, obtained from IMS time-of-flight measurements. Reduced χ^2 fits for mass spectra give high confidence for identification of the ions. Figure from Tokar et al. [2006].

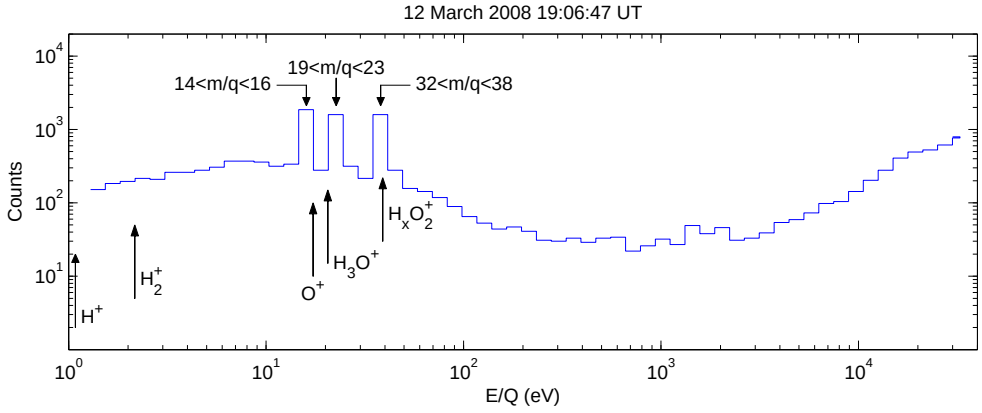

Figure CAPS-11. Individual ion counting rates versus energy per charge measured by IMS anode 5 within the plume during the March 12, 2008 (E3) flyby of Enceladus. Figure from Tokar et al. [2009].

The E7 encounter on November 2, 2009 provided additional observations of the plume stagnation region as Cassini passed directly through the Enceladus plume. The IMS detector sensitive to rammed ions observed stagnation and fresh ions at the ion ram energies (Figure CAPS-12). The strong interaction region within the plume is clearly visible in the CAPS IMS data as are the water group ions near 10 eV that are at rest in the Enceladus frame.

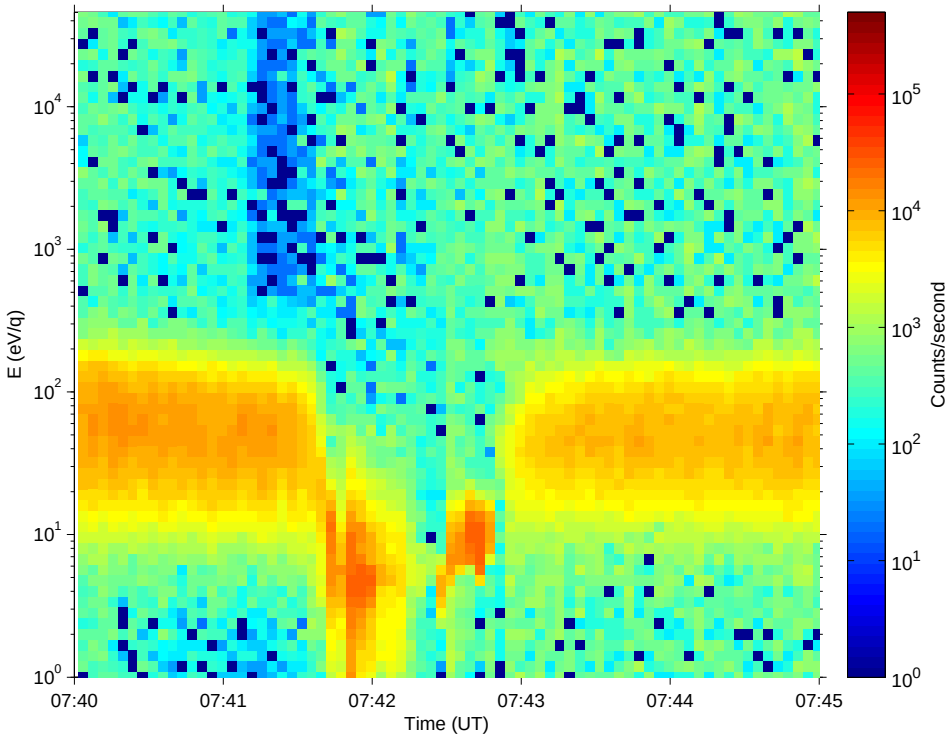

Figure CAPS-12. CAPS energy-time spectrogram from the E7 encounter. Figure from Smith et al. [2017].

Data from the E7 encounter also exhibited the close correspondence between IMS observations of ion slowing and the observed entry into the dense water vapor plume measured by INMS. This is depicted in Figure CAPS-13, which shows the IMS ion flow speed and the INMS mass 44 counts, a proxy for plume water vapor concentration. The E7 closest approach (C/A) is at ~07:41:58 universal time (UT) when IMS observed a rapid decrease in the ion flow speed ~20 sec before C/A. Similarly, INMS observed an increase from 29 to 399 counts at m/q = 44 from 17.5s to 11.3s before C/A. The data suggest that magnetospheric plasma enters the dense plume leading to charge exchange with plume water vapor followed by subsequent pick-up into the co-rotating flow. The signature of this process is very sharp on the Saturn-ward side of the plume as the new ions are picked-up and gyrate away from Saturn. The transition out of the plume opposite Saturn for E7 is more extended due to several factors, e.g., ion drift velocity and variable ion gyroradius for the various masses created. Note in the figure that the observed ion flow speed obtained from count distributions in the ram direction imply speeds as low as a few km/s in the Enceladus frame.

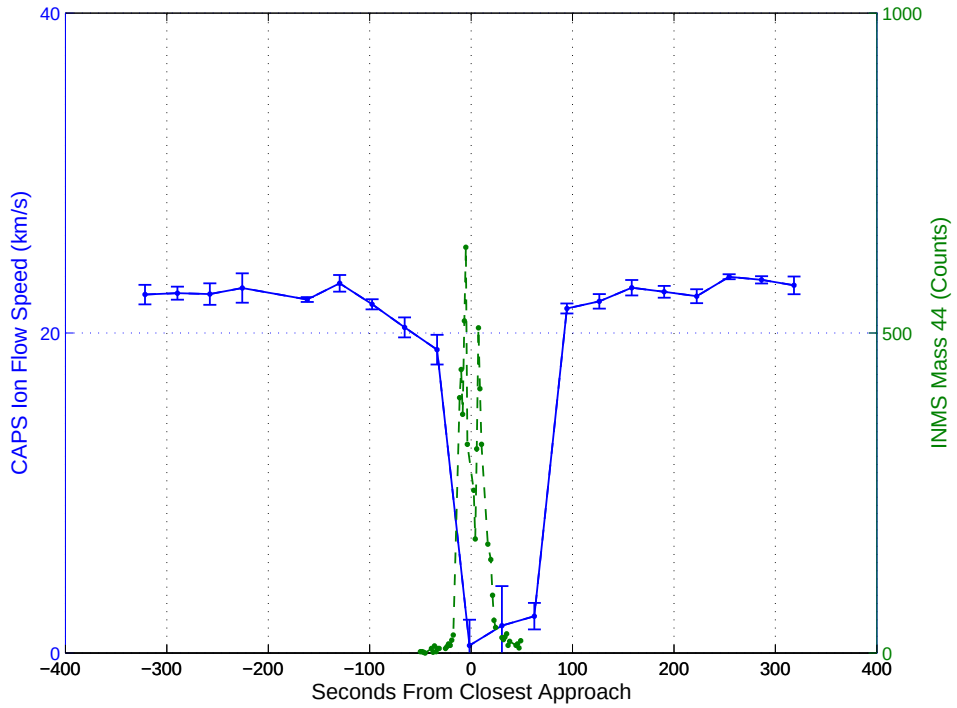

Figure CAPS-13. The CAPS IMS ion flow speed and the INMS mass 44 counts which serve as a proxy for plume water vapor concentration. The E7 closest approach was at ~07:41:58 UT on November 2, 2009.

In addition to the dense neutral water vapor measured by INMS and the resulting cold plasma measured by CAPS and RPWS Langmuir Probe, the south-polar plume of Enceladus was also found by CAPS to carry singly charged nanometer-size water-ice grains [Coates et al. 2009; Jones et al. 2009; Hill et al. 2012; Meier et al. 2014; Dong et al. 2015; Meier et al. 2015]. Such nano-grains had been inferred to exist in various cold, tenuous geophysical and astrophysical environments, but the close Enceladus plume encounters by Cassini offered the first opportunity to measure and characterize nano-grains in situ. Before the CAPS shutdown in June 2012 there were three close Enceladus encounters that provided the ram pointing required to measure these high mass-per-charge particles—E3 on 12 Mar 2008, E5 on 9 Oct 2008, and E7 on 2 Nov 2009. The detailed analysis was reported by Hill et al. [2012].

Hill's analysis confirms that the nano-grains are largely uncharged when they emerge from the surface vents and become increasingly (mostly negatively) charged as they approach Cassini a few tenths of Enceladus radii away. The charged nano-grain density versus distance from the surface source is shown in Figure CAPS-14, from Hill et al. [2012]. The dashed line shows the r^{-2} dependence that would be expected if the grains were already charged when they emerged from the source. The most plausible charging mechanism is electron attachment from the dense plume plasma. The non-neutrality of the nano-grains observed by CAPS, n(−) >> n(+), plausibly cancels the opposite non-neutrality of the plume plasma observed by RPWS-Langmuir Probe (LP). Most of the electrons missing from the plume plasma reside on the nano-grains.

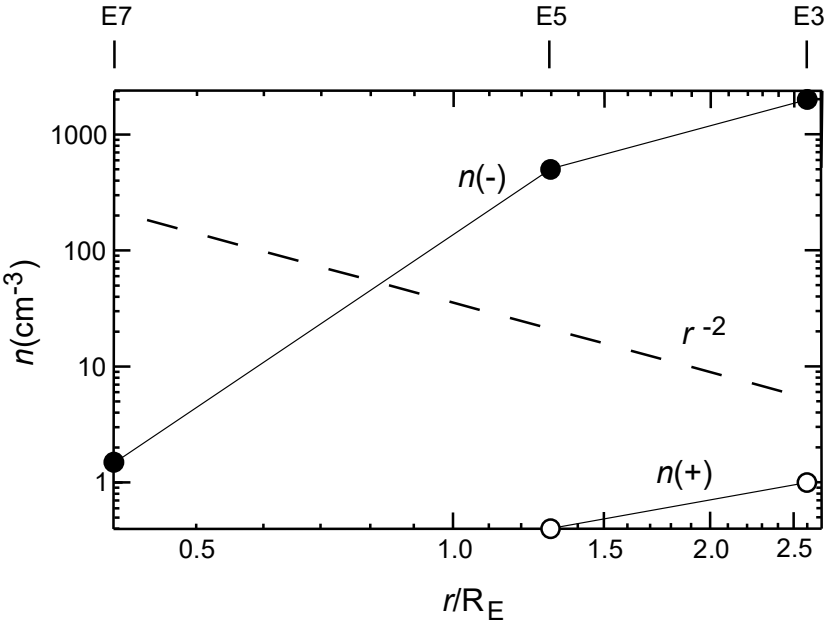

Figure CAPS-14. Total charged nano-grain number density within the CAPS E/q range versus distance from the south-pole source vent.

The link between Jupiter's aurora and its inner large moons was well known, which raised the question of whether a similar relationship might exist between Enceladus and Saturn's aurora. The necessary electrodynamic coupling was established by combining ELS data showing strong field-aligned electron beams, with magnetic field measurements indicating field-aligned currents. Pryor et al. [2011] then used the Cassini UVIS camera to take UV images of the region around Saturn's north pole about two weeks later. The Enceladus footprint was seen as predicted by field line tracing at 64.5° N latitude and the correct longitude.

Icy Satellites

In addition to Enceladus, IMS also detected signatures of magnetosphere-moon interactions at both Dione and Rhea. Dione is in an approximately circular orbit at a radial distance from Saturn of about 6.3 R_S, which is outside Enceladus (R = 3.9 R_S) and Tethys (R = 4.9 R_S) and inside Rhea (R = 8.7 R_S) orbits. Early in the mission IMS observations suggested the presence of an exosphere around Rhea—for example, Martens et al. [2008]—that was produced by radiolysis and sputtering of the surfaces by magnetospheric particles [Johnson et al. 2008]. Subsequent data from CAPS and INMS led to confirmation of very tenuous exospheres around both Dione and Rhea—for example, Tokar et al. [2012] and Teolis et al. [2010]—that have similar density and chemical composition consisting primarily of carbon dioxide and molecular oxygen. During Cassini's April 7, 2010, flyby of Dione (D2), at an altitude of about 500 km, IMS detected O_2^+ pick-up ions that likely originated from a neutral O_2 exosphere. The interaction is depicted in Figure CAPS-15.

Figure CAPS-16 shows IMS and ELS observations of pickup ions. The positive ions are from Rhea's exosphere (denoted by blue trajectories) and are identified as O_2^+ in the IMS data. The distribution of ion arrival directions in the vicinity of Rhea also indicate the presence of a tenuous dust ring or halo [Jones et al. 2008]. Note that negative ions are also visible in the ELS spectrogram.

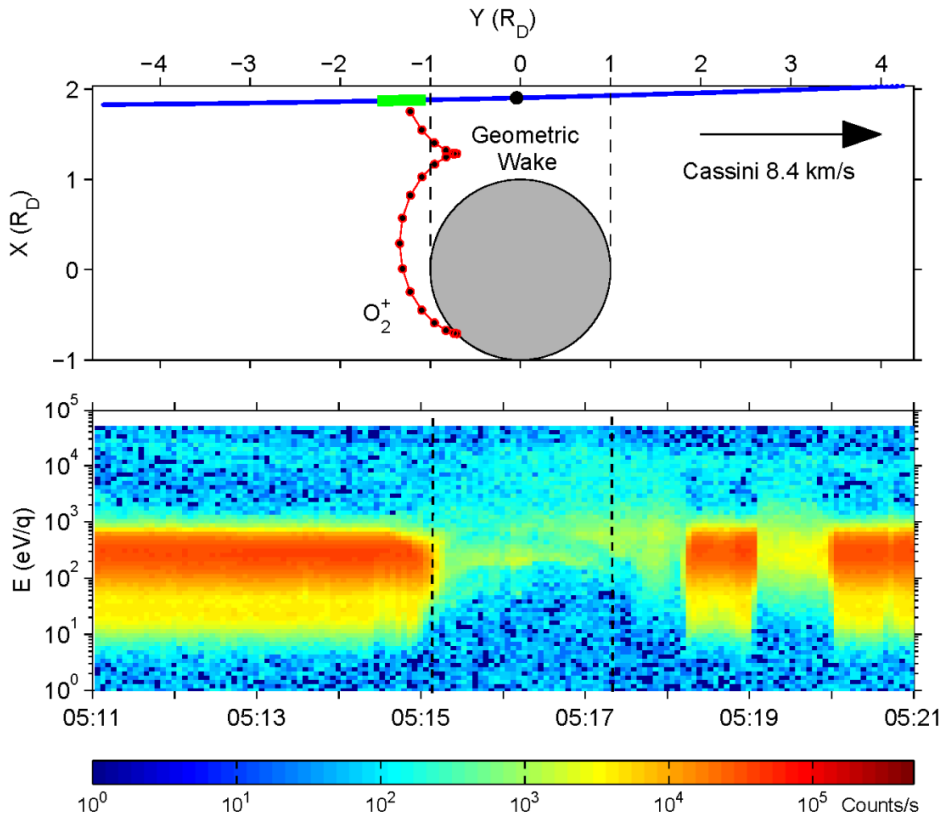

Figure CAPS-15. Depiction of the orbit of O_2^+ at Dione showing the mapping of O_2^+ ions from the observation point of CAPS (green line along trajectory) back to the moon. Figure from Tokar et al. [2012].

The observation of the so-called Pac-Man thermal feature on Mimas by the Independent Review (IR) Team came to be interpreted and modeled by the CAPS team. Schaible et al. [2017] developed a quantitative description of the effect of highly penetrating energetic electrons observed by CAPS causing sintering of the ice grains which increased the thermal inertia of the icy regolith causing the Pac-Man feature.

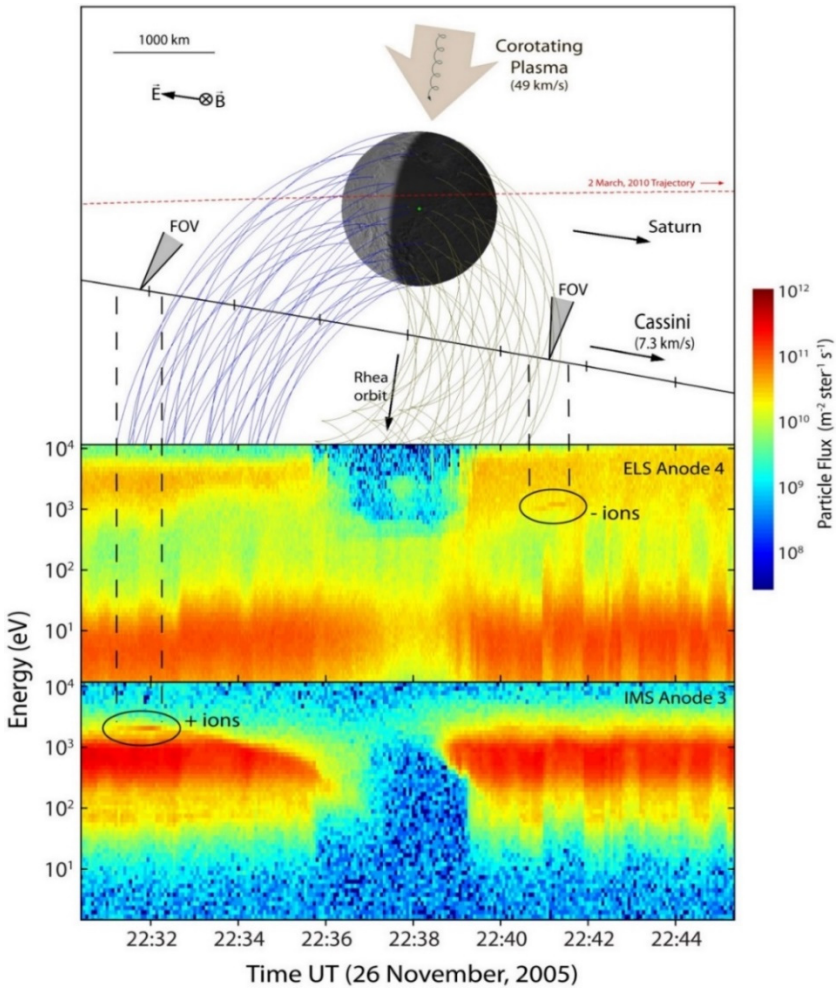

Figure CAPS-16. IMS and ELS observations of pickup ions. Energy spectrograms of ELS (top panel) and IMS (bottom panel) data for the March 10, 2010 shows the encounter with Rhea. Figure from Teolis et al. [2010].

Rings

IMS observed an enhanced ion flux (compared to background outside the rings) outside of the main rings and in the vicinity of the F-ring and G-ring as Cassini crossed the ring plane during orbit insertion on July 1, 2004. Near the edge of the main rings the ion flux as a function of energy per charge provided strong evidence for the presence of O_2^+. Analysis led to the conclusion that the enhanced ion flux between the F-ring and G-ring consisted of the water group ions O^+, OH^+, and H_2O^+ (the other water group ion H_3O^+ could not be identified) coming from Enceladus with an admixture of O_2^+, predominantly from the extended ring O_2 atmosphere. The O_2^+ component appeared to be dominant at Saturn Orbit Insertion (SOI) and was later found to vary with season [Elrod et al. 2012; 2014] due to the changing orientation of the ring plane relative to the solar UV flux (Figure CAPS-17).

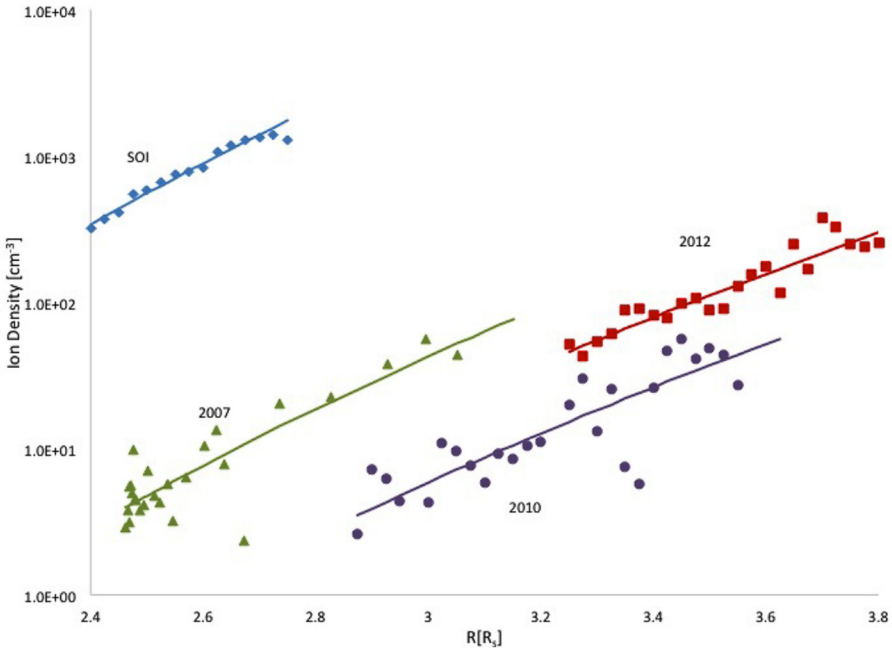

Figure CAPS-17. Ion densities extracted from IMS data at SOI in 2004, and inferred for subsequent years by modelling. The modeling indicates the seasonal dependence of ring plasma. This region contains ions formed from neutrals scattered out of the ring atmosphere as well as ions formed from neutrals in the Enceladus torus. SOI observations were dominated by O_2^+ and in the later years by water group ions. Figure from Elrod et al. [2014].

The seasonal dependence observed and modeled using CAPS data (Figure CAPS-16) confirmed that the O_2^+ ionization source was indeed solar UV acting on oxygen in the ring atmosphere as predicted by Tseng et al. [2010]. Seasonally varying oxygen was subsequently observed at much larger radii by the MIMI instrument, confirming that oxygen originating in the rings can be scattered throughout the inner magnetosphere and, consequently, also into Saturn's atmosphere. This likely accounts for oxygen observed in Saturn's thermosphere. Subsequent modeling [Tseng et al. 2013a] shows that model calculations based on the CAPS data were in reasonable agreement with that data.

Laboratory data showed that radiation decomposition of ice would lead to the production of roughly twice as much H_2 as O_2, thereby maintaining the near stoichiometry of irradiated ice grains —for example, Brown et al. [1982]. Indeed, CAPS measurements have shown that the Saturnian magnetosphere is permeated with H_2^+ and H^+ from a variety of sources (Titan, the Enceladus torus, and Saturn's atmosphere as discussed above), including the ring atmosphere [Tseng et al. 2011; 2013b]. Since H_2 is much lighter than O_2 it has a proportionately larger neutral scale height and can also be easily scattered throughout the magnetosphere by the heavier molecules. Ionization of the H_2 component of the extended ring atmosphere, and the pick-up of H_2^+ formed by this process, was shown by Tseng et al. [2011] to be an important component of magnetospheric H_2^+ detected by CAPS [Thomsen et al. 2010].

Possibly even more important, the very clean mass spectrum seen by CAPS over the rings (Figure CAPS-18) is indicative of the absence of significant levels of contaminants in the ring's ice particles [Cuzzi et al. 2009). In other words, irradiation of samples containing, for instance, carbon, would have produced CO molecules as well as other volatiles, all of which would subsequently have been scattered into the outer magnetosphere, forming pick-up ions that would be detected by CAPS. Although Cassini never flew over the main rings again, INMS data taken during the proximal orbits (when CAPS was off) did suggest that carbon species were indeed coming from the main rings.

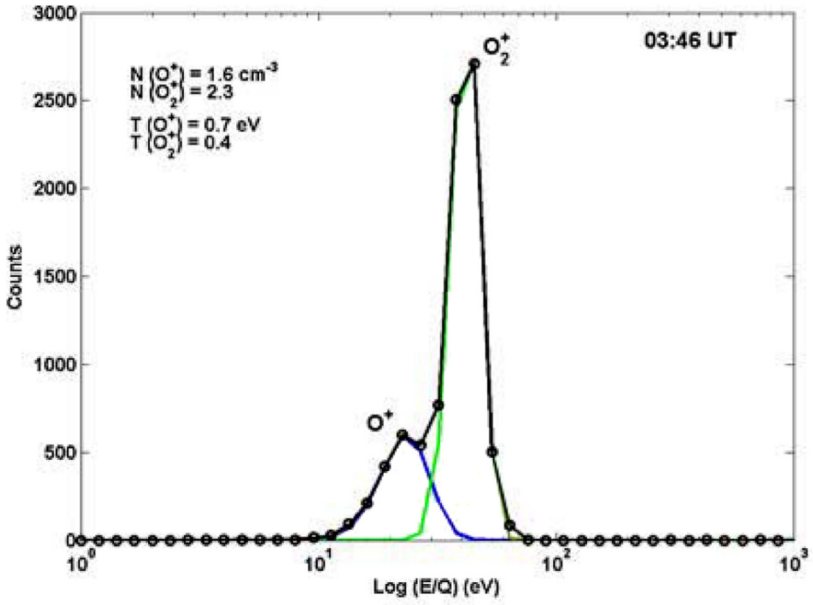

Figure CAPS-18. IMS mass spectrum over the rings taken during SOI at an altitude of ~0.2 R_S above the magnetic equator. Figure from Tokar et al. [2005].

It is worth noting that the INMS team is of the opinion that mass 28 signals seen during the Grand-Finale mission were mostly made by impact dissociation of CO_2 inside the INMS spectrometer ionization chamber. It is, therefore, unclear which molecule would be easier to produce from radiolysis of carbon-contaminated water ice. Both CO_2 and CO are possibilities. The INMS team detected only O_2 and CO_2 in Rhea and Dione exospheres.

Surprisingly, the ion densities observed by IMS between the outer edge of the main rings and Mimas (Figure CAPS-18) are derived from ionization of neutrals from the ring atmosphere and the Enceladus torus and exhibited an unexpected radial dependence [Elrod et al. 2012; 2014]. Not only did the plasma detected by CAPS in this region exhibit a seasonal dependence, with the O_2^+ component dominated by the water products from the Enceladus torus at Equinox, but the observed radial dependence suggested that an ion loss process other than electron-ion recombination, charge exchange or diffusion was acting [Elrod et al. 2014; Tseng et al. 2013a]. Since the CAPS ion densities and the RPWS electron densities differed, particularly at SOI, the observed radial dependence of the CAPS ion data was subsequently determined to be due to quenching of the

ions on nano-grains. These grains, a fraction of which were negatively charged, were presumed to be emitted from the edge of the main rings and present in the tenuous F-ring and G-ring, acted as ion sinks [Johnson et al. 2017]. That this process was occurring in this region of the magnetosphere was subsequently confirmed by the RPWS instrument during the F-ring orbits when, unfortunately, the CAPS instrument was turned off.

Rings-Magnetosphere Interactions

During SOI on July 1, 2004, the spacecraft passed over the B-ring, A-ring, and F-ring and the Cassini division before descending, inside the G-ring, through the ring plane. The trajectory provided the first in situ plasma measurements over Saturn's main rings, complementing data obtained by the Voyager 2 plasma science instrument outside the main rings. During SOI, IMS observed ion fluxes over the main rings consistent with the presence of atomic and molecular oxygen ions [Young et al. 2005]. IMS observations over the main rings detected both O^+ and O_2^+ at densities of a few per cm^3 using the IMS TOF sensor (Figure CAPS-19) [Tokar et al. 2005; Elrod et al. 2012]. Further analysis by Elrod et al. [2012] shows much higher densities of O^+ when CAPS was over the outer edge of the B-ring and again when CAPS was over the inner edge of the A-ring.

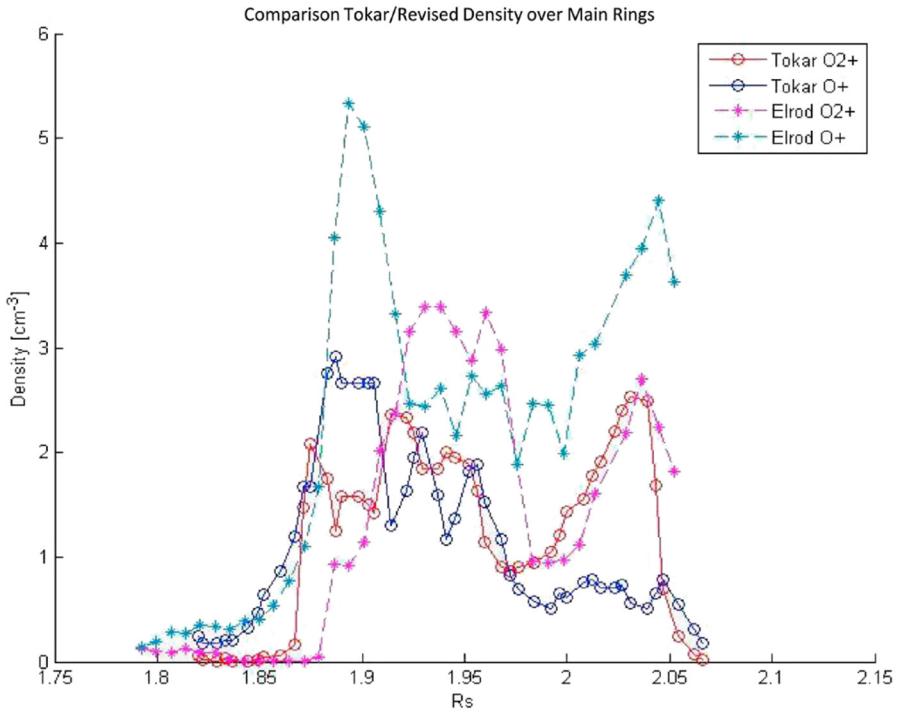

Figure CAPS-19. Densities of O^+ and O_2^+ obtained from IMS data over the main rings as a function of radial distance from Saturn in R_S. Data from Tokar et al. [2005] and re-analyzed by Elrod et al. [2012].

The IMS data suggested the presence of a ring atmosphere that was predominantly O_2 rather than H_2O and much more robust than predicted. Since the energetic ion density in this region is highly depleted due to absorption by ring particles—for example, Cooper et al. [2015], the CAPS

team proposed that the atmosphere was produced by UV-induced decomposition of ice on the ring particles [Johnson et al. 2006b]. Such a neutral atmosphere would have a scale height confining it close to the ring plane. Because ions were detected well above the ring plane, this also led to the prediction that ion-neutral scattering would produce both a ring ionosphere with a much larger scale height, and a neutral oxygen cloud that permeated Saturn's magnetosphere [Johnson et al. 2006b; Luhman et al. 2006; Bouhram et al. 2006]. Following ionization, pick-up and scattering of the neutrals from this atmosphere was shown to populate the magnetosphere with oxygen atoms and molecules which are eventually ionized far from the main rings [Johnson et al. 2006b]. Molecular oxygen ions were eventually discovered in the inner magnetosphere as well [Martens et al. 2008]. This has been subsequently confirmed by additional data and modeling as discussed in the section entitled Rings and Satellites.

Magnetosphere Composition, Sources, Transport, and Losses

The Cassini mission enabled an extensive exploration of Saturn's magnetosphere: its structure, plasma sources, transport, dynamics, loss mechanisms, and interaction with satellites, rings, and other neutral material. In this section we address CAPS findings regarding magnetosphere structure, plasma sources, transport, variability, and loss. More extensive discussions of the magnetospheric dynamics, the interaction with satellites and rings, and the interaction with the solar wind at the bow shock and magnetopause are presented in the separate section entitled Magnetosphere Dynamics. Thomsen [2013] has given a short but very useful overview of magnetosphere dynamics.

Structure

Global Structure. The orbital coverage of Cassini allowed a good determination of the global structure of Saturn's magnetosphere. Based on multiple-instrument observations, summary descriptions of the global structure have been published [Gombosi et al. 2009; Arridge et al. 2011b; Krupp et al. 2018]. As suspected from previous fly-by missions, Saturn's magnetosphere is similar in some respects to the Earth's: Its strong intrinsic magnetic field creates a bubble standing in the incident supersonic solar wind, separated from it by a magnetopause, magnetosheath, and bow shock. The magnetospheric bubble is bullet-shaped, compressed by solar wind dynamic pressure on the dayside and stretching out into a long magnetotail on the night side. The distinguishing factors that determine the structure and dynamics of Saturn's magnetosphere are its strong magnetic field, rapid rotation, and dominant source of magnetospheric plasma deep within the magnetosphere (i. e., neutral water molecules from Enceladus).

Radial Variation. The primary spatial dependence of magnetospheric properties is in the radial direction. From the first pass through the magnetosphere during SOI [Young et al. 2005], several distinct magnetospheric regions could be identified: an outer region (inside the magnetopause) with extremely low density, later understood as magnetospheric lobe; then a significantly denser region with variable density dominated by H^+, later understood as the higher-latitude manifestation of the plasma sheet/ring current; and finally, a much denser inner

plasmasphere dominated by W^+. Subsequent analyses of the SOI data [Rymer et al. 2005; Sittler et al. 2005, 2006a, 2008] provided quantitative estimates of the H^+, W^+, and electron plasma parameters in the inner magnetosphere and demonstrated that the plasma flow velocity is near co-rotation throughout the region (co-rotation is the azimuthal flow that results from essentially rigid rotation with the planet; it is enforced by currents flowing along the magnetic field lines between the upper atmosphere and the magnetospheric plasma). The proton and water-group temperatures were consistent with local ionization and pick-up into the co-rotating flow. The electrons in the inner magnetosphere consist of two populations: 1) a cool component whose temperature tracks the proton temperature; and 2) a hotter population that increases in energy with decreasing radial distance [Young et al. 2005; Sittler et al. 2006b; Schippers et al. 2008]. Later work [Rymer et al. 2007; Rymer 2010; Schippers et al. 2009] showed that the cold electron component was consistent with a local pick-up source and subsequent heating via Coulomb collisions with the protons. The hot component was consistent with adiabatic transport inwards from a source in the plasma sheet/ring current region.

Calculation of the ion plasma moments (density, temperature, flow velocity) from CAPS data is complicated by incomplete and variable viewing directions. Nonetheless, application of a numerical computational scheme to the full data set through March 2009 enabled a survey of the properties of H^+, W^+, and H_2^+ (the third most common ion species in the magnetosphere, as revealed by CAPS time-of-flight measurements) throughout the magnetosphere (Figure CAPS-20)

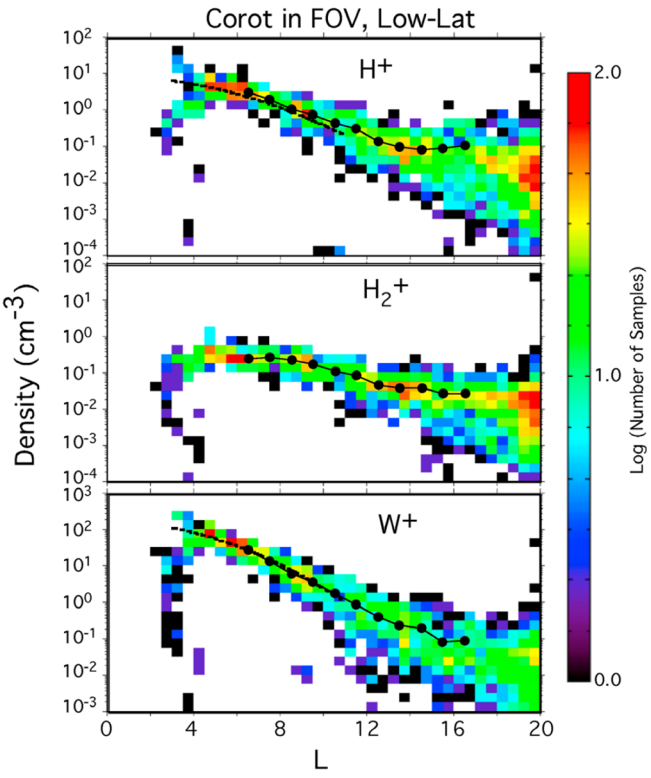

Figure CAPS-20. Radial dependence of low-latitude plasma density when co-rotation was in the CAPS field of view. Figure from Thomsen et al. [2010].

[Thomsen et al. 2010]. The survey confirmed that densities decrease, and temperatures increase, with radial distance inside ~20 R_S, and the W^+ density declines more rapidly than light ions. The flow velocity remains primarily in the co-rotational direction essentially all the way to the magnetopause, but the speed is lower than full co-rotation, as discussed below in the Transport section. Combined with the higher-energy measurements of MIMI, the CAPS data enabled a comprehensive survey of the total plasma pressure throughout the magnetosphere and thus an understanding of the currents that distort the dipole field within the plasma sheet and ring current region [Sergis et al. 2010, 2017]. A more recent survey of plasma moments calculated with a forward modeling approach that includes anisotropic temperatures explores both the radial and local time variations of the plasma (Figure CAPS-21) [Wilson et al. 2017].

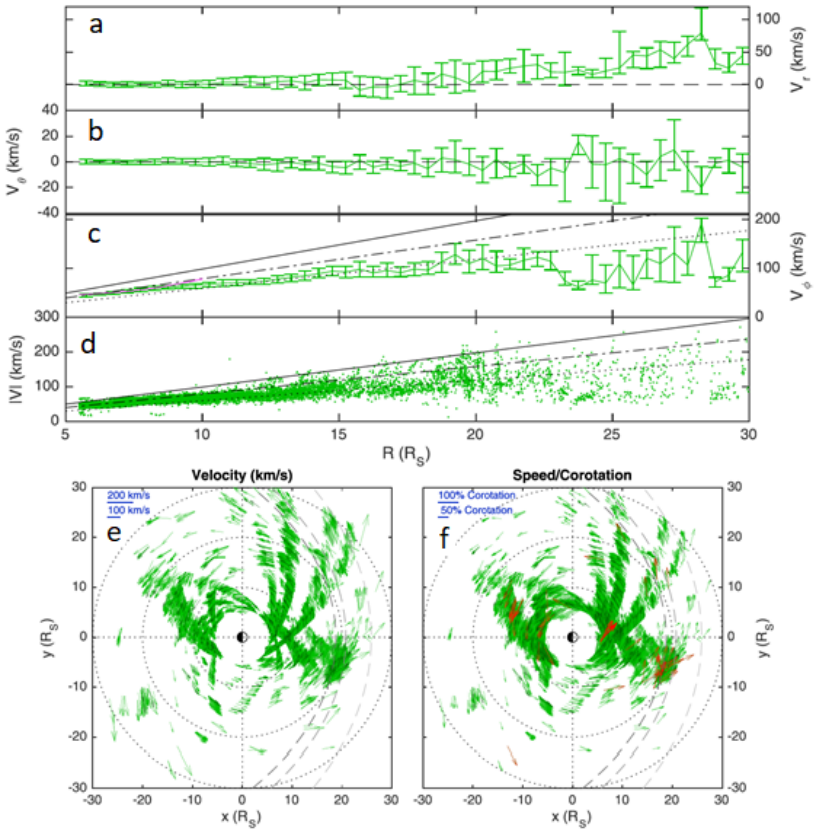

Figure CAPS-21. A low-latitude heavy ion layer displaying narrow substructures, and a higher-latitude, smooth, broad ion layer composed dominantly of light ions. *Panels a–c:* Radial profiles of plasma velocity components, in 0.5-R_S bins. *Panel d:* All measured flow speeds. *Panel e:* Equatorial plane projections of flow vectors with length proportional to flow speed. *Panel f:* Same as panel e, but with length proportional to the fraction of co-rotation. All data points are shown in green, while dark green shows every thirtieth data point. Figure from Wilson et al. [2017].

Disk structure, low-latitude confinement. Because of strong centrifugal forces on co-rotating plasma, Saturn's magnetosphere is flattened into a disk shape, especially on the night side and during times of relatively low solar wind dynamic pressure—for example, Arridge et al. [2007, 2008]. CAPS data allow determination of the latitudinal scale heights of H^+, W^+, and H_2^+ and show

that the heavy ions are more strongly confined to the equatorial plane—for example, Thomsen et al. [2010]. In the magnetotail, the magnetodisk structure is particularly prominent, with the current flowing in a relatively thin region of dense plasma separating the lobes of oppositely directed magnetic field. The magnetodisk consists of a structured plasma sheet: a low-latitude heavy ion layer displaying narrow substructures, and a higher-latitude, smooth, broad ion layer composed predominantly of light ions (Figure CAPS-22) [Szego et al. 2011]. The density and azimuthal flow speed decline with increasing latitude [Nemeth et al. 2015] as a direct consequence of the sub-corotation of the plasma in the outer magnetosphere—for example, McAndrews et al. [2009]; Thomsen et al. [2013, 2014b]; Wilson et al. [2017]. Highest speeds occur on field lines at lowest latitudes mapping to the rapidly rotating inner regions of the plasma sheet, and the speed falls as one moves to higher latitudes where the field lines are connected to strongly sub-co-rotating plasma at large radial distances.

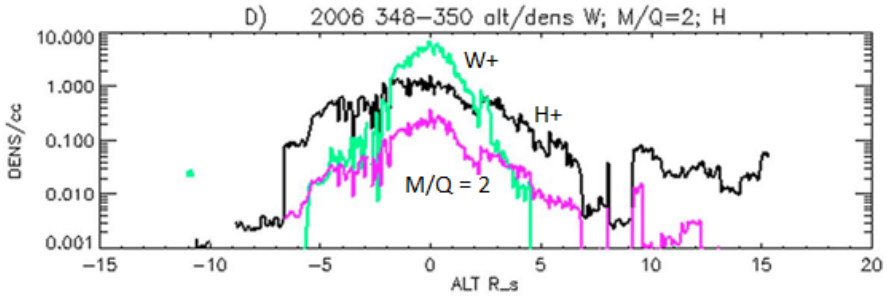

Figure CAPS-22. Density of three species: water W^+ (green), hydrogen H^+ (black), and mass/charge 2 (magenta); as a function of distance from the equatorial plane for a crossing of the magnetic equator at ~9 R_S. W^+ is more confined to the equator than light ions, so the relative composition varies with latitude. Figure from Szego et al. [2011].

Local time dependence. Although CAPS had relatively little low-latitude coverage with appropriate viewing near dawn, several observations were made of the local time dependence of plasma properties. For example, interchange injections (see the section entitled Magnetosphere Dynamics and Radial Transport) appear to be stronger and penetrate more deeply into the inner magnetosphere on the night side compared to the dayside [DeJong et al. 2011]. Also, in the inner magnetosphere, there is a day-night asymmetry in both ion and electron temperatures [Thomsen et al. 2012], which is further discussed in the section entitled Magnetosphere Dynamics and Radial Transport. The day-night asymmetry in the hot electron component extends to high latitudes, but there is no such asymmetry in the plasma sheet thickness, at least in the cold electron population [Carbary and Rymer 2014]. At larger radial distances, there is only modest variation with local time [Wilson et al. 2017].

Cusp and Polar Cap. As seen already during SOI [Young et al. 2005], at latitudes above the extended plasma-sheet/ring-current there is a region that is largely devoid of plasma, known as the magnetospheric lobe. The lobe is commonly seen in the magnetotail—for example, Thomsen et al. 2015b]—as the plasma sheet rocks and flaps up and down (see discussion in the section entitled Periodicities). Lobe field lines are thought to be connected by magnetopause reconnection into the solar wind and have thus lost their magnetospheric contents. At low altitudes, the lobe maps into

the polar cap. The polar cap boundary is identified based on a sharp drop in ELS electron fluxes and corresponding signatures in other data sets (Figure CAPS-23)—e.g., Jinks et al. [2014]. A survey of polar cap boundary crossings showed that the main upward field-aligned currents associated with the aurorae reside equatorward of the open-closed boundary [Jinks et al. 2014].

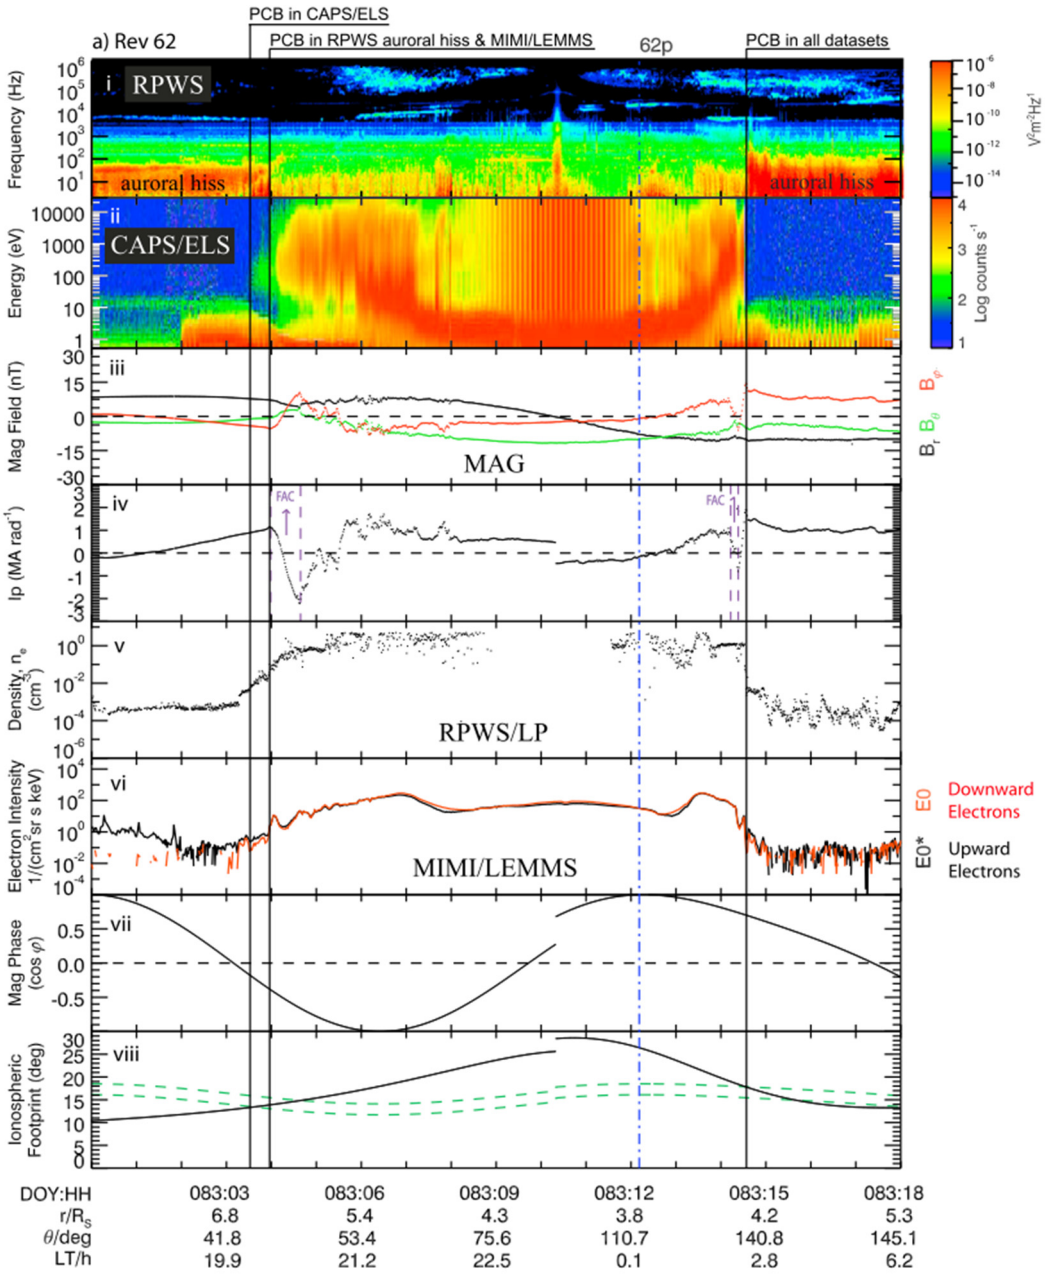

Figure CAPS-23. Polar cap boundary as seen in several different Cassini data sets. The sharp change in the ELS electron spectrum is the most definitive signature. The polar cap is largely devoid of electrons (counts below ~20 eV are due to spacecraft photoelectrons). Figure from Jinks et al. [2014].

Near noon, open magnetic field lines (which will ultimately become the lobe/polar cap) are filled with incoming magnetosheath plasma, which penetrates down to low altitudes. CAPS observations of this region, known as the cusp, demonstrate that the process of reconnection occurs at Saturn's magnetopause, with indications that the reconnection is pulsed [Jasinski et al. 2014]. The first cusp observation was associated with the arrival of a solar wind shock front, which compressed the magnetosphere and probably provided more favorable conditions for magnetopause reconnection [Jasinski et al. 2014]. Evidence for both bursty and more continuous reconnection is observed during different cusp events, and the locations of the reconnection site vary along the subsolar magnetopause. Magnetic reconnection and plasma injection into the cusp can occur for a variety of upstream conditions [Jasinski et al. 2016, 2017; Arridge et al. 2016].

Temporal variability

Seasonal and long-time scale. On the time scale of months to years, most of Saturn's magnetospheric plasma does not exhibit strong variability—less than a factor of three [Wilson et al. 2017]—in spite of the fact that the Enceladus plume source (see Figure CAPS-17) does appear to vary on the scale of several months [Smith et al. 2010; Elrod et al. 2014]. In the innermost magnetosphere, just outside the main rings, heavy ion densities (O_2^+ and W^+) show a seasonal dependence, as could be expected for a ring source that depends on the solar illumination angle [Elrod et al. 2012, 2014] (see the section entitled Rings in Plasma Sources).

Short time scale. On the scale of minutes to hours or days, there is significant variability in plasma properties (Figure CAPS-24)—for example, Young et al. [2005]; Gombosi et al. [2009], Figures 9.28 and 9.29; Thomsen et al. [2015a], Figure 1. Variability at this scale may be due to the

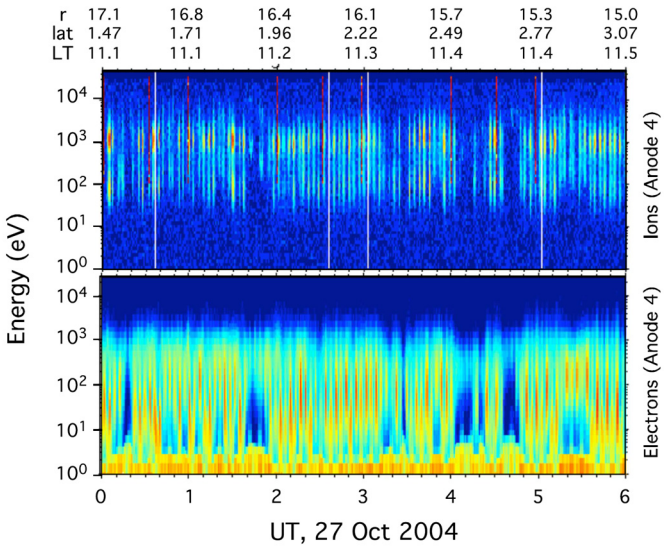

Figure CAPS-24. Temporal variability in plasma found in the middle magnetosphere ~16 R_S. Both panels show CAPS count rate as a function of energy and time for ions (*top panel*) and electrons (*bottom panel*). Regularly periodic variations are due to the CAPS actuator scanning the instrument into different look directions. Aperiodic variations show frequent changes in the spectral shape and intensity of magnetospheric plasma. Figure from Gombosi et al. [2009].

outward transport of interchanged flux tubes from the inner magnetosphere (see the section entitled Magnetosphere Dynamics). At the orbit of Titan, the ambient plasma environments are variable but can be organized into four types by the nature of the electron populations [Rymer et al. 2009a; Smith and Rymer 2014]. The plasma environment at Titan's orbit appears to be determined by the motion of the magnetodisk current sheet [Arridge et al. 2008; Szego et al. 2011].

Periodicity. Many properties of Saturn's magnetosphere exhibit periodicities at approximately the planetary rotation rate, a significant puzzle given the near-alignment of the magnetic and rotational axes. In the plasma data, the periodicities are clearest in the plasma sheet region. The density varies by more than an order of magnitude, depending on the SLS3 longitude [Arridge et al. 2008]. This variability is likely due to periodic up-and-down motion of the plasma sheet. The temporal and spatial variations in plasma and field parameters are well organized by the flapping of the plasma disk about a periodically varying position [Arridge et al. 2008; Szego et al. 2011, 2012, 2013; Nemeth et al. 2016]. Asymmetries in Cassini's periodic plasma sheet crossings [Thomsen et al. 2017] are consistent with predictions of plasma sheet rocking and thickness variation made both by the global magneto-hydrodynamic (MHD) models that incorporate the effects of hypothesized atmospheric vortices [Jia and Kivelson 2012] and by the closely-related dual rotating current systems inferred from magnetic field observations—for example, Cowley et al. [2017] and references therein.

In the inner to middle magnetosphere, evidence was found for a plasma cam in which the plasma density varies roughly sinusoidally with SLS3 (Figure CAPS-25) [Burch et al. 2008, 2009; Goldstein et al. 2016]. Theoretical arguments suggest that asymmetric ring-current pressure coupled to Saturn's ionosphere can initiate a rotating two-cell interchange potential that is long-lived and stable [Goldstein et al. 2014]. Outflow from the dense sector was suggested as the driver of recurrent tail reconnection and plasmoid production (see sections entitled Plasma Sources and Magnetosphere Dynamics) inferred from periodic magnetic field variations in the tail [Burch et al. 2009], but subsequent authors argued that the field variations were more consistent with simple wave-like motion or periodic rocking of the plasma sheet rather than plasmoid formation [Jackman et al. 2009]. In the more recent forward-modeling dataset of ion densities [Wilson et al. 2017], the cam is not seen, so there remain questions about its existence and its consequences.

Response to Solar Wind. Because of its strong magnetic field, rapid rotation, and internal plasma source, most magnetospheric dynamics appear to be internally driven (see the section entitled Magnetosphere Dynamics). Nonetheless, evidence has been found for significant dynamical effects attributable to solar wind variability. CAPS observations in the pre-dawn tail outbound from SOI, showed sudden energization of plasma associated with a field dipolarization, which was interpreted as evidence of a solar wind compression-related tail collapse via magnetic reconnection. Under conditions of high solar wind dynamic pressure, the magnetotail appears to enter a state of sustained lobe reconnection, resulting in a more Dungey-like configuration [Thomsen et al. 2015b]. In the inner magnetosphere, there is no apparent relation between the depth of electron penetration and solar wind properties [Thomsen et al. 2016a], although the energization of ions in a large-scale standing wave might be caused by a solar wind pressure impulse [Thomsen et al. 2017].

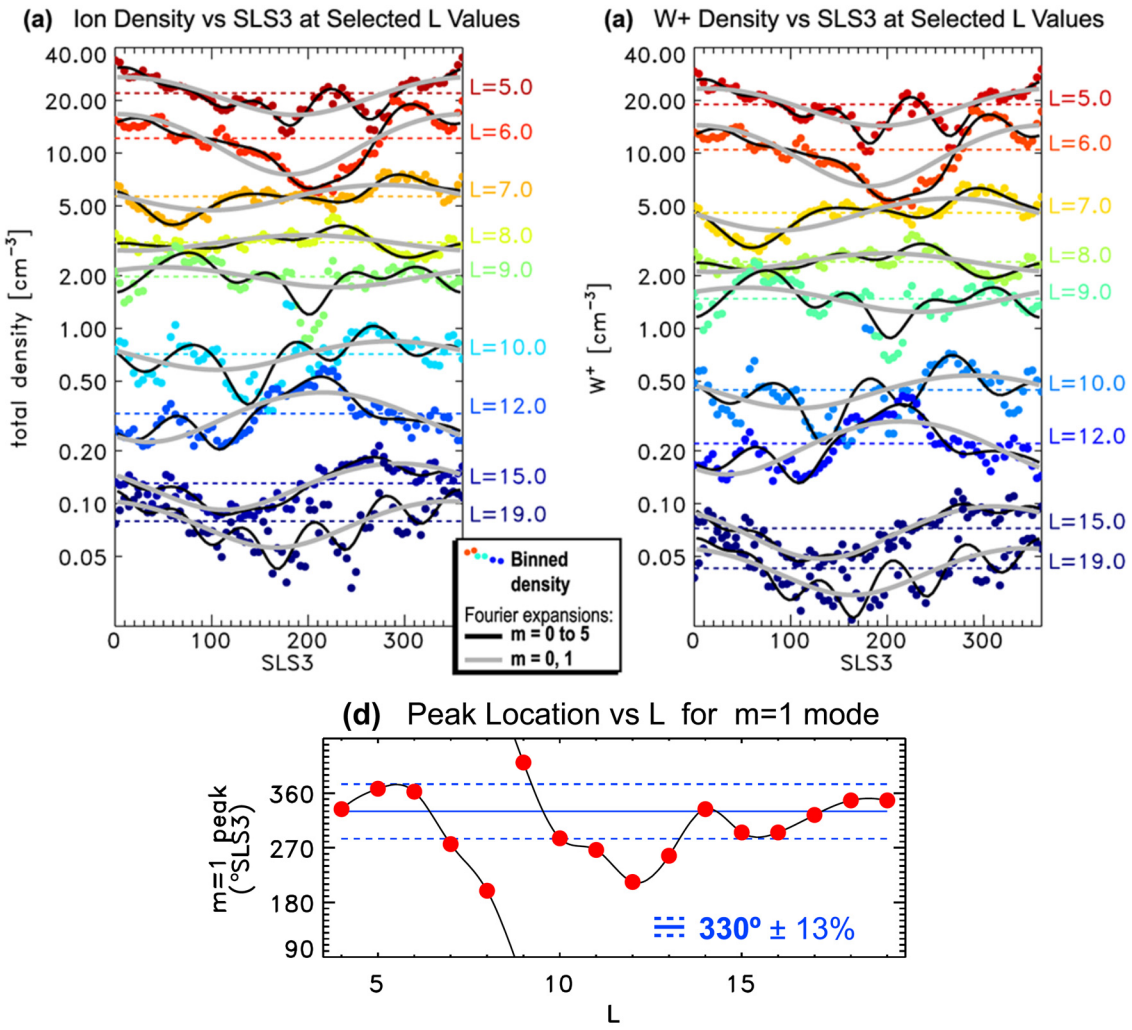

Figure CAPS-25. Evidence for the existence of a plasma cam, in which the density is generally highest in a particular SLS3 longitude sector. Figure from Goldstein et al. [2016].

Plasma sources

Clues from Composition. The composition of plasma ions is one of the best pointers to the source of the plasma. CAPS findings that the dominant magnetospheric ions are W^+, H^+, and H_2^+ [Young et al. 2005; Thomsen et al. 2010] were well explained by the later discovery of the prodigious output of water from the south-polar plumes of Enceladus. It was noted by Young et al. [2005] that the presence of H_3O^+ within the W^+ ion group indicated ion-molecule reactions occurring in a water-rich atmosphere, attributed to the E-ring and inner icy satellites, which ultimately was determined to be Enceladus. A careful separation of the individual components of the water-group species and determination of the radial distance dependence of their relative proportions [Tokar et al. 2008; Wilson et al. 2015] provided vital constraints on models of the physics and chemistry of Enceladus-originating material.

Another example of source determination through composition is N^+ [Smith et al. 2005, 2007, 2008]. Originally expected from Titan, the radial dependence of the N^+ phase space density and the energy of this population suggested instead an inner magnetosphere source [Sittler et al. 2006b], probably Enceladus, with both molecular nitrogen and ammonia emitted there (Figure CAPS-26). Surprisingly little N^+ has been found in the outer magnetosphere, indicating that nitrogen ions coming from Titan do not accumulate to significant densities [Smith and Rymer 2014].

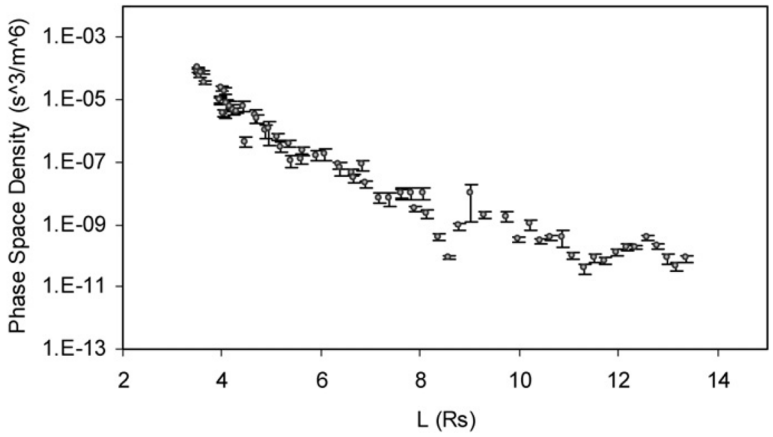

Figure CAPS-26. Nitrogen ion phase space density averaged over energy and angle, as a function of distance from Saturn. Clear decline with distance indicates a source in the inner region, inconsistent with a Titan source in the outer magnetosphere (L ~20). Figure from Smith et al. [2007].

Clues from Energy and Pitch-Angle Distributions. Examples of how the energy distribution illuminates plasma sources were noted above. For example, the way ion energies in the inner magnetosphere track the co-rotational energy was strong evidence for local pick-up from a distributed neutral gas source [Young et al. 2005; Thomsen et al. 2010]. Similarly, the different radial dependence of the two electron populations suggested a local pick-up source with subsequent collisional heating of the cold electrons, while the hot electrons are more likely adiabatically transported inward from the outer magnetosphere (Figure CAPS-27)—for example, Schippers et al. [2008]; Rymer et al. [2007]; Rymer [2010]. Butterfly angular distributions found in inner magnetosphere electrons adjacent to interchange injections (see the section entitled Hot Plasma Injections in Magnetosphere Dynamics) suggest an origin near Dione and Tethys [Burch et al. 2007] but might also be consistent with a hot electron circulation process associated with the injections, rather than an inner magnetospheric source [Rymer et al. 2008].

Enceladus. As can be seen from Figure CAPS-20 and Figure CAPS-22, the dominant ion species seen throughout the magnetosphere are well explained by ionization of material from the water plumes of Enceladus. CAPS observations of the plumes themselves are detailed in the section entitled Enceladus. CAPS data also showed Enceladus to be the probable source of most of the N^+ observed in Saturn's inner magnetosphere (Figure CAPS-26), and CAPS measurements further helped reveal the existence of temporal variability in the plume source [Smith et al. 2010].

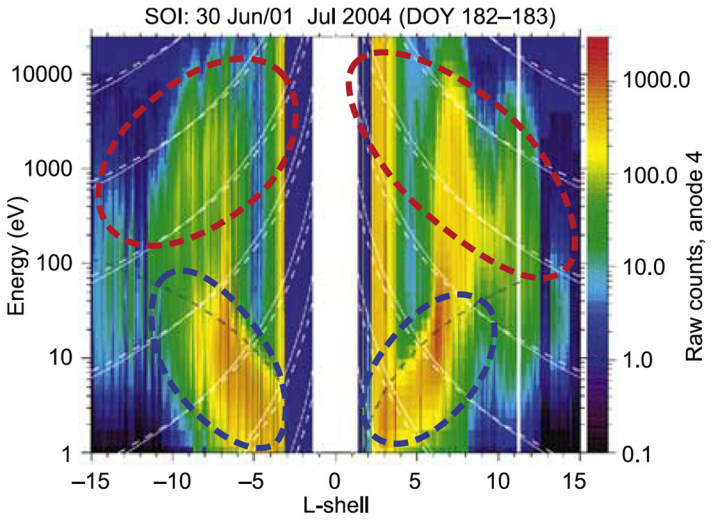

Figure CAPS-27. Two-component electron spectra from the part of the orbit insertion trajectory passing through the inner magnetosphere. White dotted curves show expected L dependence of the energy of particles conserving their first adiabatic invariant. Blue dotted lines show expected energy for local pickup of H^+. The cold electrons are most consistent with non-adiabatic collisional coupling to pick up H^+, whereas the hotter electrons are consistent with adiabatic transport from outside the inner region. Figure from Rymer et al. [2007].

Titan. A summary of CAPS observations during the many encounters with Titan are described elsewhere. The primary tracers of Titan's contributions to magnetospheric plasma, have been N^+ and H_2^+. The finding of very little N^+ in the outer magnetosphere [Smith et al. 2005] indicates that Titan's contribution to the heavy-ion plasma is limited, whereas the fact that H_2^+ becomes comparable to H^+ and W^+ in the outer magnetosphere [Thomsen et al. 2010] indicates that Titan is an important source of lighter ions in that region. From observations during passage through Titan's wake region, the total mass loss rate from Titan is estimated to be a few × 10^{25} amu/q/sec (~0.8 kg/s) [Coates et al. 2012], compared to estimates of ~60-100 kg/s from Enceladus [Fleshman et al. 2013].

Rings. CAPS was turned off before the F-Ring and Proximal Orbits, so the only direct exploration of ring-associated plasma occurred during SOI, where a layer of O^+ and O_2^+ was discovered over the A-ring and B-ring [Young et al. 2005]. Subsequent analysis of the SOI data [Tokar et al. 2005] produced densities and temperatures of these two species (Figure CAPS-28). The ring atmosphere and ionosphere are likely produced by UV photosputtering of the icy rings and subsequent photoionization of O_2^+. Significant O_2^+ was also detected outside the main rings, near the F-ring [Tokar et al. 2005], and analysis of the O_2^+ and W^+ profiles showed the seasonal dependence mentioned above, consistent with a ring source that depends on the solar illumination angle [Elrod et al. 2012, 2014; Tseng et al. 2010]. The result indicates that the rings are an important source of O_2^+ and O^+ ions inside the orbit of Mimas.

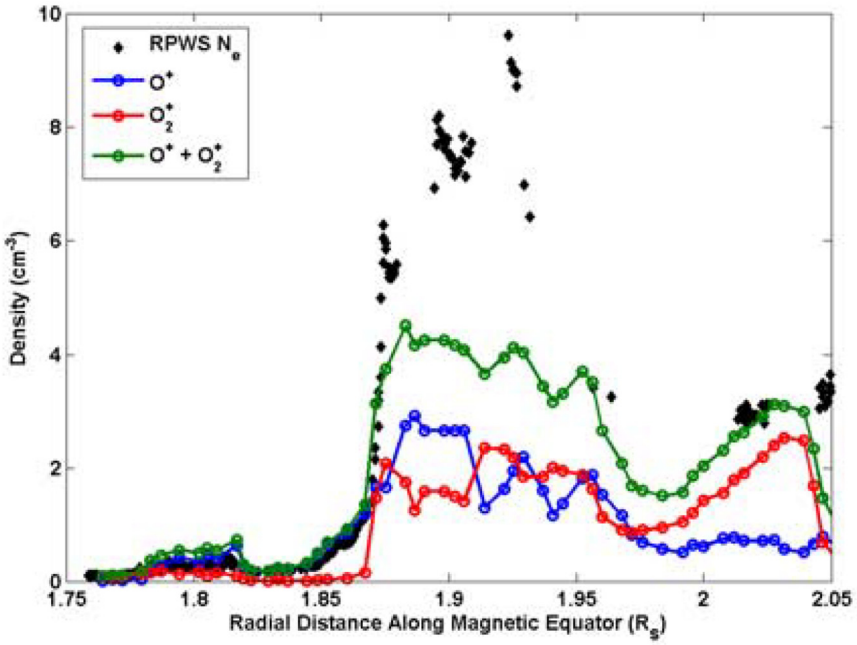

Figure CAPS-28. Radial dependence of O^+ and O_2^+ densities from CAPS observations over the main rings during SOI. Figure from Tokar et al. [2005].

Other satellites. CAPS has also detected O_2^+ in the vicinity of Dione [Tokar et al. 2012], and the observed radial dependence of the ratio O_2^+/W^+ suggested that there is a neutral O_2 source in the vicinity of Rhea [Martens et al. 2008]. Although the evidence for oxygen from Rhea is somewhat skimpy, CAPS has clearly detected non-gyrotropic outflowing CO_2^+ there, as well as another negatively charged species, previously thought to be O^- but now found to be closer to mass 23 [Desai et al. 2018]. The latter is perhaps a carbon-based ion deriving from implanted exogenic compounds. Examination of the plasma conditions on flybys of Rhea [Wilson et al. 2010] revealed that the plasma flowing near it had no radial component on the Saturn-side of the moon but had a radially outward component on the anti-Saturn-side. This is potentially due to an electric field enhancement near the moon, which is suggested in hybrid simulations.

Saturn ionosphere. Observation of probable plasma outflows from the ionosphere at the outer edge of the night side plasma sheet and extending into the lobes led to an estimate of some tens of kg/s lofted from the ionosphere (Figure CAPS-29) [Felici et al. 2016].

The observations occurred during a probable solar wind dynamic pressure enhancement, which may be important for producing significant outflow. It is not yet clear how often such outflow occurs, nor whether the outflow is captured into the closed region of the magnetosphere, rather than just escaping into the solar wind. Additionally, the field-aligned angular distributions of the suprathermal electrons within the plasma sheet/ring current region may indicate an ionospheric origin [Schippers et al. 2008], but no supporting evidence from the ion data has been reported.

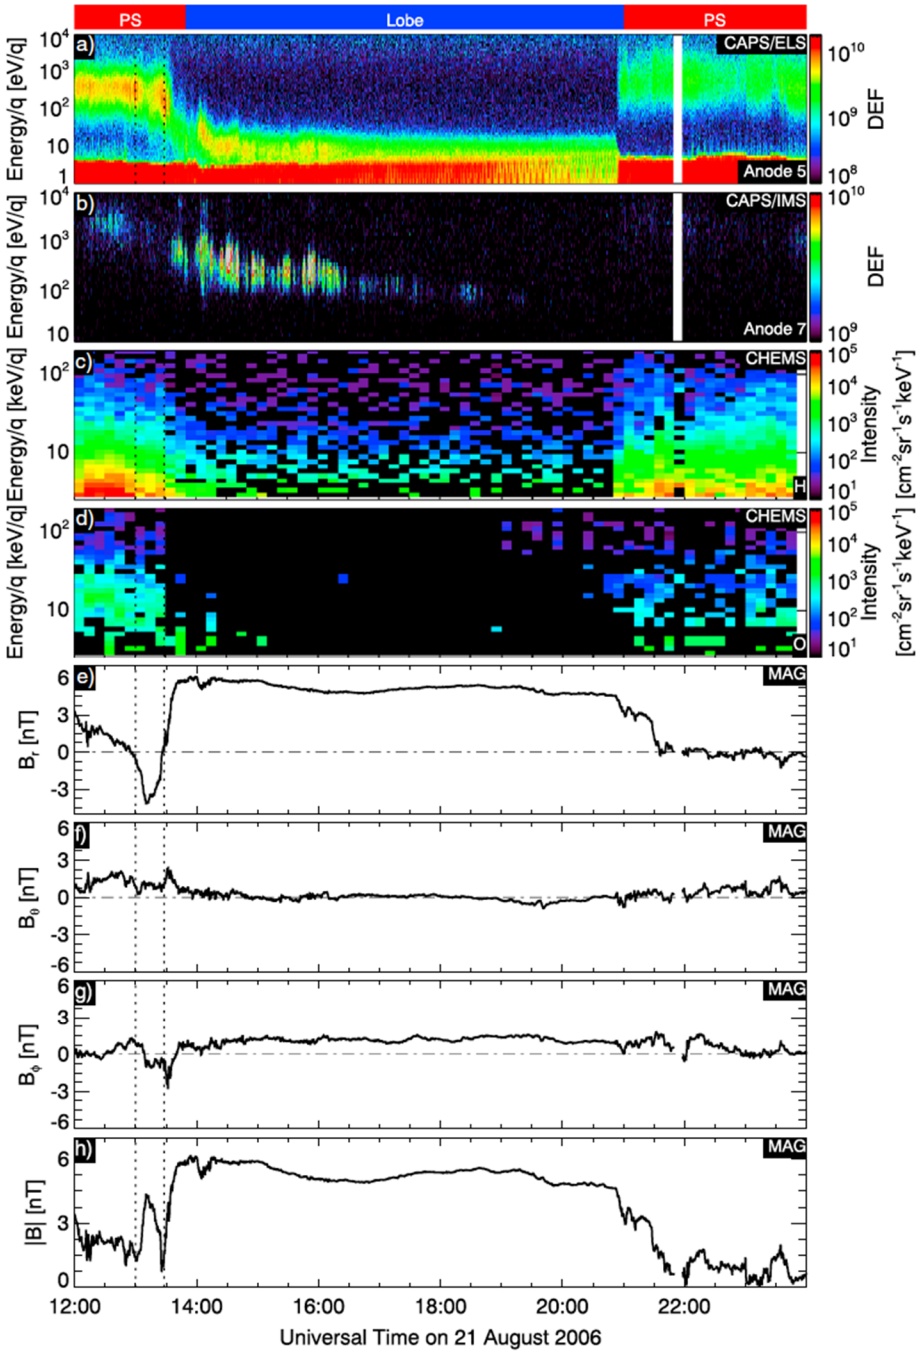

Figure CAPS-29. CAPS observations of an outflowing H^+ population from Saturn's ionosphere, seen in the lobe near the plasma sheet boundary at 36 R_J down tail. Figure from Felici et al. [2016].

Solar wind. Regarding dayside entry of solar wind plasma via reconnection or the Kelvin-Helmholtz instability, there is considerable evidence that both processes take place (see the section entitled Bow Shock, Magnetosheath, and Outer Magnetosphere). Magnetopause encounters frequently exhibit a low-latitude boundary layer (LLBL), in which magnetosheath

plasma can be found just inside the magnetopause. From a survey of 354 crossings of the LLBL [Masters et al. 2011a, 2011b], the estimated thickness is only of the order of one Saturn radius, with no clear dawn-dusk asymmetry. Thus, while solar wind plasma can and does enter the magnetosphere on the dayside, it does not get very far in. This is supported by the fact that the ratio of m/q = 2 to H^+ ions in the outer magnetosphere is almost always significantly greater than the values of 1 to 10% typically seen within the solar wind [Thomsen et al. 2010], indicating that plasma in the outer magnetosphere is predominantly of inner magnetospheric and/or Titan origin, with very little contribution from solar wind plasma.

On the night side, plasma with solar wind-like composition has been observed at 37 R_S near local midnight [Thomsen et al. 2015b]. In that event, it appeared that prolonged high solar wind dynamic pressure may have caused erosion of the tail plasma sheet through ongoing Vasyliunas-type reconnection that then involved open lobe field lines and created a more Earth-like, Dungey-style outer plasma sheet predominantly of solar wind origin. Other evidence for Dungey-style reconnection following a Vasyliunas-style reconnection event is the post-plasmoid plasma sheet— for example, Jackman et al. [2011]. One other event that showed the possibility of a Dungey region, in which field lines were probably closed but the densities were quite low and there was very little O^+, was seen in a rapid high-latitude pass near dawn with clear evidence of Vasyliunas-type reconnection at latitudes just equatorward of the Dungey region [Thomsen et al. 2015a].

One unanticipated discovery of the Cassini mission is the existence of an inner magnetospheric convection pattern superimposed on the dominant co-rotation pattern.

Transport

Inner Magnetosphere. As noted in the section entitled Magnetosphere Structure and in Figure CAPS-21, CAPS measurements consistently show that plasma flow in the inner magnetosphere is predominantly in the co-rotation direction, with a magnitude near full co-rotation at low radial distances but tending toward a fraction (~60%) of full co-rotation by 10 R_S—see Sittler et al. [2005]; Wilson et al. [2008, 2009, 2017]; Thomsen et al. [2010]; Livi et al. [2014]. Radial velocities are much smaller and difficult to measure [Wilson et al. 2008].

There is widespread agreement that the primary mechanism for radial transport within the inner magnetosphere, which is needed to remove the continuously-produced plasma from Enceladus, is the process of centrifugally-driven flux-tube interchange. This process is described in detail in the section entitled Magnetosphere Dynamics, but CAPS data have been instrumental in the discovery [Young et al. 2005; Hill et al. 2005; Burch et al. 2005] and diagnosis [Andre et al. 2007; Chen and Hill 2008; Menietti et al. 2008; Rymer et al. 2009b; Chen et al. 2010; DeJong et al. 2010; Thomsen et al. 2014b; Paranicas et al. 2016] of hot-plasma injection events that are the inward-moving half of the flux-tube interchange. There has been only one reported observation of outward-moving cold plasma fingers that should form the other half of the process [Thomsen et al.

2015a]. Estimates of the inflow speeds within the injection channels range from a few km/s to ~260 km/s [Burch et al. 2005; Rymer et al. 2009b; Chen et al. 2010; Paranicas et al. 2016]. Composition suggests that the plasma inside the injection channels comes from the outer magnetosphere [Thomsen et al. 2014b].

One unanticipated discovery of the Cassini mission is the existence of an inner magnetospheric convection pattern superimposed on the dominant co-rotation pattern [Andriopoulou et al. 2012, 2014; Thomsen et al. 2012; Wilson et al. 2013]. The pattern consists of a general dusk-to-dawn drift, such that particles drift inward while they co-rotate from noon to midnight and outward as they return from midnight to noon (Figure CAPS-30). The result is an inward displacement at midnight compared to noon. Several hypotheses regarding this convection have been advanced, but it remains an unsolved puzzle.

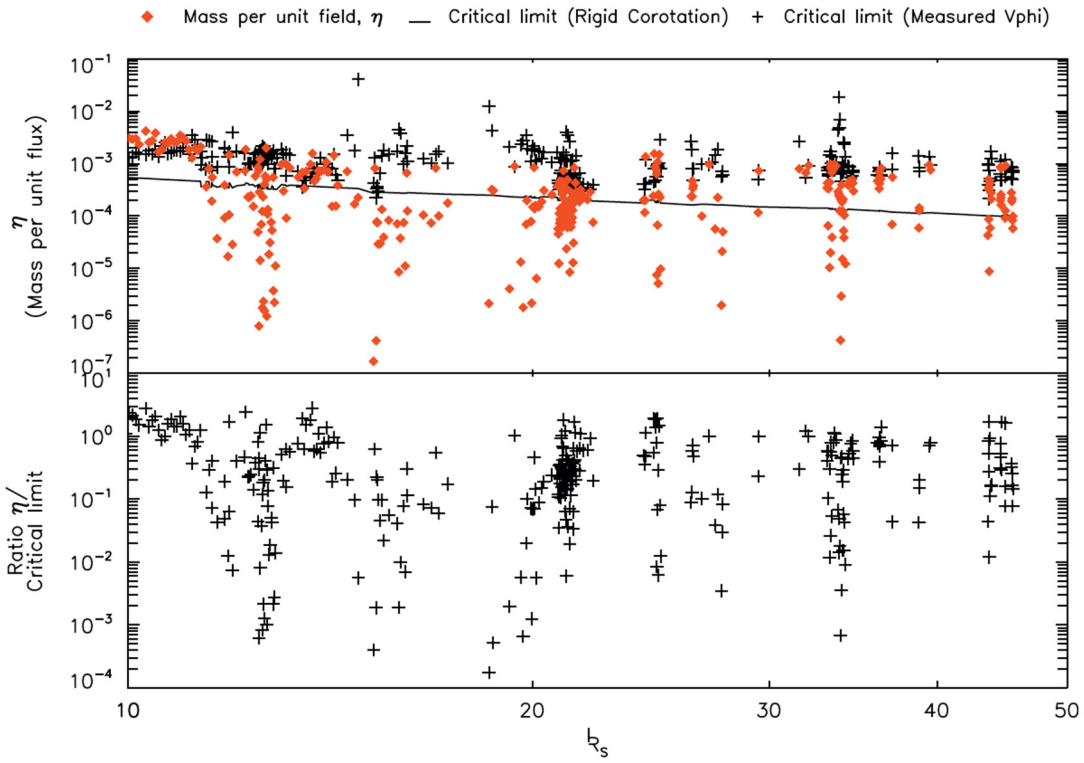

Figure CAPS-30. Comparison of night-side flux-tube content (red ♦), estimated from CAPS/IMS data, with the theoretical critical limit above which the flux tube will pinch off and release a plasmoid downtail (black +). The observed flux-tube content is roughly bounded by the critical limit, suggesting that night-side reconnection and plasmoid formation keep the tail near marginal stability. Figure from McAndrews et al. [2009].

Outer Magnetosphere. Beyond 10 R_S, CAPS measurements show consistently that the plasma flow overwhelmingly remains in the co-rotational direction at essentially all local times, indicating continued influence of connection to the co-rotating ionosphere, but the speed of the flow is well below full co-rotation—for example, McAndrews et al. [2009]; Thomsen et al. [2010, 2013, 2014a]; Wilson et al. [2017]. Beyond about 15–20 R_S, there is little evidence for inflowing plasma

on the night side, where, particularly near the flanks, flows tend to have more of an outward component. From the lack of inward flow in the pre-dawn sector, it appears that dense plasma is not often able to make the turn and return sunward to the dayside magnetosphere at distances beyond ~15 R_S (see Figure CAPS-21).

Plasma loss

Plasmoid formation. One of the principal ways in which plasma produced in the inner magnetosphere can be shed to the solar wind is through the process of magnetic reconnection in the tail. This is covered in greater detail later in the section entitled Magnetosphere Dynamics. Essentially, flux tubes loaded with inner magnetospheric plasma are transported via interchange to the outer magnetosphere. Strong centrifugal forces distend them radially, especially near the equatorial plane. On the dayside, the pressure of the solar wind helps confine the distended flux tubes, but when they rotate into the night side, that confinement goes away, and centrifugal force can overwhelm the magnetic tension. The result is that the flux tubes pinch off (or reconnect), shedding a plasmoid that is no longer connected to the planet and which carries away the load of plasma the flux tube bore before reconnection occurred (Figure CAPS-30). This is the so-called Vasyliunas cycle. CAPS data have been instrumental in identifying the resulting down-tail flows of the disconnected plasmoids [Hill et al. 2008; McAndrews et al. 2009; Jackman et al. 2014, 2015; Arridge et al. 2015; Smith et al. 2016, 2018]. There is ongoing debate as to whether plasmoids can carry away enough plasma to balance new production in the inner magnetosphere.

Magnetopause processes. Magnetic reconnection and nonlinear Kelvin-Helmholtz waves at the magnetopause could both potentially allow magnetospheric mass loss. Evidence for the operation of both processes has been seen—for example, McAndrews et al. [2008]; Masters et al. [2009, 2010, 2012]; Wilson et al. [2012]; Delamere et al. [2013]; Fuselier et al. [2014]; Jasinski et al. [2016]. However, to date the contribution of neither process to the overall mass balance problem has been quantitatively assessed. While energetic W^+ ions are commonly seen in the dayside magnetosheath, there is no evidence for thermal W^+ there [Sergis et al. 2013] or in the upstream region [Thomsen et al. 2007].

Planetary wind. As mentioned above, plasma flows along the night side flanks of the magnetosphere tend to have an outward component, suggesting the likelihood that plasma is lost as a planetary wind down the flanks. An estimate of total mass loss from the tail (excluding plasmoids) [Thomsen et al. 2014a] is within the range of previous estimates of the total mass-loading rate from ionization of water gas from Enceladus.

Magnetosphere Dynamics

Radial transport – centrifugal interchange instability

Magnetospheric plasma motion transverse to the magnetic field, usually called magnetospheric convection, is key to dynamics in any magnetosphere. As discussed in the section entitled

Magnetosphere Composition, Sources, Transport and Losses, such motion in Saturn's magnetosphere is dominated throughout the equatorial region by (partial) co-rotation with the planet. This was widely expected before the Cassini encounter, and although the expectation was not universally held, the basic result was no big surprise.

The surprises are in the details. It is now clear that the dominant source of plasma for Saturn's entire equatorial magnetosphere is the inner icy satellites, in particular, the south-polar geyser plumes of Enceladus orbiting Saturn at L = 3.95, where L is the planet-centered distance normalized to Saturn's equatorial radius, $R_S \approx 60{,}300$ km—see the section entitled Magnetosphere Composition, Sources, Transport and Losses; and Young et al. [2005]. If tiny Enceladus is to dominate the source of Saturnian plasma, and hence its dynamics, there must be a mechanism for transporting this plasma radially from its inner-magnetospheric source to a sink in the outer magnetosphere and ultimately to the downstream solar wind. This transport mechanism is now known to be the centrifugal interchange instability.

A schematic illustration of this process, projected on the equatorial plane, is shown in Figure CAPS-31 [Hill et al. 2005].

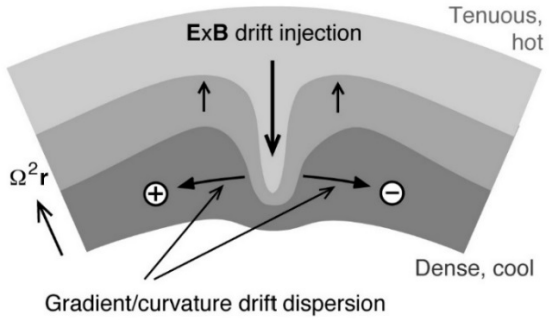

Figure CAPS-31. In the centrifugally driven interchange convection process, flux tubes containing hot but tenuous plasma (*light gray shading*) from an exterior source move inward, toward Saturn, and are replaced by outward moving flux tubes of cooler but denser plasma (*dark gray shading*) moving outward from an interior source.

The centrifugal acceleration Ω^2/r is outward and exceeds Saturn's inward gravitational acceleration beyond L ~2. Outward moving flux tubes release centrifugal potential energy from the system at a rate Ω^2/r per unit mass, and inward moving flux tubes add centrifugal potential energy to the system at the same rate per unit mass. Because of the inward density gradient of the combined plasma distribution (per unit magnetic flux), the combined flux-tube interchange process releases potential energy from the system and is therefore gravitationally unstable. The reverse would be true if the background density gradient (per unit magnetic flux) were reversed. In this sense the interchange motion is centrifugally driven. Flux-tube interchange motions, by definition, involve no net radial transport of magnetic flux.

Hot plasma injections

Figure CAPS-31 also illustrates the azimuthal gradient and curvature drifts of the hot tenuous plasma injected inward by the interchange process, relative to a co-rotating frame of reference. This drift is prograde (eastward) for positive ions and retrograde (westward) for negative ions and electrons. Its speed at a given distance is proportional to particle thermal energy. The injection process thus gives rise to an energy-longitude dispersion signature of the injected plasma, which has been called the smoking gun of interchange convection. This signature was repeatedly observed by CAPS on every Cassini pass through the inner magnetosphere, (L between ~5 and ~12), where the magnetic configuration is well described by an aligned dipole model [Burch et al. 2005; Hill et al. 2005; Young et al. 2005; Chen and Hill 2008; Chen et al. 2010; Rymer et al. 2008, 2009]. An early example of this injection-dispersion signature, appropriate to this off-equatorial orbit, is shown in Figure CAPS-32 from Hill et al. [2005]. In the inner magnetosphere the interchange convection scenario accounts for all key aspects of the morphology and composition results summarized in the section entitled Magnetosphere Composition, Sources, Transport and Losses.

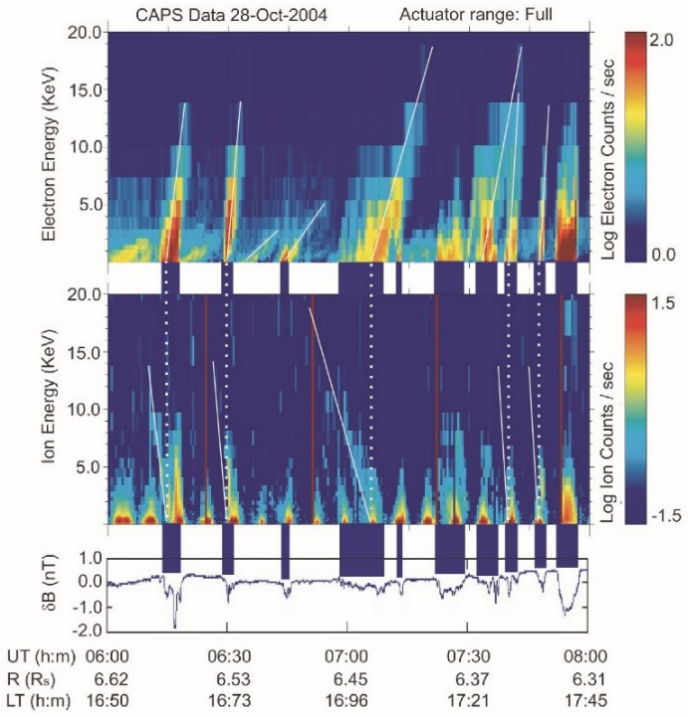

Figure CAPS-32. Energy-longitude dispersion signature of injected plasma. Linear energy-time spectrograms for electrons (*top panel*) and positive ions (*middle panel*) from the CAPS detectors during the second Cassini orbit of Saturn. The *bottom panel* shows simultaneous magnetic-field magnitude perturbations.

One unexpected feature of these observations is that Saturn's inflow channels (containing hot tenuous plasma) are always narrower in longitude than the neighboring outflow channels (containing cooler denser plasma), by a factor ~10 [Chen and Hill 2008; Chen et al. 2010]. All

previous theoretical models of interchange convection had inflow and outflow channels of equal width, because of assumptions made for analytical convenience. Recent numerical simulations using the more flexible Rice Convection Model (RCM), driven by CAPS observational inputs [Liu et al. 2010; Liu and Hill 2012; Hill 2016, 2017; Hill et al. 2018], have clarified the reason for this apparent discrepancy between observation and theory. At Saturn (unlike at Jupiter) the source region for newly injected plasma, both from new ionization and from charge-exchange reactions with ambient neutral molecules, is broadly distributed throughout the radial range in which the resultant interchange radial transport occurs (L between ~5 and ~12).

Co-rotation lag and plasma loading

There are useful and well-established relationships between the local rate of plasma mass or momentum loading (through new ionization, charge exchange, or outward mass transport), on one hand, and the radial variation of the rotational lag behind rigid co-rotation with the planet, on the other. Rates of ionization, charge exchange, and net outward mass transport are difficult if not impossible to measure directly. But the co-rotation lag is straightforward to measure directly if one has access to reliable in situ plasma measurements. If one side of the equation is measurable, it can provide proxy information about the other side of the equation that is not. This method of data analysis has been developed and employed successfully at Jupiter for several decades using Voyager, Galileo, and even Earth-based spectroscopic data, and has now been generalized and employed successfully by the CAPS team.

Tokar et al. [2006] reported surprisingly strong and asymmetric plasma flow perturbations during the distant and highly inclined July 2005 Cassini encounter with Enceladus. The flow measurements are depicted by arrows in Figure CAPS-33, projected onto the equatorial plane. The background flow contours are provided by an analytical model [Pontius and Hill 2006] that is based on earlier Jupiter-Io models, but generalized to account for, among other things, the fact that the Enceladus plasma source is centered, not at Enceladus, but at a position clearly southward of Enceladus, thus anticipating the more-or-less concurrent discovery of the south polar Enceladus plumes. This study also concluded that plasma mass is added to Saturn's magnetosphere at a rate > ~100 kg/s in the near vicinity of Enceladus, a conclusion that was controversial at the time but was subsequently verified by many independent analyses—for example, Chen et al. [2010].

Pontius and Hill [2009] applied a similar analysis, not to the localized plasma loading in the immediate vicinity of Enceladus, but to the much broader region ~3 < L < ~10 where significant co-rotation lag was reported by Wilson et al. [2008, 2009] from their analysis of CAPS data. This study utilized the modeled neutral gas distribution of Johnson et al. [2006b], also based on CAPS results. The red symbols in Figure CAPS-34 [Wilson et al. 2009, Figure 4] show the co-rotation lag as a fraction of the local rigid co-rotation speed. The data-model comparison of Pontius and Hill [2009] concludes that the plasma loading rate in this much larger volume is also > ~100 kg/s, comparable to that in the near vicinity of Enceladus.

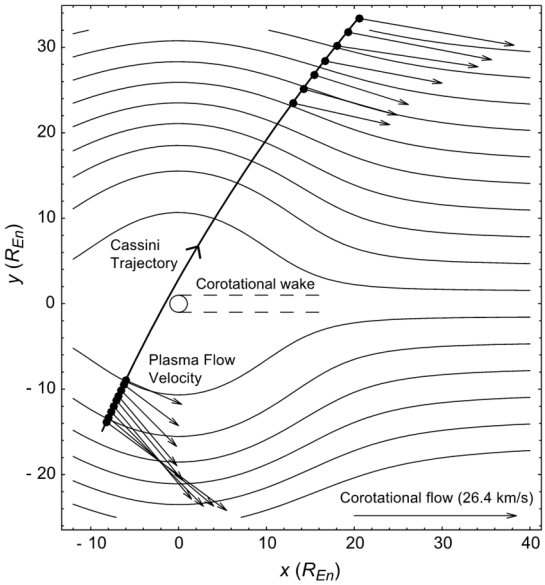

Figure CAPS-33. Strong and asymmetric plasma flow perturbation measurements. Observed plasma flow vectors (arrows), projected onto the equatorial plane, during the July 2005 Cassini encounter with Enceladus, at times (indicated by large dots) when the Cassini orientation was favorable for detection of such flows [Tokar et al. 2006]. The background flow contours are from the theoretical model of Pontius and Hill [2006] as described in the text.

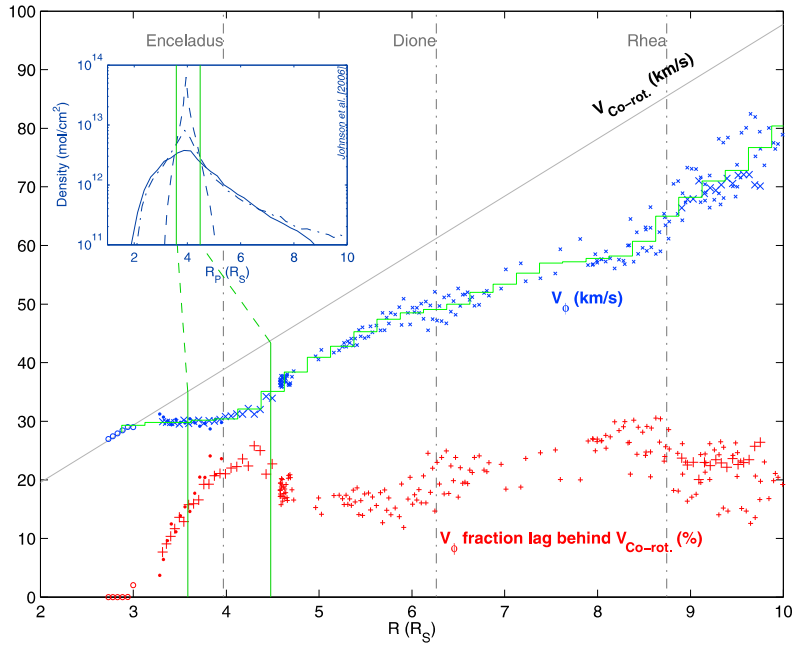

Figure CAPS-34. CAPS plasma flow measurements. Data for L > 5.5 are from forward modeling of thermalized ion velocity moments [Wilson et al. 2008]. Data for L < 5.5 are obtained from analysis of freshly picked-up charge-exchange products under the assumption of gyrotropy. Red symbols at the bottom show azimuthal speeds as a fraction of the local co-rotation speed. Figure from Wilson et al. [2009], Figure 4.

Magnetotail plasmoids and their consequences

Magnetic reconnection in the magnetotail current sheet can produce plasmoids, magnetic flux ropes (or closed magnetic loops) that are disconnected from the planet at one (or both) ends. These structures have been routinely observed in the magnetotails of Earth and Jupiter. Observations at Saturn were limited by orbital geometry because the deep magnetotail passes in 2006 occurred near Saturn's northern winter solstice, when the warped magnetotail current sheet was presumably displaced well northward of Cassini's orbital plane—see Figure CAPS-35. Despite this problem, three plasmoid-like magnetic signatures were identified in the Cassini magnetometer data [Jackman et al. 2007]. Two of these events crossed the current sheet, where ion fluxes were sufficient to permit composition and velocity-moment information to be extracted from CAPS data. These two events were analyzed in detail by Hill et al. [2008]. The most dramatic event occurred on March 4, 2006 at a planet-centered distance of 44 R_S and at 0300 local time (LT). Results are shown in Figure CAPS-36.

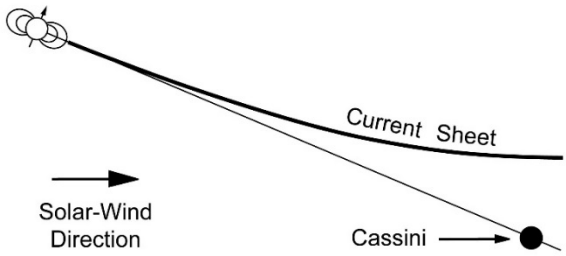

Figure CAPS-35. Orbital geometry during the deep-tail passes of Cassini. Figure from Hill et al. [2008], Figure 1.

Early in this event, before the sharp B_θ reversal near 2300 UT, water-group ions dominated plasma composition, indicating pinching off of a formerly closed flux tube containing plasma from the interior source, as in Vasyliunas-cycle reconnection. At about 23:10 UT the W^+ peak went off-scale above the energy-per-charge range of the CAPS IMS (50 keV), so W^+ velocity moments became unavailable though their flux remained high. The velocity moments (based on H^+ after 23:10) indicate sub-co-rotational azimuthal flow throughout the event and a dramatic tailward acceleration (with V_r increasing up to ~800 km/s) late in the event. Rigid co-rotation at this distance would be 430 km/s in the V_Φ direction.

A particularly interesting feature of this event is that Cassini was in a position to see not only the plasmoid properties observed in situ by CAPS and MAG, but also the plasmoid's earlier initiation closer to Saturn as observed by MIMI in energetic neutral atom (ENA) bursts. The viewing geometry is shown in Figure CAPS-37. The ENAs were hydrogen and oxygen atoms having speeds consistent with covering the distance from source to Cassini (~26.5 R_S) in the allotted time (~25 min). The plasmoid structure itself could also have covered the same distance in the same time interval [Hill et al. 2008].

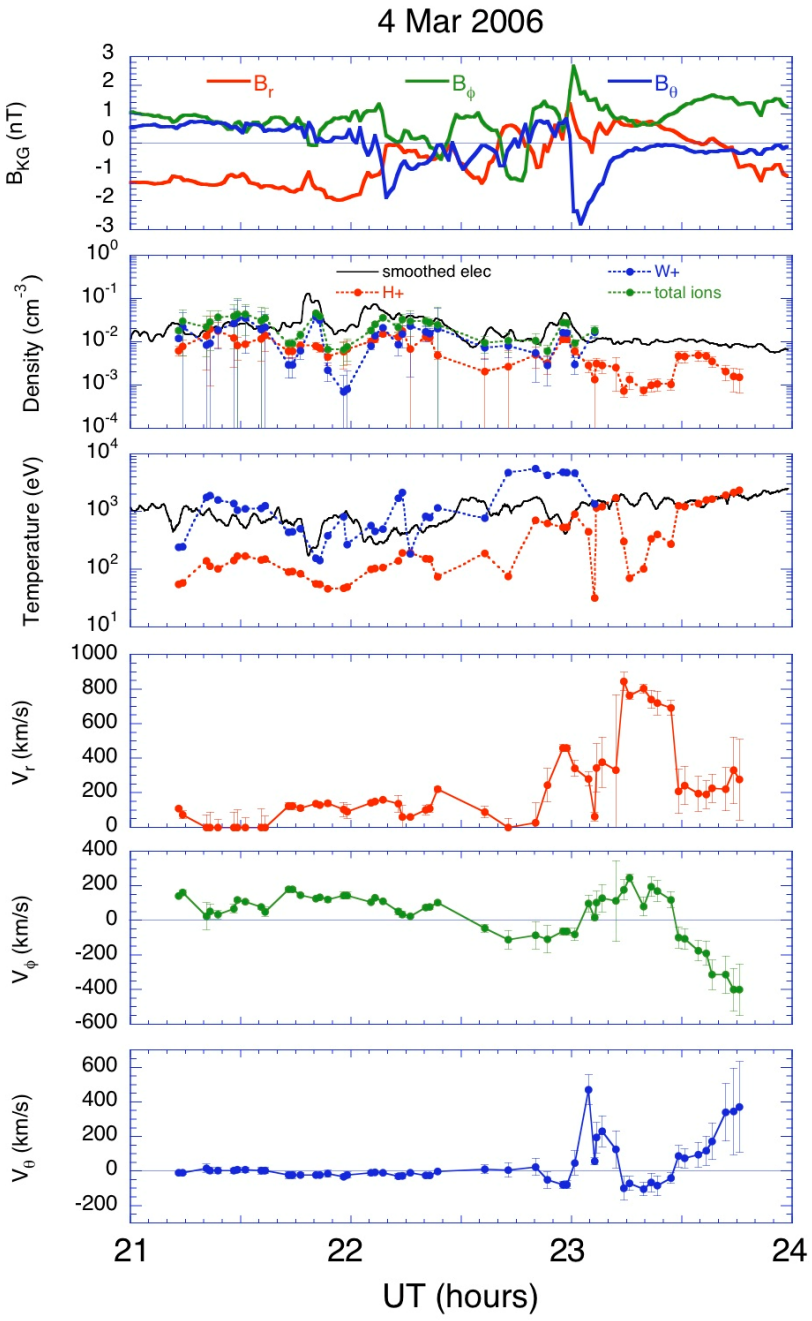

Figure CAPS-36. Magnetic field components and particle velocity moments for the plasmoid encountered by Cassini at 44 R_S near 0300 LT [Hill et al. 2008, Figure 3].

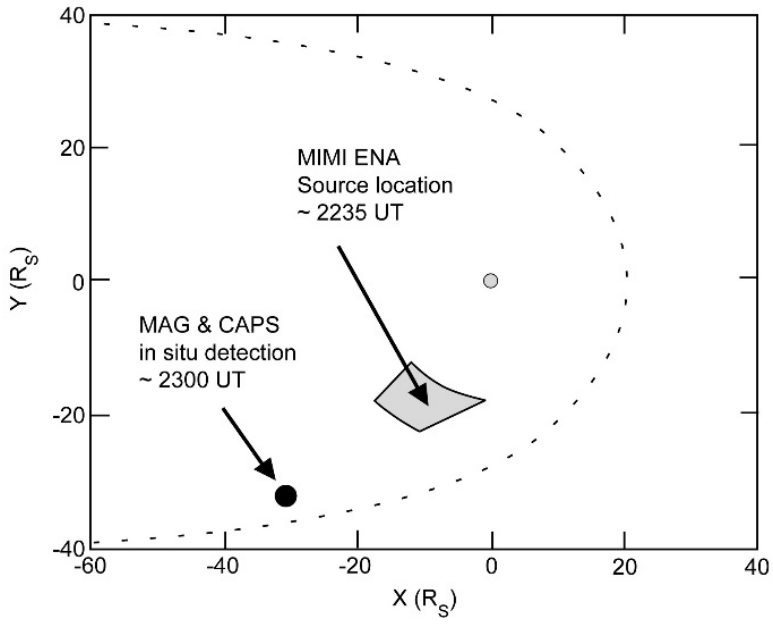

Figure CAPS-37. During the in situ CAPS and MAG plasmoid observations on March 4, 2006 (see Figure CAPS-36 above), Cassini was within the large dot indicated. The ENA bursts observed from the same location ~25 min earlier were deduced to have a source within the quasi-rectangular shaded box. The dashed contour is a cartoon depiction of the typical shape and location of Saturn's magnetopause.

Plasmoid formation provides an escape route for cool W^+ plasma that has accumulated from the interior source region. There remains some controversy as to whether this escape route is adequate to balance the interior source rate, estimated to be roughly 100 kg/s or more. It is plausible, but not yet demonstrated, that an unseen spectrum of smaller but more frequent plasmoids could contribute importantly to the escape rate.

Magnetotail reconnection also provides a fresh source of hot, tenuous plasma to the region planetward of the reconnection site, where it causes a dipolarization signature in the magnetic field. It can also provide seed particles both for the inflow channels of the interchange cells in the inner magnetosphere, as described earlier, and for the intermittent ENA bursts observed by MIMI from the middle and outer magnetosphere, and the associated SKR bursts observed by RPWS from the footprints of the same field lines.

Theoretically, there is a clear distinction between Vasyliunas-cycle reconnection involving the pinching off of formerly closed flux tubes containing cool dense plasma from the inner-magnetosphere source, and the more Earth-like Dungey-cycle reconnection involving the closure of formerly open flux tubes of the magnetotail lobes, containing hotter and more tenuous plasma of magnetosheath origin. The large plasmoid event described above (Figure CAPS-36) is readily explained by the Vasyliunas cycle alone. But two detailed multi-instrument event studies [Thomsen et al. 2015a, 2015b] have also found evidence of both Vasyliunas and Dungey cycles occurring either simultaneously or sequentially.

Thomsen et al. [2015a] examined a high-latitude dawn-side Cassini pass moving from the low-density lobe region into the higher-density closed field-line region. They inferred a stripping of plasma from the outer region of closed magnetic flux tubes as those tubes cross the night side magnetosphere from dusk to dawn, attributable to Vasyliunas-cycle reconnection, together with an interval (or region) of Dungey-cycle reconnection at the high-latitude boundary between open and closed field lines.

Thomsen et al. [2015b] also examined a deep-tail near-equatorial Cassini pass near 37 R_S near midnight LT. They found a prolonged period (~5 hr) of planet-ward plasma-sheet flow attributable to an even more prolonged period of magnetotail compression due to the passage of a recurrent solar-wind structure containing enhanced dynamic pressure. They concluded that Dungey-cycle reconnection takes precedence over Vasyliunas-cycle reconnection when the solar-wind pressure is high.

Bow Shock, Magnetosheath, and Outer Magnetosphere

The Cassini spacecraft crossed Saturn's bow shock for the first time at 09:45 UT on June 27, 2004, at a radial distance of 49.2 R_S from the planet. Clarke et al. [2010] investigated 35 orbits on which the spacecraft crossed Saturn's magnetopause and bow shock during 2004–2007 and concluded that the bow shock and magnetopause oscillate approximately in phase, within a phase uncertainty of about ±25°. The typical amplitude is 1–2 R_S and the period is organized by the phase of the interior magnetic field oscillations, with a period near that of planetary rotation. Saturn's (dayside) bow shocks are predominantly quasi-perpendicular by virtue of the shape of the Parker spiral at 10 AU. Sulaiman et al. [2016], analyzing data between 2004 and 2014, found that Saturn's bow shock, which is principally controlled by the upstream magnetic field strength, exhibits characteristics similar to both terrestrial and astrophysical regimes (Alfven Mach number of order 100). Went et al. [2011] used a semi-empirical model to show that the shock is axisymmetric about the solar wind flow direction.

The Cassini spacecraft crossed the bow shock of Saturn for the first time at 09:45 UT on June 27, 2004, at a radial distance of 49.2 R_S from Saturn.

How stable is the bow shock? Sulaiman et al. [2015] carried out a study of very high Mach number shocks in a parameter space that has been poorly explored previously. They identified re-formation of the shock at 10 AU using in situ magnetic field observations from the MAPS suite of instruments. They found evidence for cyclic re-formation of the shock (Figure CAPS-38) controlled by specular ion reflection occurring on a predicted time scale of ~0.3 τ_C, where τ_C is the ion gyro period. In addition, they showed that the magnetic structure of re-forming shocks at the same M_A, a re-forming shock exhibits stronger magnetic field amplification than a shock that is not re-forming.

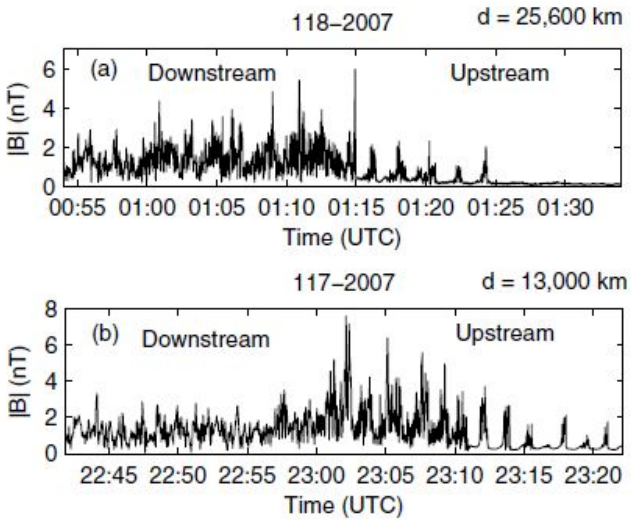

Figure CAPS-38. Magnetic field plots. The panels are two examples of magnetic field plots showing quasi-perpendicular bow shock crossings with re-formation cycles occurring upstream of the shock.

The long-term statistical behavior of the large-scale structure of Saturn's magnetosphere has been investigated by Achilleos et al. [2008]—see also the section entitled Magnetosphere Composition, Sources, Transport and Losses. Statistical techniques established for Jupiter have been applied to the kronian system, employing Cassini magnetometer data and a new empirical model of the shape of the magnetopause based on these data. The resulting distribution of the standoff distance R_{MP} for Saturn, covering a time interval of ~400 days, is well described by a bimodal model—the sum of two normal distributions with different means at ~22 and ~27 planetary radii. Achilleos et al. [2008] also produced a new mathematical model of magnetopause shape. It was noted that the shape of the magnetopause obstacle has an elliptical cross-section with a major (equatorial) axis ~25% larger than its minor (polar) axis. Saturn's bow shock can occasionally reach a high Mach number typical of astrophysical shocks. In this regime Cassini measurements have provided the first in situ evidence for suprathermal electron acceleration under quasi-parallel upstream magnetic conditions [Masters et al. 2016].

Using CAPS and other MAPS data, Sergis et al. [2013] investigated the properties of the magnetosheath. At energies of a few keV the magnetosheath is comprised of shocked solar wind plasma, while at energies above a few keV there is a strong presence of water group ions forming localized structures that are being convected downstream in the plasma flow. Under average magnetic field conditions in the magnetosheath, the kinetic properties of these hot water group ions can enable their escape upstream from the bow shock—see also the section entitled Magnetosphere Composition, Sources, Transport and Losses.

A new magnetosheath data set introduced by Thomsen et al. [2017] is based on a comprehensive survey of intervals in which the observed magnetosheath flow was encompassed within the CAPS plasma analyzers' fields-of-view, and for which the computed numerical moments are accurate. The data extend over eight years from 2004 day 299 to 2012 day 151 and comprise 19,155 measurements of 416 s each. In addition to the plasma ion moments (density, temperature,

and flow velocity), merged values of the plasma electron density and temperature, the energetic particle pressure, and the magnetic field vector are also included in the data set. The magnetosheath population is characterized by ion energies between ~100 eV and ~2 keV and electrons up to about 100 eV. The solar wind is best identified in the electrons, which have energies generally below 10 eV.

The proton-to-electron temperature ratio is very similar to typical values found in Earth's magnetosheath. Approximately 95% of the flows in Saturn's magnetosheath are found to be super-Alfvénic. The proton temperature tracks the predicted solar wind speed well. The clear correspondence between the magnetosheath proton temperature and the predicted solar wind speed suggests that temperature might provide a useful means of monitoring the upstream solar wind flow speed. Although the presence of the magnetosphere obstacle and its influence on the flow certainly affects the overall energy balance, one might nonetheless expect a rough equivalence between the upstream energy per particle and the downstream energy per particle. An analysis of the total magnetosheath energy (defined as magnetosheath bulk flow energy plus thermal energy plus magnetic energy per particle) using CAPS data, compared to the upstream bulk flow energy at several terrestrial bow shock crossings reported by Song et al. [1999], gives ratios ~0.4 to 0.6. This is similar to simulations of the total energy of plasma carried in Saturn's magnetosheath. On average, the solar wind bulk flow energy is ~1.860 ±0.797 times the combined magnetosheath bulk flow energy and proton temperature. Similarly, it is ~1.69 ±0.76 times the total magnetosheath energy.

The large set of magnetosheath electron temperature measurements made by ELS in this dataset, combined with the statistically-based estimates of the upstream flow speed based on IMS data, reveals how the magnetosheath temperature is related to the solar wind bulk flow energy, in a statistical sense. The median ratio of 3.8% is consistent with the findings of Masters et al. [2011a]. Accounting for other factors, the typical fraction of electron heating is probably closer to 4 than 3.5, which is significantly lower than the typical value for lower-Mach number shocks at Earth.

The rotation period of Saturn's magnetosphere was found to vary with time, and changing periodicities were identified in magnetic fields, radio emissions, and charged particles [Andrews et al. 2008, 2011, 2012; Provan et al. 2009, 2011, 2013, 2014]. The motion of the magnetodisk is very much affected by the oscillating magnetic field of Saturn, which is different in the two hemispheres. These planetary period oscillations strongly influence the magnetic and plasma properties of the outer magnetosphere [Andrews et al. 2010; Provan et al. 2012] as well as the density of thermal ions [Nemeth et al. 2011; Szego et al. 2011]. The thermal plasma sheet properties are different for the different ion species. The proton sheet is smoothly modulated by the flapping of the magnetodisk while heavy ions form a narrow sheet surrounding the magnetic equator—see also the section entitled Magnetosphere Composition, Sources, Transport and Losses. The periodicity of the observed heavy-ion rich events was found to be close to the SKR period of the southern hemisphere.

Szego et al. [2012] observed that the ion density moments derived by Thomsen et al. [2010] exhibit peaks around zero-crossings of the magnetic field. The proton peaks are broader while the

heavy ion peaks are sharper. They found that the positions of these peaks can be explained by the simple structural model of Arridge et al. [2011a]. Szego et al. [2013] modified this simple structural model to include the dual periodicity of the magnetic field and found an even better agreement for the positions of the ion peaks.

Using numerical ion moments, Nemeth et al. [2015] investigated the azimuthal flow velocities measured by CAPS along with their periodicities. They observed a significant positive correlation between the azimuthal plasma speed and the plasma density, while both are anti-correlated with the magnitude of the radial component of the magnetic field. They found that the dense plasma near the magnetic equator rotates around the planet at high speed, but the dilute plasma of higher latitudes is rotating significantly slower.

Nemeth et al. [2016] analyzed the quasi-periodic variation of several plasma parameters. The variation of the magnetic field was used to recover the position of the magnetodisk, and the position information was further used to model the variation of the density and azimuthal velocity moments of the thermal ions. This simple technique provides very good fits for all three parameters simultaneously.

Synergistic Science

Many plasma observations during the mission featured data collected simultaneously by most, if not all, of the particles and fields instruments (CAPS, INMS, MAG, MIMI, and RPWS), collectively referred to as MAPS. Prior to the Cassini mission it was understood from the experience of Voyager at Saturn and investigations of other magnetospheres, as well as space plasma physics in general, that many of Cassini's science objectives could only be met by synergistic measurements made by the MAPS instrument suite. Many details of synergistic science emerging from these measurements are discussed in the section entitled Detailed Magnetosphere Science Results and can easily be judged by the multitude of references cited in this volume. Below is a short list of the most important contributions made by CAPS to synergistic science.

- CAPS and INMS collaborations to elucidate the composition of neutral and charged particles at Titan and Enceladus. This is undoubtedly one of the most productive examples of synergistic science.
- CAPS, MAG and MIMI collaborations on the acceleration and transport of plasma throughout the magnetosphere.
- CAPS and MAG studies of periodic oscillations of the magnetodisk and plasma sheet, as well as investigations of the properties of shocks at Jupiter and Saturn.
- CAPS data inputs to the Rice Convection Model which was then used to simulate plasma convection throughout the magnetosphere.
- CAPS, RPWS, INMS, and CDA—Investigations of the makeup of charged ions, nano-grains and dust in the Enceladus plume.

Open Questions

Although CAPS operated for only the first eight years of the 13-year Cassini mission (2004 through 2012), as might be expected it left behind numerous open questions. Some of the most significant remaining questions concern the nature of the chemistry and formation of heavy negative ions in the atmosphere of Titan and the plumes of Enceladus. Other issues include the source, acceleration, transport and loss of cold, heavy water group ions, and finally, the role of the magnetodisk in controlling plasma sheet dynamics and generation of plasmoids.

Titan and Titan-magnetosphere interactions

Titan's atmosphere and its interaction with the magnetosphere are so complex that there remain many issues to address. Foremost among them are:

1. Search for methane ions in Saturn's outer magnetosphere which should be detectable if the high outward fluxes of methane estimated by Yelle et al. [2008] and Strobel [2008] are correct.

2. Continue IMS composition measurements of ionospheric outflows initiated by Sittler et al. [2010], and later by Woodson et al. [2015]. Look for evidence of minor species such as N^+, H_2O^+, NH_4^+ and more specific identifications of the mass 12–17 amu/q ions and mass 28–30 amu/q ions.

3. Perform more theoretical modeling of the ion composition of these outflows.

4. The Desai et al. [2017] analysis of negative ions measured by ELS showed that negative long carbon chains are forming in Titan's ionosphere, and that doubly-charged fullerenes could explain the main heavy negative ion peak at ~400 amu/q at lower altitudes. More work is required in this area including studies of the conversion of oxygenated fullerenes on Titan's surface, and on the bottom of its hydrocarbon lakes, into exobiological molecules such as amino acids by galactic cosmic rays.

5. Clearly studies of the kinetic interactions between Titan's upper atmosphere and upstream flow (light or heavy ion dominated) need to be continued, but such analysis will require the continued development of hybrid codes so the observed interaction details can be fully understood.

6. Detailed analysis of pickup ions and ionospheric outflows for Titan flybys at different heights still needs to be carried out, for example using ELS data as Coates et al. [2015] have done.

7. In order to characterize neutral energy distributions in the exosphere region, continued development of rarefied gas dynamics theory is needed in order to

understand the energy deposited by pickup ions and the population of hot recoil atoms and molecules that result.

8. Further calibration of the IMS prototype using molecular ions such as HCN^+, and NO^+ is needed in order to get C/N and N/O efficiency ratios. Calibration measurements of NH_4^+ would also be useful.

9. INMS data indicates that Titan's upper atmosphere is highly variable on timescales less than a Titan day [Cui et al. 2009]. However, the dynamics driving the variability are not well understood. Current ideas include gravity waves propagating from the lower atmosphere [Snowden and Yelle 2014], and/or magnetospheric energy inputs [Sillanpaa and Johnson 2015; Johnson et al. 2016; Jiang et al. 2017]. CAPS measurements of plasma energy spectra can provide constraints for numerical simulations of the effect that precipitation has on the thermal structure and escape of Titan's upper atmosphere. Understanding the physics of escape in Titan's current atmospheric environment will provide insight on how Titan and other bodies have evolved over their lifetimes.

Enceladus, rings, and the icy satellites

1. How are heavy negative ions formed in the plume at Enceladus, and what is their contribution to nano-grain formation?

2. How are ions such as O_2^+ which originate over and near the rings distributed throughout the magnetosphere?

3. What happens to the charged nano-grains? Do they contribute to a dusty plasma near Enceladus orbit, or are they eroded by local energetic plasmas?

4. What processes remove material from icy satellite surfaces to create their exospheres, and are they steady-state?

Magnetosphere structure and dynamics

The CAPS data set is exceedingly rich and has enabled great progress in identifying and understanding the structure and behavior of Saturn's magnetosphere. Further understanding will almost certainly be derived from the data in the future. Some of the findings described in this report have been clear and definitive; others need additional confirmation, either by inclusion of more data or by other means such as modeling. The interpretation of many of the findings need more rigorous examination or development. (Note: Some open questions identified in the sections entitled Magnetosphere Composition, Sources, Transport and Losses and Magnetosphere Dynamics dealing with magnetospheric structure and dynamics and seasonal variations of Saturn's magnetosphere appear in the book, Saturn in the 21st Century, Cambridge, 2019).

1. Are the growth of the Kelvin-Helmholtz instability and magnetic reconnection coupled?

2. What is the dominant mode of solar wind interaction with the magnetosphere, the viscous interaction or the large-scale reconnection interaction?

3. How is plasma transported outward, and magnetic flux returned, in the region between ~12 and ~20 to 25 R_S?

4. Where in the Saturnian system does Vasyliunas-type reconnection take place, and where does Dungey-type reconnection take place? Is there a region in Saturn's magnetosphere where one or the other dominates?

5. Where and how does the magnetosphere unload its cold, dense plasma?

6. How does the solar wind drive magnetospheric dynamics at Saturn? Is solar wind dynamic pressure the primary influence?

7. What causes the inner magnetospheric electric field that drives the noon-midnight asymmetry in plasma temperature, plasma density, energetic particle intensity, etc.?

8. What other solar cycle effects can be found in Saturn's magnetosphere?

9. How important is Titan as a source of magnetospheric H_2^+? What is the fraction of N^+ contributed by Titan?

10. What is the relationship between large-scale, tail-reconnection-driven injections and small-scale interchange injections?

11. What determines the scale size and inflow speed of interchange injections? What determines the apparently variable rate and depth of such injections?

12. What is the nature of the very low density layer often seen in lower energy electrons between the plasma sheet and the lobes? Is it related to ionospheric outflow reported by Felici et al. [2016]?

Cruise Science Results

CAPS took advantage of two gravity-assist flybys to gather data on the magnetospheres of Earth and Jupiter and, particularly at Earth, to perform calibration measurements and analysis. During those two flybys CAPS contributed measurements never made before—at Earth with a high-speed traverse that gave a freeze-frame picture of the magnetosphere in addition to real-time observations of the substorm cycle in progress [Khan et al. 2001]—and at Jupiter by establishing characteristics of its bow shock and magnetosheath.

Solar Wind and Heliosphere

During cruise, the CAPS investigation made its first major discovery with the in situ observation of interstellar pickup ions beyond the orbit of Jupiter …

On October 15, 1997, the Cassini-Huygens spacecraft was launched on an almost seven-year journey to Saturn. On its way, Cassini-Huygens performed gravity-assist maneuvers at Venus (on April 25, 1998 and June 24, 1999), Earth (August 17, 1999), and before arriving at Jupiter (technically) on December 29, 2000. The Jupiter flyby was followed by a ~3-month long exploration down the dusk flank of the magnetosphere. CAPS then operated at programmed intervals between 6.4 and 8.2 AU searching for interstellar pickup ions, before arriving at Saturn on July 1, 2004. During much of the cruise before Jupiter and for two years afterwards CAPS was in hibernation as were other MAPS instruments. The Cruise phase was partly devoted to commissioning the instrument, but also to making measurements in the solar wind that led to new science.

Interstellar pickup ions. During cruise, the CAPS investigation made its first major discovery with in situ observations of interstellar pickup ions beyond the orbit of Jupiter. [Gloeckler et al. [1998] had previously measured pickup ions inside Jupiter's orbit using the Solar Wind Ion Composition Spectrometer (SWICS) instrument onboard Ulysses. This was the first direct detection of mass-resolved interstellar pickup ions. It confirmed the existence of helium focusing at these distances caused by the solar gravitational field (Figure CAPS-39). CAPS also made the first direct, in situ, measurements of a large shadow in the interstellar atomic hydrogen population downstream from the Sun caused by its motion through the interstellar medium [McComas et al. 2004]. The shape of the distribution function of He^{+} as a function of energy was characteristic of a pickup distribution with a flat top and cut off at about four times of the solar wind energy.

Saturn's aurora. Geomagnetic storms and associated auroral activity at Earth are tied to the interaction of the disturbed solar wind with the magnetosphere. Saturn's magnetosphere is dominated by co-rotating plasma out to large distances from the planet, and it is unclear to what extent the solar wind plays a role in high latitude phenomena such as the aurora. Crary et al. [2005] combined Hubble Space Telescope (HST) images of Saturn's aurora taken over one month in 2004, with solar wind data from IBS taken while Cassini was ~3 × 10^7 km (~500 R_S) upstream from Saturn, to show that Saturn's aurora responds strongly to changes in solar wind conditions. Auroral power was best correlated with solar wind dynamic pressure (which is similar to that found at Earth) rather than the direction of the interplanetary field. This is a finding apparently unique to Saturn.

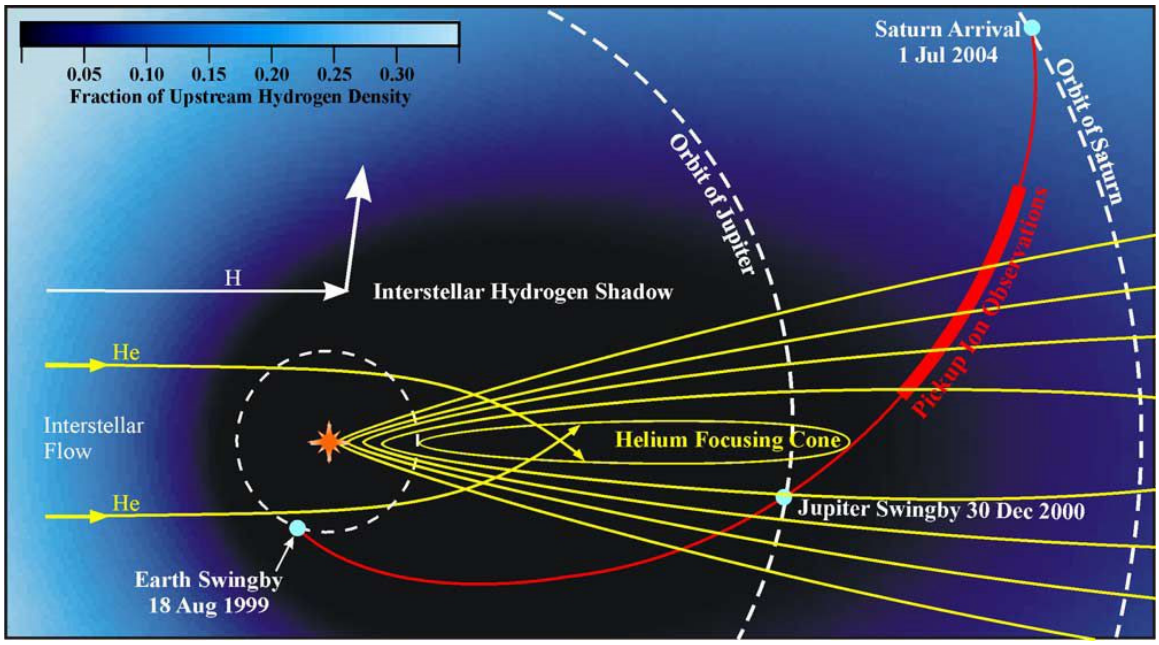

Figure CAPS-39. Schematic diagram of Cassini's trajectory between Earth swing-by and arrival at Saturn. Pickup ion measurements were made between 6.4 and 8.2 AU (heavy line) as Cassini emerged from the down-stream direction. Simulation results show: 1) the gravitational focusing of interstellar He in contours of 5/3, 2, 7/3, 8/3, and 3 times the upstream He density; and 2) the color-coded H density as a fraction of the interstellar value. The dark region downstream from the Sun represents the interstellar hydrogen shadow. Figure from McComas et al. [2004].

Venus

CAPS was not operating during the Venus encounters.

Earth

Earth's gravity-assist encounter on August 18, 1999, was the fastest traversal of Earth's magnetosphere to date. It was effectively a freeze-frame picture of the magnetosphere and an important chance to sample phenomena and boundaries that could later be compared with Saturn's. Inter-comparison of planetary magnetospheres, including that of Jupiter, was a critical, but usually overlooked, feature of the Cassini mission. Most of the following discussion is a condensed version of the definitive study by Rymer [2004] and Rymer [2001].

The spacecraft trajectory allowed CAPS, and particularly ELS, to make measurements of all large structures within the magnetosphere. Since Earth's magnetosphere is a well-known object, the flyby was also an excellent opportunity to calibrate CAPS sensors, particularly ELS, which is subject to spacecraft-plasma interactions that obscure part of its FOV. Figure CAPS-40 shows the Cassini trajectory through the magnetosphere.

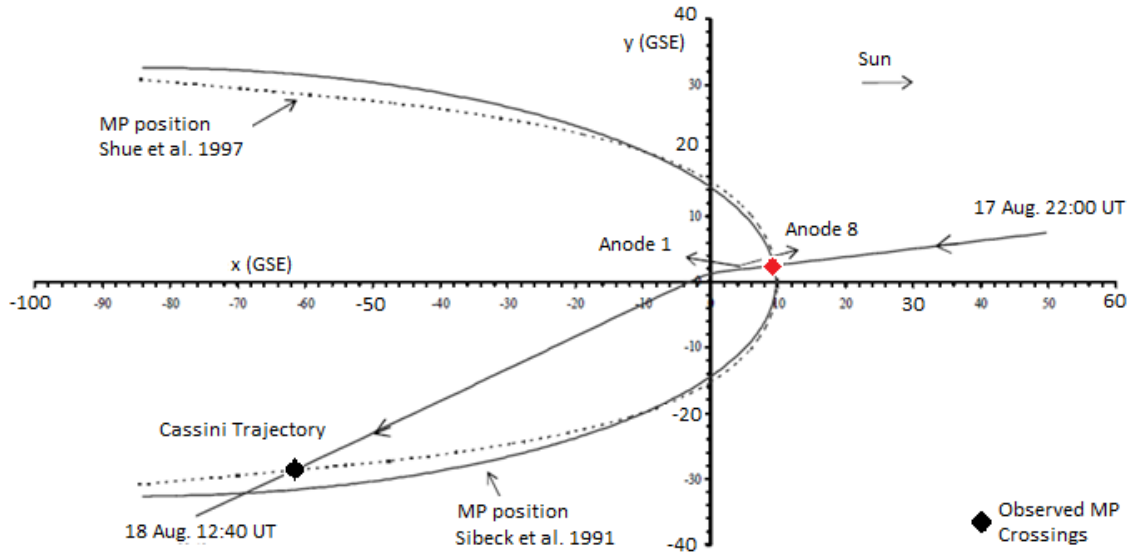

Figure CAPS-40. The Cassini trajectory through the magnetosphere in the x-y Geocentric Solar Ecliptic (GSE) co-ordinate plane showing a model for expected magnetopause shape and position based on Sibeck et al. [1991] and Shue et al. [1997] together with the positions of magnetopause crossings observed by ELS.

During the encounter ELS collected almost ten hours of solar wind data upstream of Earth, and almost nine hours inside the magnetosphere. During the pass ELS sampled electrons in the solar wind, bow shock, magnetosheath, magnetopause, radiation belts, an eclipse, the plasmasphere, plasma sheet, and lobes, and made several crossings of the tail magnetopause. Although this was a period of enhanced solar activity, results were mainly consistent with previous observations of various parts of the magnetosphere with a few exceptions. In addition, two substorms were taking place and there was evidence for low-energy field-aligned electron beams in the plasma sheet [Khan et al. 2001].

A spectacular energy-time spectrograph from ELS covering the entire pass and magnetosphere structures (Figure CAPS-41) can be used to briefly discuss magnetosphere features.

Data taken in the solar wind demonstrated ELS response to photoelectrons down to 0.5 eV, and solar wind electrons up to ~110 eV. Cassini then crossed the very sharp bow shock into the magnetosheath, jumping from solar wind conditions (energy ~10 eV) to the magnetosheath (~52 eV). The radial standoff distance of the bow shock was measured at 15.18 R_E while the magnetopause was at 9.88 R_E, a ratio of 1.55, in good agreement with theoretical predictions of 1.53 [Rymer 2004].

Inside the magnetosheath the core electron population was heated to between 20 eV and 110 eV. The photoelectron flux increased while the energy dropped, which is typical of spacecraft charge becoming more positive. The shift in spacecraft potential was typical of what would be seen

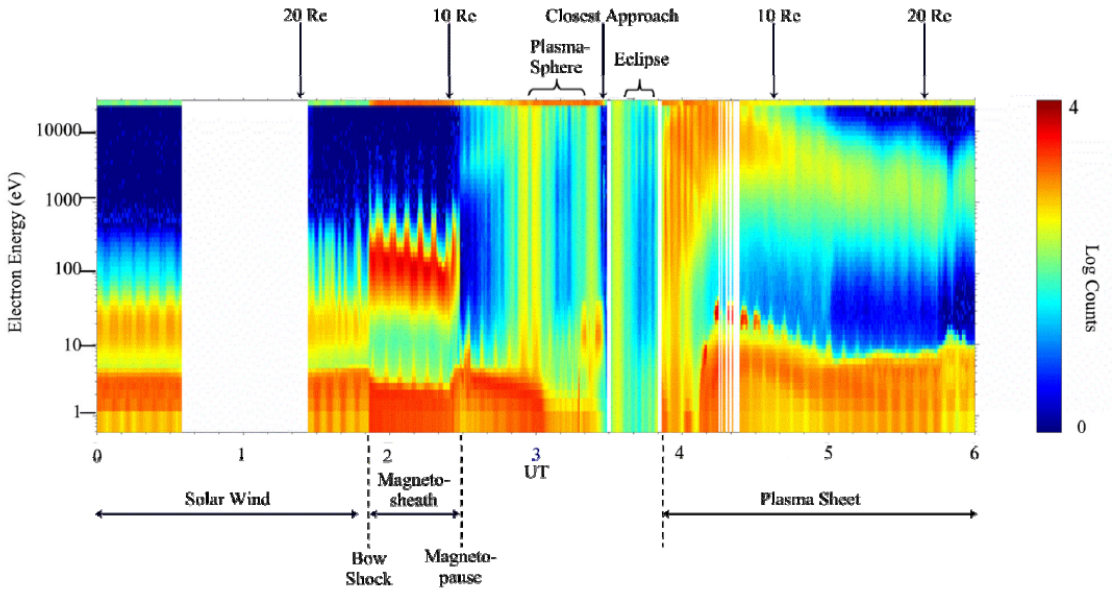

Figure CAPS-41. Six hour energy versus time spectrogram of ELS data from 0000–0600 UT August 18, 1999, for one central anode (out of eight). Counts per accumulation interval (23.4 ms) are indicated by the color scale. Modulation visible in the spectrogram is caused by actuator sweep cycles lasting four minutes.

later at Saturn. Thickness of the magnetopause boundary appears to be rather sharp (956 ±32 km) but its speed past the spacecraft position has an effect on the measurement and is unknown. The LLBL (an appendage of the magnetosheath electron population) is an important feature also seen at Saturn (see the section entitled Bow Shock, Magnetosheath, and Outer Magnetosphere). It carries a mix of both magnetosheath and magnetosphere plasmas and is an important loss process in both magnetospheres.

Once inside the magnetosphere at ~2:30 UT at a distance of 9.38 R_E, Cassini encountered the plasmapause, another feature also seen regularly at Saturn [Young et al. 2005]. The spectrum shows the plasma temperature dropping, which is characteristic of the response expected in the relatively cold plasma of the plasmasphere. Just prior to the encounter Cassini passed through the trapped radiation belts, confirming that shielding of ELS and the other CAPS sensors is effective.

Following the geometric encounter at 03:28 UT, Cassini entered an eclipse period, and then entered the plasma sheet just before local midnight. Electron energies within the plasmapause extended from ~100 eV (identified as accelerated photoelectrons), to above the ELS energy rage of 26 keV. The latter is identified as the plasma sheet distribution calculated to have a density of 0.2 cm^{-3} and a temperature of 2.4 keV about as expected and in agreement with values found with other measurements—for example, Lui et al. [1987].

Starting at 07:27 UT at 36.7 R_E Cassini crossed into and then out of (07:35 UT, 37.9 R_E) the magnetosphere lobe region [Abel et al. 2001]. Finally, at ~6000 R_E downstream from Earth and 12:00 to 22:00 UT, about where the extended magnetotail might be expected under the then current

solar wind conditions, data from several MAPS instruments suggested an encounter with the extended magnetotail. Unfortunately, the measurements were all at the extreme limits of detection and the issue was never resolved [Lagg et al. 2001].

Jupiter

Cassini carried out a gravity assist maneuver at Jupiter on December 30, 2000 at 10:05 UT. The closest approach brought Cassini to within about 9.7 million km of Jupiter's cloud tops. The science it made possible was an additional bonus, more so because Cassini had much superior instrumentation compared to that that of the previous two Voyagers, Ulysses and Galileo missions. The Galileo probe was still active during the flyby (Figure CAPS-42) and joint MAPS measurements provided a chance to study the dynamic effects of the solar wind perturbations on the global configuration of the Jovian magnetosphere [Joy et al. 2002]. The dual Cassini/Galileo spacecraft measurements by MAPS showed clearly that magnetospheric particles leak directly into the interplanetary medium from the closed magnetosphere and are the source for upstream particle events [Krupp 2002].

Cassini made at least five bow shock crossings, one at ~1929 LT and four more between 2100 and 2130 LT on DOY 21. During the flyby, shock activity was high and variable making a moving target for Cassini instruments. Cassini found that the shock is enormous, extending at least 700 R_J down the flank.

All three CAPS sensors were used to identify shock conditions and the times at which Cassini crossed into and out of it—see Szego et al. [2003] for a full description of shock studies based on all Cassini observations. By combining RPWS identification of Langmuir waves and IBS energy spectra, the upstream density could be measured at 0.5 to 1 cm^{-3} while at the same time ELS provided a measure of electron temperature at 2.6 eV. The data allowed the team to solve the Rankine-Hugoniot relations for transitions between the upstream and downstream conditions, deriving plasma density ratios of 2.74, and a downstream ion bulk energy of ~360 eV. The calculated downstream electron bulk temperature prediction was ~44 eV whereas ELS data gave ~11 eV and IMS ~24 eV, in decent agreement with the total energy jump predicted by theory.

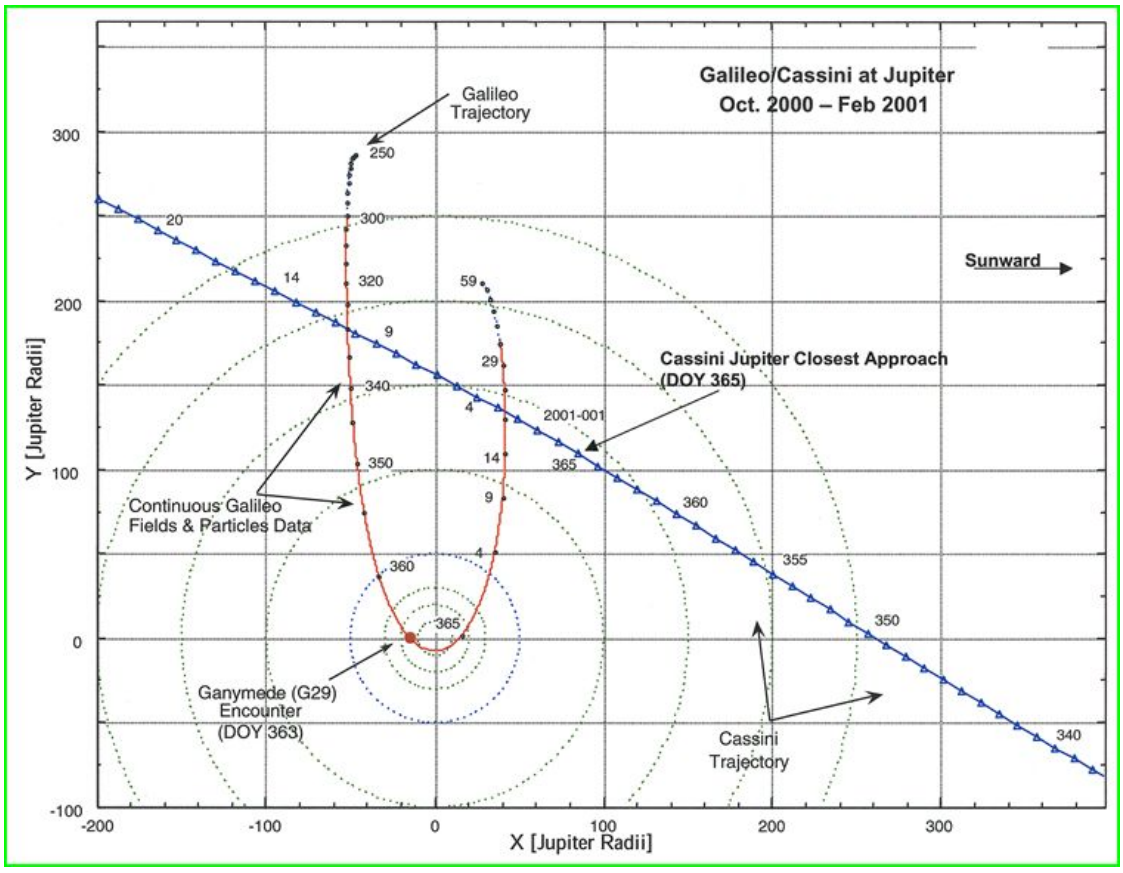

Figure CAPS-42. The orbits of Galileo and Cassini at Jupiter.

IBS energy-time spectrograms were used to easily identify shock crossings far down the flank of the magnetosphere. Figure CAPS-43 is one example of four that were observed at 576, 618, 744, and 770 R_J [Szego et al. 2003].

Using primarily IBS and ELS data in addition to MAG and RPWS, Bebesi et al. [2010] were able to investigate features of the downstream Jovian shock and magnetosheath out to ~700 R_J; a region not previously visited by any other spacecraft. As might be expected, the shock transition layer was broad and turbulent at that distance, but the transits were always easily observed using IBS data.

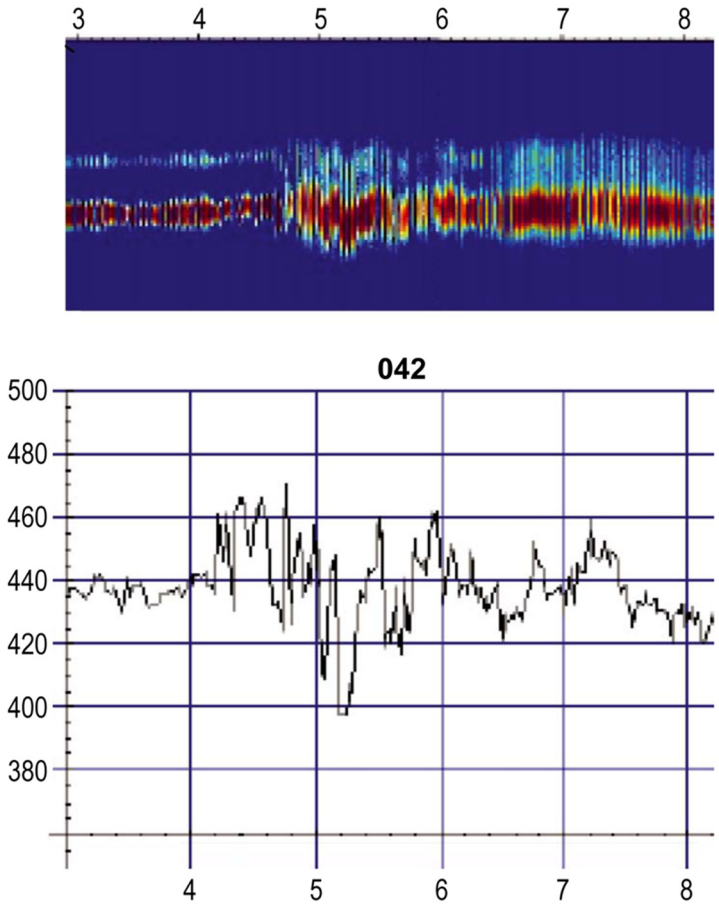

Figure CAPS-43. IBS data taken on DOY 042, 2000, 0300 to 0900 UT along the flanks of the Jovian magnetosphere. The velocity jump across the shock shows up as a jump in the velocity measured by IBS beginning at approximately 0420 UT. The most apparent feature is at ~4:40 UT when Cassini is inside the sheath and density and temperature both increase.

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

ACT	actuator
amu	atomic mass unit
AO	Announcement of Opportunity
au	astronomical unit
C/A	closest approach
CAPS	Cassini Plasma Spectrometer
CSM	Cassini Solstice Mission
DPU	data processing unit
DSMC	Direct Simulation Monte Carlo
ELS	Electron Spectrometer
ENA	energetic neutral atom
ESA	electrostatic energy analyzer
eV	electron volt
FOV	field-of-view
GSE	Geocentric Solar Ecliptic
HST	Hubble Space Telescope
IBS	Ion Beam Spectrometer
IMS	Ion Mass Spectrometer
INMS	Ion and Neutral Mass Spectrometer
IR	Independent Review
keV	kiloelectron volt
kg	kilograms
km	kilometer
LEF	linear electric field
LLBL	low-latitude boundary layer
LP	Langmuir Probe
LT	local time
MAG	Magnetometer
MAPS	Magnetospheres and Plasma Science
MHD	magneto-hydrodynamic
MIMI	Magnetospheric Imaging Instrument
MLI	multi-layer insulation
NESC	NASA Engineering and Safety Center
NESC	National Electrical Safety Code
RCM	Rice Convection Model
RPWS	Radio and Plasma Wave Science
R_S	Saturn radii

s	seconds
SKR	Saturn Kilometric Radiation
SOI	Saturn Orbit Insertion
ST	straight through
SWICS	Solar Wind Ion Composition Spectrometer
TM	Traceability Matrix
TOF	time-of-flight
UT	universal time
UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph

Cosmic Dust Analyzer

The Cosmic Dust Analyzer (CDA) directly sampled the composition, mass, impact direction, and speed of dust and ice particles in the Saturn system, as well as the Jupiter system and in interplanetary space. The **science objectives** of CDA included mapping the size distribution and chemical composition of ring material in the Saturn system, studying dynamical processes responsible for the diffuse E-ring structure, obtaining information on the chemical composition of satellites, and determining the role that dust plays as source and sink of charged particles in the magnetosphere.

CDA was composed of two sensors, the high-rate detectors (HRDs) designed to measure high impact rates in dust-rich environments such as ring plane crossings and the dust analyzer (DA) that measured the electric charge carried by dust particles, their impact directions, speeds, masses, and chemical composition. CDA was on an articulated mechanism that enabled the entire instrument to rotate and reposition to enable measurements of particle fluxes over a wide range of directions.

EXECUTIVE SUMMARY

The science objectives of the Cassini-Huygens CDA were to carry out in situ characterization of the dust environments in order to infer properties of the dust-emitting sources as well as to study the underlying processes associated with dust. The capability to measure both the compositional and dynamical properties of incident dust grains makes the CDA measurements uniquely useful to explore the dust environment in the Saturnian system, as well as other dust populations from the Jovian system (i.e., the nanodust stream particles), and from interplanetary and interstellar space.

The CDA instrument performance over the entire time from 1999 until the last second of Cassini in September 2017 was outstanding.

At Saturn, CDA has successfully characterized the structure and the composition of Saturn's diffuse E-ring, its relation to the geologically active icy moon Enceladus, and how the E-ring interacts with the magnetosphere. CDA results contributed significantly to our understanding of Enceladus and its subsurface ocean, promoting the exploration of the habitability of the ocean worlds in the outer solar system. CDA also provided observational constraints for other diffuse rings (e.g., G-ring and Pallene ring) and the ejecta cloud around the major icy moons of Saturn. During the Grand Finale orbits, CDA detected material directly from Saturn's main rings and revealed ring-planet interactions through charged nanodust.

In addition, the dust populations arriving at the Saturnian system, i.e., interplanetary dust particles (IDPs) and interstellar dust (ISD), were also characterized thanks to the extended mission. Tiny grains expelled from both the Jovian and Saturnian systems by electromagnetic forces were also detected, providing additional information about their source moons and helping to understand the coupling between the interplanetary magnetic field (IMF) and the dynamics of these charged grains.

The CDA instrument performance over the entire time was outstanding. CDA switched on in 1999 and measured almost continuously until the last second of Cassini in September 2017. All five measurement channels (primary charge grid, targets, ion grid, and multiplier) worked the entire time. The multiplier of the spectrometer showed only a minor gain change. No issues with instrument high voltage were identified and the CDA thermal parameters were in the nominal range. The only instrument degradation that occurred was related to close Enceladus plume crossings where the gain of the two target channels decreased. This had no effect on charge or compositional measurements, instead the lower sensitivity was used to perform measurements in the dense E-ring with a higher mass threshold to avoid instrument saturation. A major concern was the Cassini pointing profile and although CDA used its articulation platform approximately once a day in order to track the dust RAM direction, many observations were not possible. Updates of the CDA flight software optimized the instrument performance during special events (Enceladus flybys). Very high impact rates required special instrument settings due to the long instrument dead time of one second. The noise behavior of CDA remained constant during the entire time and no significant interference with the spacecraft or other subsystems was observed. Only the Radio and Plasma

Wave Science (RPWS) active sounder operation led to interferences in the primary charge channel (QP) of CDA.

The major CDA findings are listed below for each science working group as well as during the cruise phase:

Rings

- The exogenous mass influx and the age of the main rings are determined.
- In situ measurement of E-ring particles shows the large extension of the ring all the way to Titan's orbit (~20 R_S).
- Charged grains are the result of dust-plasma interactions in Saturn's magnetosphere. The grain charge polarity switches from negative to positive at a radial distance of around 7 R_S as predicted by models.
- The E-ring is asymmetrical with respect to local time—it is denser and the peak locations are closer to Saturn near local noon and vice versa.

Icy satellites

- In situ characterization of the dusty plume of Enceladus.
- Discovery of the subsurface liquid water reservoir below the icy crust of Enceladus, inferred from the salt-rich E-ring ice grains.
- Ongoing hydrothermal activities within Enceladus' subsurface ocean, inferred from nano-phase silica particles.
- Discovery of complex organic molecules in ice grains from Enceladus.

Magnetosphere and plasma sciences

- Discovery of fast nanodust from Saturn.
- Fast nanograins are probes of the interplanetary magnetic field, as a result of their dynamical interactions with the interplanetary magnetic field.

Others

- Interstellar dust grains penetrate deep into the heliosphere and reach the Earth orbit. Its composition is found to be homogeneous and rich in silicates.
- Sodium chloride is the dominant constituent of the Jovian stream particles, implying they are early condensates from the volcanic plumes of Io.

- Interplanetary dust particles carry surface charges in agreement with the charging models in interplanetary space.
- In situ analysis of two metal-rich interplanetary dust particles by time-of-flight mass spectrometry (TOF MS) in the inner solar system.

CDA is the first dedicated dust instrument operated at Saturn. While its results have changed our view on the role of microscopic dust grains in the system and space exploration, several open questions remain to be resolved in the future:

- What expected ejecta clouds stemming from interplanetary micrometeorite impacts have not been detected around major icy moons (except Rhea) embedded in the E-ring?
- What is the production yield and the size distribution of impact-ejecta particles produced from Saturn's icy moons and the main rings?
- What is the original origin of silicates apparently coming from Saturn's main rings, as detected during the Grand Finale orbits?
- What, if any, are the effects on Saturn's upper atmosphere of nanograins from the main rings?
- What is the dusty plasma status in the plume of Enceladus and the core of the E-ring? What would be its impact on E-ring grain dynamics?

CDA was a highly reliable and versatile instrument with a mass sensitivity 10^6 times higher than those of the Pioneer 10 and 11 dust detectors that measured dust at Saturn prior to Cassini.

CDA Instrument Summary

The CDA was designed to provide direct observations of the impacting dust grains. CDA investigated the physical, chemical, and dynamical properties of impacting dust particles, and their interactions with satellites, rings, and Saturn's magnetosphere [Srama et al. 2004]. The chemical composition of interplanetary meteoroids was successfully compared with asteroidal and cometary dust, as well as with dust in orbit about Saturn and the ejected dust particles from rings and satellites at Saturn and during the flyby at Jupiter. The electrical charging of dust particles in the magnetosphere and the subsequent effects of the ambient plasma and magnetic fields on the trajectories of dust particles have been successfully observed by CDA.

CDA was a highly reliable and versatile instrument with a mass sensitivity 10^6 times higher than those of the Pioneer 10 and 11 dust detectors that measured dust at Saturn prior to Cassini. CDA had significant heritage from former space instrumentation developed for the Vega, Giotto, Galileo, and Ulysses missions.

CDA consisted of two independent subsystems, the High Rate Detector (HRD) and the Dust Analyzer (DA). HRD was designed to monitor high impact rates (up to 10^6 m^{-2} s^{-1}) in dust-rich environments such as during the Saturn ring plane crossings. HRD uses polyvinylidene difluoride (PVDF) foils to detect the impact energy of particles larger than approximately 1 micrometer.

The DA was sensitive to particles within a large mass range of 5×10^{-18} to 10^{-12} kg for impact speeds of ~20 km s^{-1} and covered an impact velocity range of 1 to 100 km s^{-1}, measuring the electrical charge, mass, impact velocity, and elemental composition of the impacting dust grains. This was accomplished by a suite of three DA detectors: 1) a charge sensing unit (QP) in front of the instrument; 2) a classical impact ionization detector (IID); and 3) a time-of-flight mass spectrometer (TOF MS), the chemical analyzer (CA) as a compositional mass analyzer with a mass resolution of up to 50. Both subsystems, HRD and DA, point in the same direction. The units are mounted at 45 degrees on an articulation platform with one rotation axis and an angular range of 270 degrees. The field of views of the subsystems are 180 degrees (HRD), 90 degrees (IID), and 56 degrees (CA), respectively. The instrument had a total mass of 17 kg, a data rate between 0.1 and 4 kbps, and consumed 12 W of electrical power.

Key Objectives for the CDA Instrument

The scientific goals of the Cassini dust instrument were defined as:

- **Cruise science**. Extended studies of interplanetary dust from the Earth to the orbit of Saturn. Sample the chemical composition and the charging state of dust in interplanetary space. Determine the flux of interstellar particles during solar maximum conditions. Search for dust streams originating from Saturn.
- **Jupiter flyby**. Investigate the dynamics of the Io dust streams discovered by Ulysses and Galileo. Characterize their direction, size-mass-distribution, and correlation with the Jovian and interplanetary magnetic field. Investigate the dust stream fluxes caused by the Jovian system with respect to Jupiter distance. Analyze dust stream particles at a different epoch from Galileo. Characterize the elemental composition of dust stream particles.
- **Rings**. Map size distribution of ring material, search for ring particles beyond the known E-ring. Determine the sources and sinks of E-ring dust grains. Analyze the chemical composition of ring particles. Study dynamical processes (erosional, plasma, and electromagnetic) responsible for the E-ring structure, study interactions between the E-ring and Saturn's magnetosphere, and search for electromagnetic resonances. Study ring interaction with Titan. Determine dust and meteoroid distribution both in the vicinity of the rings and in interplanetary space.
- **Icy satellites**. Define the role of meteoroid impacts as a mechanism for surface modification. Obtain information on the chemical composition of satellites from the analysis of gravitationally bound ejecta particles in the vicinity of the satellites (within Hill spheres). Investigate interactions with the ring system and determine the

importance of the various satellites as sources of ring particles. Search for particles from retrograde moons.

- **Magnetosphere of Saturn**. Determine the role that dust plays as source and sink for charged particles in the magnetosphere. Search for electromagnetically dominated dust (small particles) and for dust streams. Constrain the origin of dust streams.

CDA Science Assessment

Table CDA-1 contains an assessment of CDA science based on the objectives in the original Announcement of Opportunity (AO) and the Cassini Traceability Matrix (TM) developed for the Equinox and Solstice missions. The key AO and TM objectives addressed are:

- **Cruise Interplanetary Dust Studies (C_AO4)** – Extend studies of interplanetary dust to the orbit of Saturn.
- **Icy Satellite Geology and History (I_AO1)** – Determine the general characteristics and geological histories of the satellites.
- **Icy Satellite Surface and Crustal Modifications (I_AO2)** – Define the mechanisms of crustal and surface modifications, both external and internal.
- **Icy Satellite Surface Composition (I_AO3)** – Investigate the compositions and distributions of surface materials, particularly dark, organic-rich materials and low melting point condensed volatiles.
- **Icy Satellite Interior Properties (I_AO4)** – Constrain models of the satellites' bulk compositions and internal structures.
- **Icy Satellite Magnetosphere and Ring Interactions (I_AO5)** – Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.
- **Enceladus Seasonal Changes (IC1a)** – Identify long-term secular and seasonal changes at Enceladus, through observations of the south polar region, jets, and plumes.
- **Enceladus Ocean (IN1a)** – Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.
- **Magnetosphere Wave-Particle Interactions (M_AO3)** – Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.

- **Enceladus Plume Variability (MC1a)** – Determine the temporal variability of Enceladus' plumes.
- **Ionosphere and Ring Coupling (MN2a)** – Determine the coupling between Saturn's rings and ionosphere.
- **Ring Structure and Dynamics (R_AO1)** – Study configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.
- **Ring Particle Composition and Size (R_AO2)** – Map composition and size distribution of ring material.
- **Ring-Satellite Interaction (R_AO3)** – Investigate interrelation of rings and satellites, including embedded satellites.
- **Dust and Meteoroid Distribution (R_AO4)** – Determine dust and meteoroid distribution both in the vicinity of the rings and in interplanetary space.
- **Ring Magnetosphere-Ionosphere Interactions (R_AO5)** – Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.
- **Changing Rings (RC1a)** – Determine the seasonal variation of key ring properties and the microscale properties of ring structure, by observing at the seasonally maximum opening angle of the rings near solstice.
- **F-ring (RC2a)** – Focus on F-ring structure, and distribution of associated moonlets or clumps, as sparse observations show clumps, arcs, and possibly transient objects appearing and disappearing.
- **Ring Age and Origin (RN1a)** – Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejecta trapped on field lines.
- **Ring Composition (RN1b)** – Determine the composition of the close-in "ringmoons" as targets of opportunity.
- **Ring Structure (RN1c)** – Determine structural and compositional variations at high resolution across selected ring features of greatest interest, using remote and in situ observations.
- **Titan Upper Atmosphere (T_AO5)** – Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.

Table CDA-1. CDA Science Assessment: AO and TM objectives are paired with CDA science objectives.

Fully/Mostly Accomplished: **Partially Accomplished:**

CDA Science Objective	AO and TM Science Objective	CDA Ring Science Assessment	Comments if yellow (partly fulfilled)
Ring Science			
Structure and dynamics of E-ring	R_AO1, R_AO2, R_AO3, R_AO4, T_AO5, RN1c, RC1a		
Seasonal variation of E-ring	RC1a		Analysis is not complete.
Composition of E-ring	R_AO2, RN1b, RN1c		
E-ring origin	R_AO1, I_AO1, I_AO2, I_AO3, I_AO5, IN1a		
G-ring	R_AO1, RC2a		HRD was damaged by a grain larger than 100 microns during a near G-ring crossing in 2005.
Other diffuse rings / ring arcs	R_AO1, R_AO2, R_AO3		
In situ composition measurements of main ring material	R_AO1, R_AO2, RN1a		
Ring rain mass flux and structure	R_AO1, R_AO2, R_AO4, R_AO5, RN1a, MN2a		
Icy Satellites			
Enceladus			
Plume ice grain structure and size distribution	R_AO2, R_AO3, I_AO2, I_AO3, I_AO4, I_AO5, IC1a, IN1a, MC1a		
Plume ice grain mass output	R_AO3, I_AO4, IN1a		
Plume ice grain composition	I_AO1, I_AO4, IN1a		
Plume dynamics			
Ejecta from hypervelocity impacts on icy moons	R_AO1, R_AO2, R_AO3, R_AO4, I_AO5		Ring/ring arcs associated with moons were detected and studied. Despite multiple attempts, the existence of ejecta clouds around other mid-sized icy moons remains ambiguous because of the higher than expected E-ring background.
Magnetosphere			
E-ring grain charge	R_AO4, R_AO5, M_AO3		
Dynamics of Saturnian stream Particles	R_AO2, R_AO3, R_AO4, R_AO5, M_AO3		
Composition of Saturnian stream particles	R_AO2, R_AO3, R_AO5, M_AO3, I_AO1, I_AO4, IN1a		
Other (including cruise, Jupiter flyby)			
IDP (cruise)	C_AO4		
Exogenous mass infall	C_AO4, R_AO4, RN1a		
Interstellar dust	R_AO4		
Jovian nanograins (Jupiter flyby)	J_AO1		

CDA Saturn System Science Results

Rings

E-ring

Saturn's E-ring was one of the prime targets of CDA from the beginning of the mission. After the discovery of the plume activity on Enceladus and its recognition as the major source of the E-ring grains—see section entitled Enceladus and Spahn et al. [2006a]—the E-ring measurements became more important. Sampling the E-ring provides insights into not only the dynamical evolution of micron-sized grains but also the structure and composition of Enceladus' interior [Postberg et al. 2009b; Postberg et al. 2011]. In situ CDA measurements have characterized the E-ring spatial distribution, the grain size distribution, the electrostatic charge state, and the grain composition [Srama et al. 2006; Kempf et al. 2006, 2008a, 2010; McBride et al. 2007; Hillier et al. 2007a; Postberg et al. 2008; Ye et al. 2014, Hsu et al. 2015]. Both DA and HRD data have been used to derive the E-ring spatial distribution and the grain size distribution. The grain charge is measured by the entrance grid signal (QP) and the grain composition by the CA.

A side projection of the global apparent dust density is shown in Figure CDA-1. One has to keep in mind that the mass threshold during the related measurements was not fixed. The mass

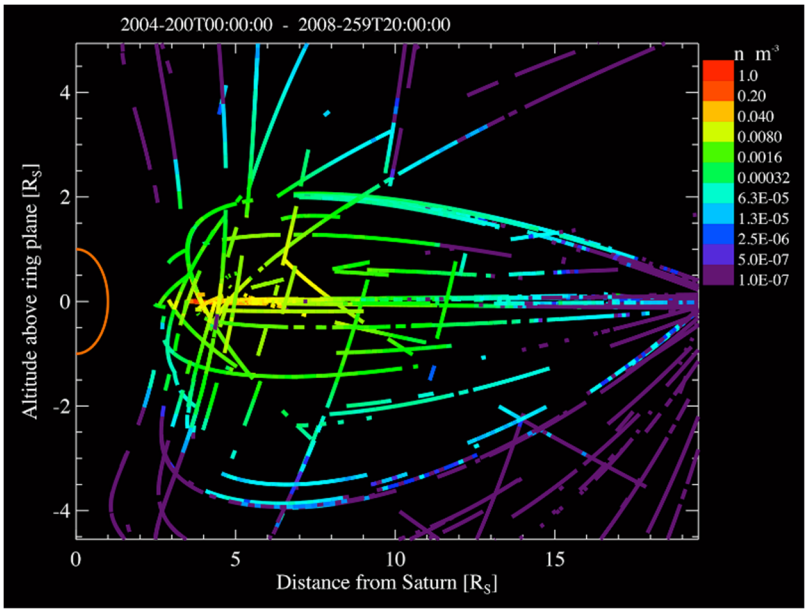

Figure CDA-1. Global apparent dust density measured by CDA in the Saturnian system. The densities are color coded along the Cassini trajectory in the time range of 2004-200 to 2008-259 (Cassini Prime Mission). High impact rates and densities are observed outside the optically measured E-ring, which was defined between 3 to 9 R_S. Enhanced dust densities are found as far as 250,000 km away from the ring plane and extend to radial distances of 20 R_S and beyond. From Srama et al. [2006].

threshold varied with relative impact speed and CDA becomes more sensitive for higher relative impact speeds. Assuming a typical relative impact speed of 8 km s^{-1}, the lower mass threshold would be 1.2×10^{-16} kg. This mass corresponds to compact water ice particles with a diameter of 0.6 µm.

Spatial Distribution

The densest part of the E-ring lies at ρ_c = 3.98 R_S (1 R_S is the radius of Saturn, 60,268 km), slightly outside the orbit of Enceladus (3.95 R_S) as known from pre-Cassini Earth-based observations [de Pater et al. 1996a]. The peak number density ranges from 16 to 21 × 10^{-2} m^{-3} for grains larger than 0.9 µm, and 2.1 to 7.6 × 10^{-2} m^{-3} for grains larger than 1.6 µm. The radial extension of the E-ring inferred from CDA measurements is much broader than that from the remote sensing observations. The E-ring encompasses all major icy moons of Saturn from 3 to 20 R_S [Srama et al. 2006, 2011], i.e., from the orbit of Mimas to that of Titan. The ring's vertical profiles are generally Gaussian, yet the vertical extension varies with the radial distance [Kempf et al. 2008b]. The narrowest part is located at ρ_c = 3.98 R_S with a full-width-half-maximum (FWHM) of 4,300 km. The vertical ring thickness increases both inwards and outwards from ρ_c. The density peak offsets towards the south with respect to the geometric ring plane at radial distances inside ρ_c. The offset is about 1,200 km at Mimas' orbit. No clear offset was found outside ρ_c in CDA data prior to 2008. An empirical, axisymmetric E-ring density model based on the CDA measurements is described in Kempf et al. [2008b].

The E-ring encompasses all major icy moons of Saturn from 3 to 20 R_S …, i.e., from the orbit of Mimas to that of Titan.

As reported by Hedman et al. [2012] based on imaging data, CDA measurements also indicate that the E-ring is asymmetric with respect to the local time [Kempf et al. 2012]. The data analysis and modeling efforts in understanding the day-night asymmetry of the E-ring are still ongoing.

Radial scans were performed by DA in the ring plane in order to determine the radial density profile of smaller grains (Figure CDA-2). As described earlier, the mass threshold was in the submicron range and variable. The density profile is compatible with a power law function of the type $n(r) = 20\ (r - 2.8)^{-4.6}$. This has to be considered a minimum density since particles below the detection threshold were not considered.

Grain Size Distribution

The grain size distribution of a diffuse ring sheds light on the grain production mechanism and the dynamical evolution of the ring. Under nominal encounter speeds in the E-ring, i.e., several km s^{-1}, DA was able to measure grains as small as 0.1 µm and HRD was sensitive to grain radii ranging from ~1 to 10 µm. The grain size distribution information is mostly derived from HRD because of the long dead time of the DA (~1 second)—see Kempf [2008b].

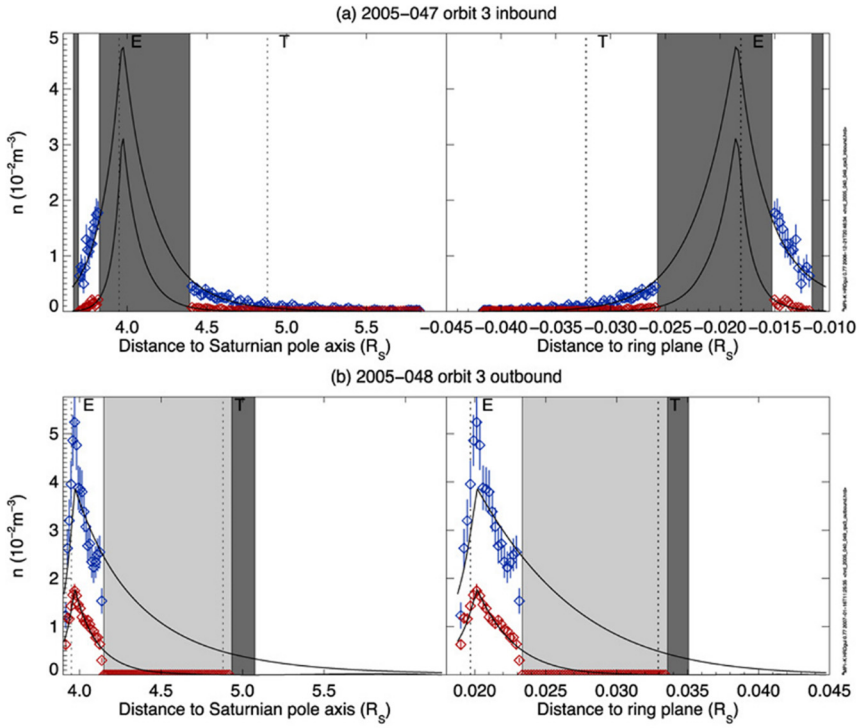

Figure CDA-2. E-ring number density profiles measured by CDA/HRD. Spatial distribution of E-ring particles 1.3 µm (red) and 2.4 µm inferred from HRD rate measurements inside 6 R_S in orbit 3. Solid curves are the empirical model given in Kempf et al. [2008b].

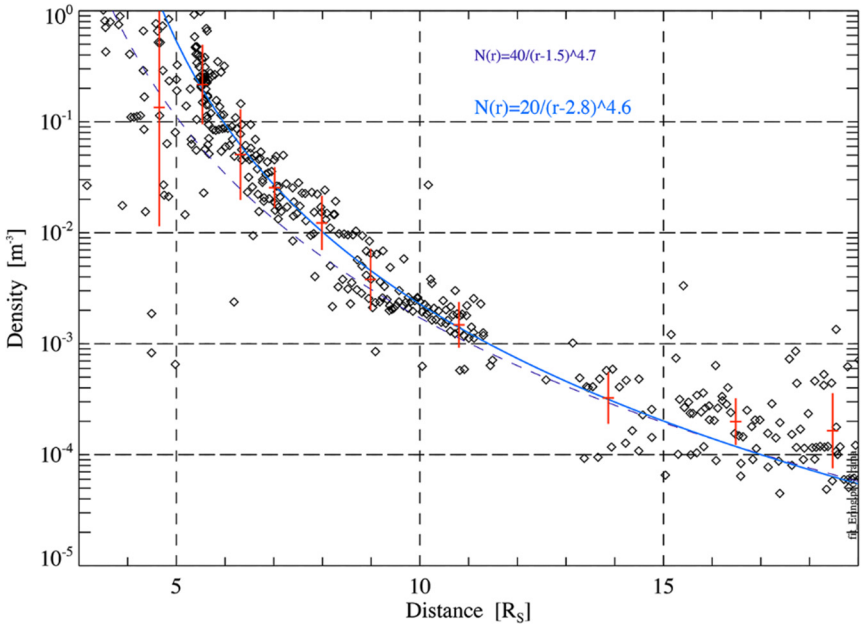

Figure CDA-3. Radial density profile of Saturn's E-ring measured in the ring plane. Data from the years between 2004 and 2008 were considered. Figure from [Srama et al. 2006].

The differential size distribution of E-ring grains is consistent with a power-law distribution, $n(s_d)\, ds_d \sim sd^{-q}\, ds_d$, with slope q = 4 to 5 for grains >0.9 μm [Kempf et al. 2008b]. s_d is the grain radius. The size slopes derived from the RPWS instrument are consistent within a range of q = 3 to 5 (Figure CDA-4) [Ye et al. 2014, 2016]. The steep size distribution slope is related to the E-ring's peculiar blue spectral color [Showalter et al. 1991; de Pater et al. 1996; Nicholson et al. 1996] and stems from the size-speed dependence of grains emitted from the plume of Enceladus (see section entitled Enceladus). In comparison, for diffuse rings supplied by ejecta from hypervelocity impacts on the source bodies, the size slopes are flatter (q ~ 2), resulting in a redder spectral color (e.g., G-ring, see section entitled Other Rings).

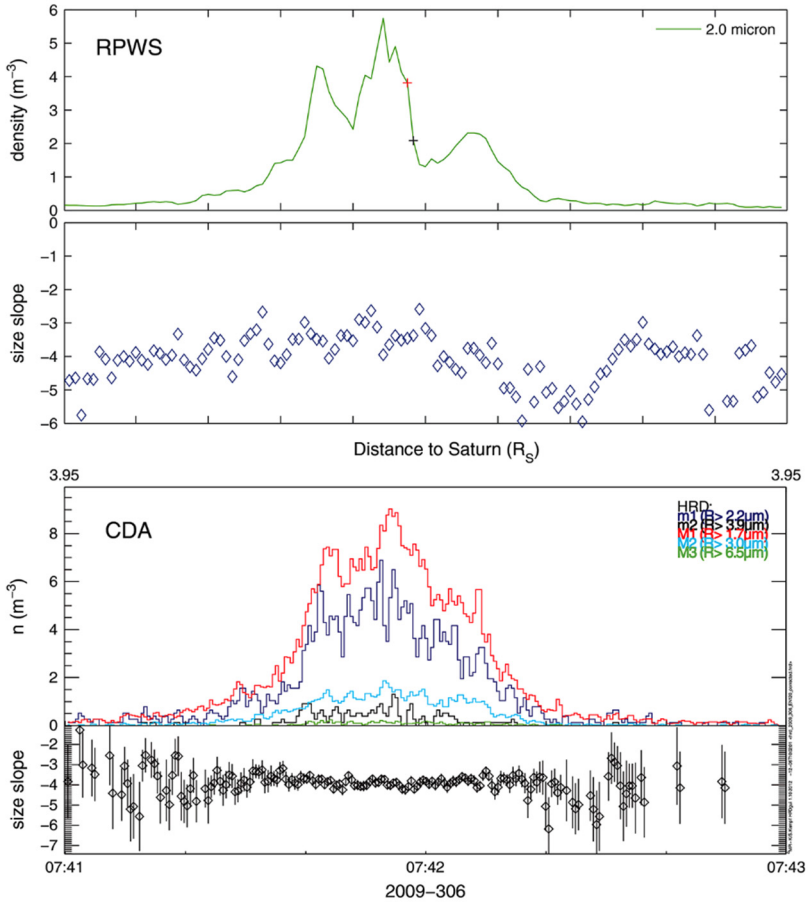

Figure CDA-4. Grain number density and the size distribution slope during E7 flyby by RPWS and CDA/HRD. Figure from Ye et al. [2014].

Grain Electrostatic Charge State

The Lorentz forces acting on a grain are determined by the number and the polarity of electric charges of a grain. The grain charge is determined by various charging processes, e.g., plasma electron and ion collections, photoemission and secondary electron emission, and thus is expected to vary with the magnetospheric plasma conditions [Horányi et al. 1992]. Figure CDA-5 shows the

CDA measurements of E-ring grain charges at various distances [Kempf et al. 2006]. Near Enceladus' orbit the grain potential is about −3 Volts, consistent with, but slightly lower than, the previous estimates based on Voyager plasma measurements [Horányi et al. 1992]. The grain potential becomes more positive with increasing distance and the polarity turns positive roughly outside the orbit of Rhea [Kempf et al. 2006] because of the decreasing plasma electron density and the increasing secondary electron emission resulting from the presence of more energetic electrons in the middle to outer magnetosphere [Arridge et al. 2011; Hsu et al. 2011b].

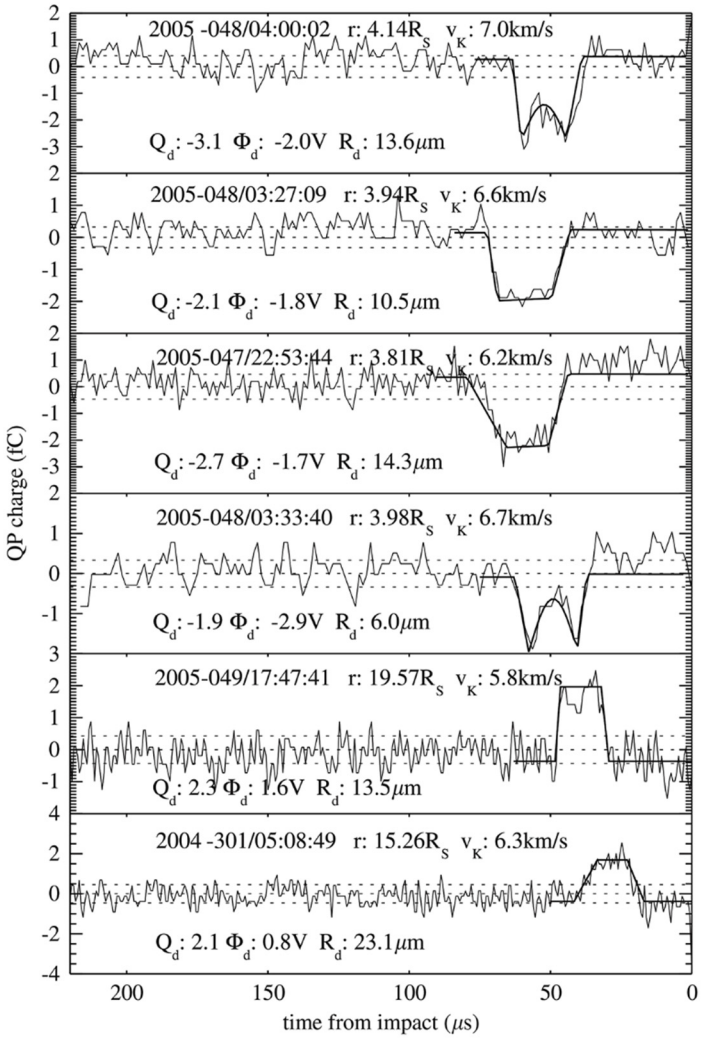

Figure CDA-5. Particle charge signals from the QP channel as measured by CDA in the E-ring at various radial distances from Saturn. The signal shape varies with particle speed (signal width), incident angle (signal asymmetry) and particle surface charge (signal amplitude). The signal sag is dependent upon the particle trajectory and its distance from the outer housing. From Kempf et al. [2006].

GRAIN COMPOSITION

E-ring grains are predominantly composed of water ice [McBride et al. 2007, Hillier et al. 2007a; Postberg et al. 2008]. The presence of minor grain constituents (up to a few percent levels), however, drastically changes mass spectral appearance because of the nature of impact ionization time-of-flight spectroscopy. Three major types of E-ring grain mass spectra have been identified (Figure CDA-6): Type I - pure water ice particles; Type II - water ice with organic compounds and/or silicate minerals impurities; and Type III - water ice rich in sodium salts [Postberg et al. 2008, 2009b, 2011]. The majority of the E-ring grains are either Type I or II, with only ~6% belonging to Type III.

The presence of Type III salty E-ring grains suggests the existence of subsurface liquid water underneath Enceladus' south polar terrain [Postberg et al. 2009b, 2011], in good agreement with the calculated thermodynamics result [Schmidt et al. 2008]. They are interpreted as frozen droplets lofted from liquid plume sources at the bottom of the fissures, representing direct samples of the subsurface waters within Enceladus [Postberg et al. 2009b, Postberg et al. 2011]. The salinity (0.5 to 2% by mass) and pH values (8 to 11) of the subsurface waters are also inferred [Postberg et al. 2009b]. Other findings about the icy moon Enceladus are addressed in the section entitled Enceladus.

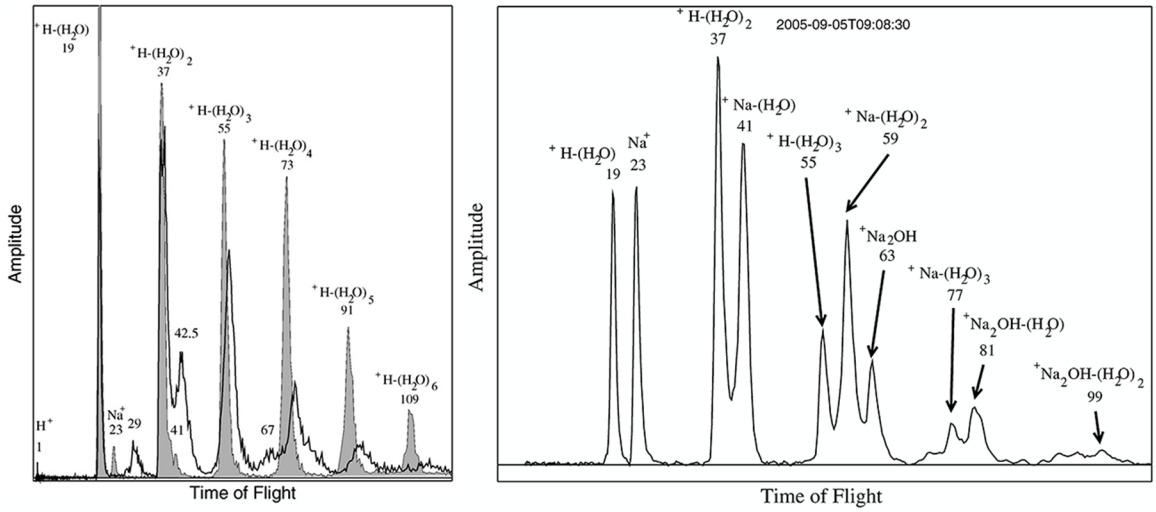

Figure CDA-6. Three major E-ring grain composition types. *Left*: Type I (pure water ice, gray) and Type II (water ice and organic compounds and/or silicate minerals, bright) E-ring grain mass spectra. The horizontal axis shows the cation time of flight. The vertical axis shows the peak amplitude. The Type I spectrum is characterized by the presence of water clusters, $H\text{-}(H_2O)^+_n$, where n = 1 to 6. Type II spectrum often show a wide feature at 42 to 43 u and 65 to 68 u. A shift of the water cluster peaks starts at n > 2 and increases towards longer times of flight. *Right*: Type III salt-rich E-ring grain mass spectrum. Water clusters ($H\text{-}(H_2O)^+_n$) seen in Type I spectrum are joined by sodium-water clusters, $Na\text{-}(H_2O)^+_n$ and $(Na_2OH)\text{-}(H_2O)^+_n$, because of the abundant Na^+. From Postberg et al. [2008].

GRAIN DYNAMICS MODELING

Joining pre-Cassini results, for example, Showalter et al. [1991]; de Pater et al. [1996]; Nicholson et al. [1996], the "ground truth" measurements provided by Cassini make Saturn's E-ring the most studied diffuse ring in the solar system. While the E-ring is particularly special because of its cryovolcanic origin, the same processes shaping the E-ring operate similarly elsewhere. Modeling efforts enable us to readily apply what has been learned from Saturn's E-ring to other environments.

> … Saturn's E-ring is the most studied diffuse ring in the solar system.

Regarding the E-ring dynamics, early modeling shows that the gravity from the oblate planet and the Lorentz forces from the electromagnetic fields lead to a size-dependent orbital precession rate ($\dot{\omega}$). For grains with radii around 1 μm, this leads to $\dot{\omega} \sim 0$ and allows a fast increase in the grains' orbital eccentricities by the solar radiation pressure force on timescales of a few years [Horányi et al. 1992; Hamilton 1993]. Additionally, the drag force asserted by the co-rotating magnetospheric plasma overtaking grains in semi-Keplerian orbits leads to an increase of the grains' orbital semi-major axes (i.e., grains gain orbital energy) [Dikarev 1999; Horányi et al. 2008]. Simultaneously, grain sizes are reduced by plasma sputtering erosion [Jurac et al. 2001; Juhasz and Horányi 2002; Horányi et al. 2008]. The combined effect of plasma drag and sputtering causes a reduction in grain sizes towards larger Saturn-centric distances without changing the size distribution [Horányi et al. 2008]. The radial extension of the E-ring up to Titan's orbit [Srama et al. 2006] also implies that Enceladus has been actively supplying the E-ring for at least hundreds of years.

Ejecta cloud and diffuse rings

In addition to the cryovolcanic E-ring, CDA also explored other diffuse rings, which are most likely supplied by impact ejecta produced from the embedded source bodies through continuous bombardment of micrometeoroids and the consequent fragmentation. Ejecta produced from airless bodies could appear in three forms, depending on the gravitational influences of the source body and its neighbors: a dust exosphere around the source body (e.g., around Galilean moons and Rhea), a complete ring (e.g., Saturn's G-ring), or a ring arc (a partial ring, e.g., the Anthe and Methone ring arcs). Modeling efforts provided theoretical support for characterizing the exogenous interplanetary mass infall [Han et al. 2011; Poppe and Horányi 2012] (see section entitled Interplanetary Dust) and the resulting ejecta cloud around major [Krivov et al. 2003; Sremčević et al. 2003; Dikarev et al. 2006; Spahn et al. 2006b] and minor [Sun et al. 2017] moons in the Saturnian system.

EJECTA CLOUD AROUND RHEA

In contrast to the clear detection of dust exospheres around Galilean moons [Krüger et al. 1999], the identification of such ejecta clouds around Saturn's major icy moons was ambiguous except at Rhea (8.75 R_S) [Jones et al. 2008], the major icy moon located furthest from the E-ring source

moon Enceladus (Figure CDA-7). Clearly, the background of the extensive E-ring renders a clear detection of a dust exosphere around the inner icy moons difficult.

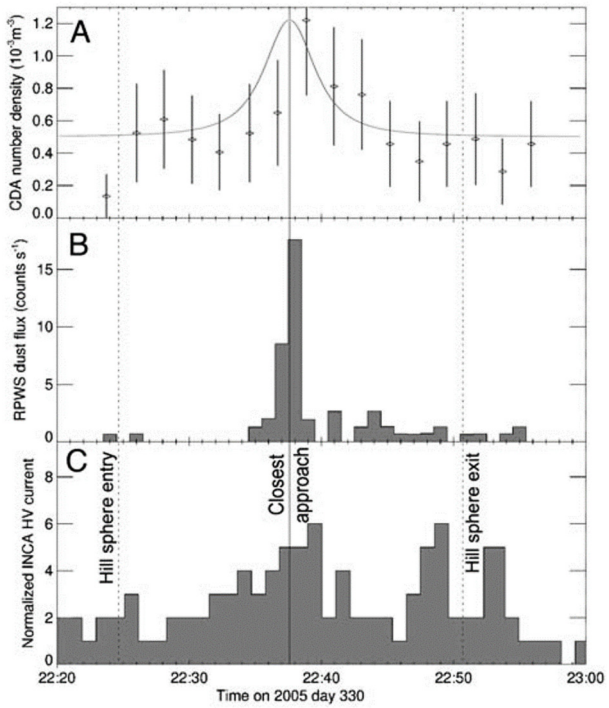

Figure CDA-7. In situ dust observations reveal the dust cloud around Rhea. Measurements from three in situ instruments during the Rhea flyby on November 26, 2005: (A) CDA (grains > 1 µm), (B) Radio and Plasma Wave Science instrument (grains ≥ 3 µm), and (C) Magnetosphere Imaging Instrument. From Jones et al. [2008].

Pallene ring

The dusty ring associated with a tiny moon, Pallene (mean radius ~2 km), at 3.52 R_S [Hedman et al. 2009b] has been detected by CDA/HRD in 2010 [Seiß et al. 2014]. The cross-section of the ring measured by HRD can be fitted with a double-Gaussian distribution, yielding a radial and vertical FWHM of 2,300 km and 270 km, respectively, and a maximum particle density of 2.7×10^{-3} m^{-3}. Additionally, the data clearly show an enhancement of larger particles in the Pallene ring compared to the background E-ring particles. In comparison, no in situ CDA detection of the ring arcs associated with Anthe (3.28 R_S) and Methone (3.23 R_S) has been reported so far.

G-ring

Collisions are expected to be the major dust production process that resupplies Saturn's G-ring, as indicated from its spectrally red color [de Pater et al. 1996; Nicholson et al. 1996]. However, no source was known prior to Cassini's arrival. The source of the G-ring was then identified, based on Cassini imaging data [Hedman et al. 2007], as a 60°-long arc. Collisional fragmentation of

centimeter- to meter-sized objects within this bright arc is believed to replenish the G-ring, which would otherwise disappear over relatively short timescales.

An impact of an exceptionally large dust grain (>100 μm) was registered and damaged HRD on September 5, 2005, when the spacecraft passed the ring plane at a radial distance of 2.93 R_S, less than 0.15 R_S from the core of the G-ring [Hedman et al. 2007]. The size of that grain is consistent with the impactor-ejecta production origin.

JANUS-EPIMETHEUS RING

During the ring grazing orbits, the spacecraft passed near the orbits of the co-orbital moons Janus and Epimetheus [Buratti et al. 2019]. A Gaussian distribution fit to the radial profile of grains larger than 1.6 μm registered by HRD show that the peak density is located very close to the orbits of Janus and Epimetheus at 151,500 km (2.51R_S) with a radial width of about 4,300 km.

Grand finale mission

The major science goals of CDA for the Grand Finale were: (1) perform in situ composition measurements of materials from the Main rings and (2) study the ring–planet interactions.

An analysis of CDA and RPWS measurements suggests that the region interior to Saturn's D-ring sampled during Cassini's Grand Finale Mission is predominantly populated by grains 10s of nm in radii, whose dynamics are consistent with high-speed impact ejecta from Saturn's main rings [Hsu et al. 2018]. Electromagnetic forces lead to the fast transport of tiny, charged ejecta grains (within hours, see Hsu et al. [2017]), which comprises a ring mass loss pathway (10^2 to 10^3 kg s^{-1}). About 20% of this ejecta falls into Saturn, mainly in the equatorial region and the southern hemisphere, leading to the observed H_3^+ ionospheric signature, i.e., the Ring Rain effect [O'Donoghue et al. 2013; Moore et al. 2015]. Two grain composition types were identified from ~25% of recorded mass spectra—water ice and silicates, with an ice fraction varying with the distance from the ring plane—decreasing from around 70–90% near the ring plane towards high latitudes. No indication of grains with pure organics, iron or iron-oxide compositions has been found in the dataset.

Icy Satellites

Enceladus

Ice grains emitted from Enceladus provide a unique window to probe the interior of Enceladus, as these tiny solid particles preserve information differently from that in gaseous and plasma phases. The micron-sized ice grains and the nanometer-sized silica stream particles probe the conditions of the subsurface water of Enceladus at different depths: the silica nanoparticles probe the pH, salinity and water temperature at the bottom of Enceladus' ocean, while the micrometer-sized ice

grains reveal composition and thermodynamical processes at near-surface liquid plume sources and in the vents.

Several sets of CDA measurements contribute to the study of Enceladus: (a) in the E-ring (described in the section entitled E-ring), (b) during the close Enceladus flybys, and (c) the Saturnian nanodust stream particles.

CLOSE ENCELADUS FLYBYS

Information provided by the CDA measurements during the plume crossings include the structure of the dusty plume (HRD) and the composition of freshly emitted grains (DA). The HRD data from the close encounter on July 14, 2005, showed that the grains in the vicinity of Enceladus are produced from a localized source near the south polar region [Spahn et al. 2006a], suggesting endogenic dust production at Enceladus as the major source of Saturn's diffuse E-ring. In addition, the structure of the plume provides constraints on the thermodynamics of the grains and vapor in the vents. The grain size distribution sampled by HRD is best explained by ice grain formation from condensation as water vapor reaches saturation when passing through the nozzles in the subsurface fissures (Figure CDA-8) [Schmidt et al. 2008]. A key characteristic successfully explained by this nozzle model is the size-dependent grain initial speeds, larger grains are emitted slower due to the longer time required to recover to the gas flow speed after a wall collision in the vent. This leads in a steepening of grain size distribution towards higher altitudes in the plume, consistent with measurements from the Visual and Infrared Imaging Spectrometer (VIMS) [Hedman et al. 2009a].

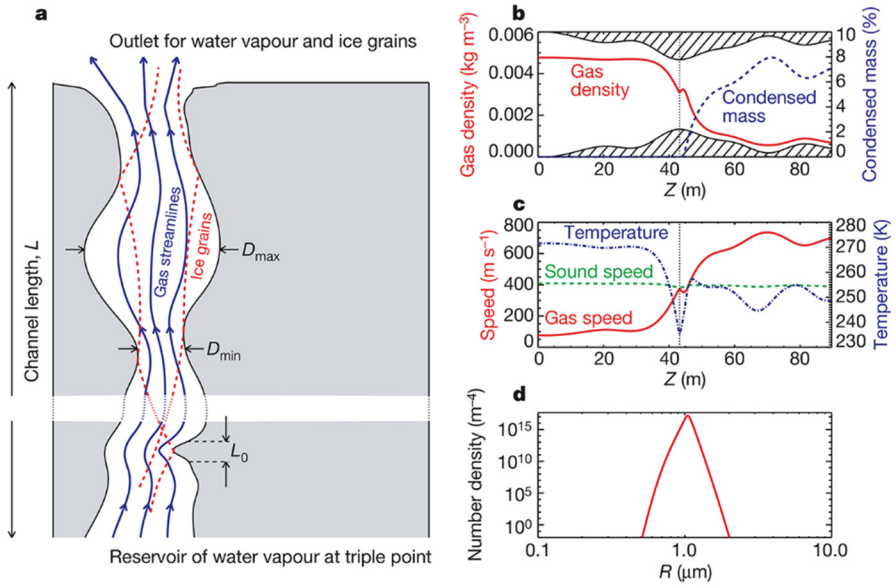

Figure CDA-8. The nozzle grain formation model. (a) Schematic sketch of the subsurface fissure profile describing the gas flow and ice grain condensation. (b, c) Thermodynamics conditions in the channel as a function of depth. (d) The resulting grain size distribution of one single channel. Figure from Schmidt et al. [2008].

Constrained by the HRD measurements, the mass production rate of micron-sized ice grains from the plume was estimated to be approximately 10 kg s^{-1} [Southworth et al. 2019], comparable with independent estimates from the imaging data [Ingersoll and Ewald 2011; Gao et al. 2016]. In addition, the deposition of plume ice grains onto Enceladus simulated with the same model shows a pattern resembling an infrared-ultraviolet brightness ratio map of Enceladus (Figure CDA-9) [Kempf et al. 2010; Schenk et al. 2011]. While this reinforces notions about the effects of the E-ring deposition and the surface albedo patterns of the major icy moons [Buratti et al. 1990; Verbiscer et al. 2007; Schenk et al. 2011], the detailed mechanisms remain unknown.

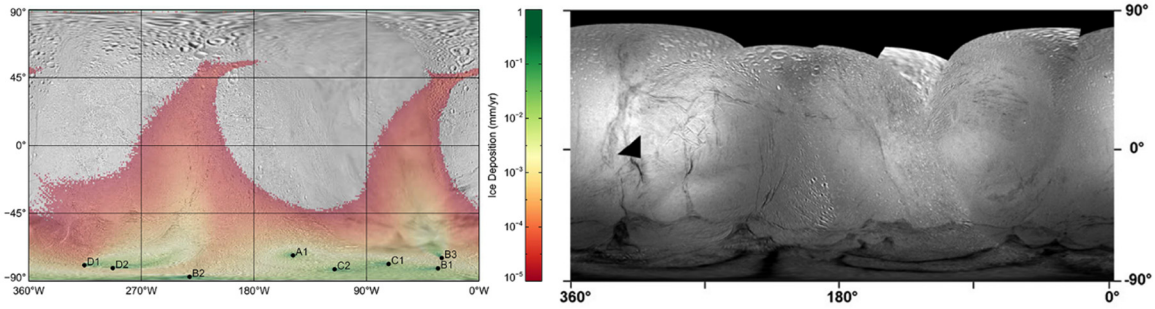

Figure CDA-9. Modeled plume deposition map (left) and the observed infrared/ultraviolet (IR/UV) ratio map of Enceladus (right). From Kempf et al. [2010] and Schenk et al. [2011].

Grain composition provides information about the subsurface waters of Enceladus. As mentioned, the presence of Type III (salt-rich) E-ring grains indicates salty, alkaline subsurface waters within Enceladus [Postberg et al. 2009b]. The grain composition profile recorded during the E5 close encounter in 2008 shows that the ratio of Type III grains increases from the E-ring background of around 6% to 40% at the closest approach (altitude of 25 km) [Postberg et al. 2011]. A clear decrease of the proportion of Type I grains in the dense plume region was confirmed by data of the E17 flyby in 2012 [Khawaja et al. 2017]. The dominance of the larger, salty ice grains at lower altitudes indicates a stratified plume [Hedman et al. 2009a; Postberg et al. 2011] and is consistent with the aforementioned modeling results [Schmidt et al. 2008]. In other words, the grain composition stratification reflects the grain formation processes in the fissures (Figure CDA-10) and thus strongly suggests that subsurface waters are the direct source of the plume [Postberg et al. 2011]. This result also agrees with the low abundance of salty ice grain (Type III) in the E-ring [Postberg et al. 2008]—most grains capable of escaping Enceladus to resupply the E-ring are smaller, and therefore faster, pure ice grains forming from condensation in the vents. Salty grains tend to be heavier/slower and mostly fall back onto the moon [Kempf et al. 2010; Postberg et al. 2011].

A subset of E-ring Type II spectra was found to contain a series of mass lines indicating the presence of complex organic molecules with a mass fraction of about 1% of the ice grain [Postberg et al. 2018]. As shown in Figure CDA-11, the species marked high mass organic cation (HMOC) show regular ~12.5 u separation and extend to beyond ~200 u mass range, indicating that they are fragments of larger parent molecules whose mass may be in the 1,000s u region. The observation suggests the existence of a thin film at the subsurface water liquid-vapor interface composed of complex organics likely originating from hydrothermal activities deep inside Enceladus.

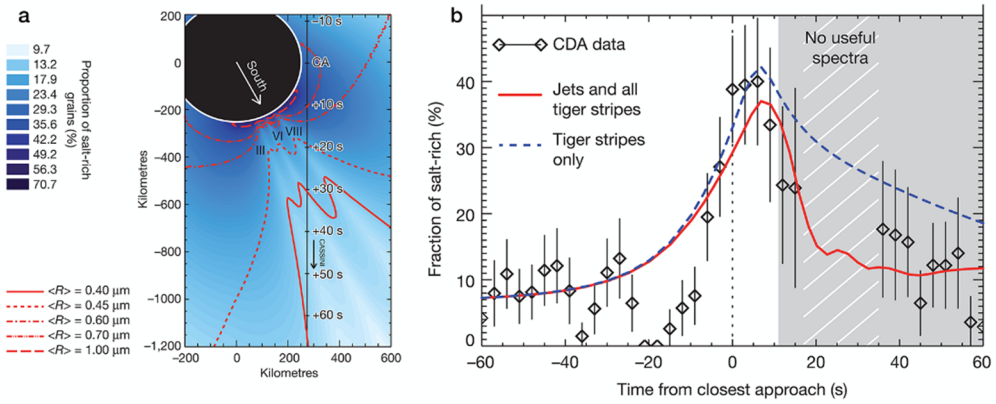

Figure CDA-10. Compositional and size profile of the ice plume of Enceladus. (a) The background color and the contour lines show the modeled fraction of salt-rich grains and the mean particle radius <*R*> of grains emitted from the plume of Enceladus. (b) Measured Type III spectrum fraction as a function of time during the E5 Enceladus flyby. Model and measurement results consistently show that the closer to the surface, the higher the fraction of Type III ice grains. Figure from Postberg et al. [2011].

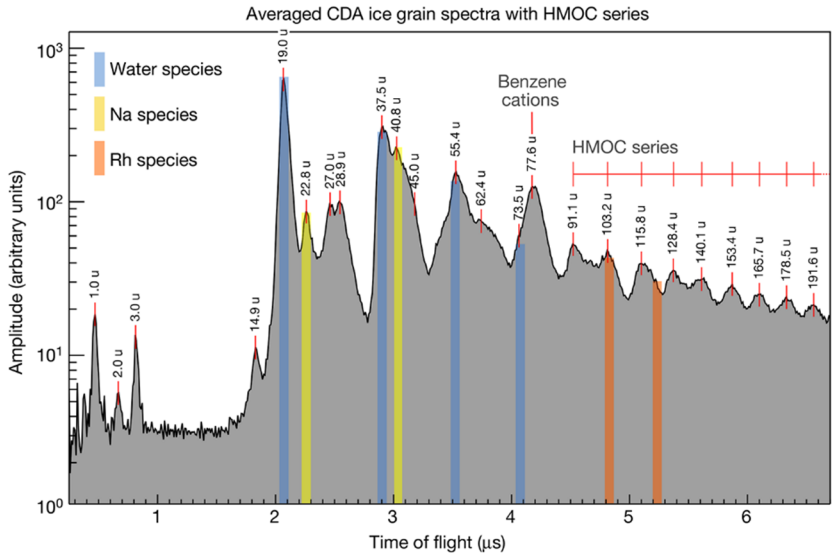

Figure CDA-11. CDA HMOC spectrum. This spectrum is co-added from 64 Type II E-ring spectra containing complex organic features. Benzene-like cations (77.6 u) and their fragments (C2 to C4 species) as well as the (HMOC, 91 u, and higher) appear distinctively from water (blue) and CDA target (Rh, orange) and target contamination (Na, yellow) mass lines. Figure from Postberg et al. [2018].

NANO-PHASE SILICA PARTICLES

The fast, nanometer-scale silicon-rich grains emitted into interplanetary space from the Saturnian system were the first CDA discovery [Kempf et al. 2005a, 2005b], despite the theoretical prediction [Horányi 2000] based on the knowledge of their Jovian counterparts [Grün et al. 1993]. These nanoparticles are in fact the silicon fingerprint of the ongoing hydrothermal activities within Enceladus [Hsu et al. 2015; Sekine et al. 2015].

Since the dynamical properties of the nanograins are beyond the CDA calibrated range, their sizes (2 to 8 nm) and ejection speeds (50 to 200 km s^{-1}) are derived based on the interactions with the IMF [Hsu et al. 2010a, 2010b, 2011a, 2011b, 2012b]. These grains are interpreted to be of Enceladus origin—they are erosion-resistant impurities embedded in micron-sized E-ring grains, which are released after the surrounding ice matrix is removed by the plasma sputtering erosion [Hsu et al. 2011b].

One surprising factor regarding their composition is their extremely low metal concentration. Detailed analysis, including the laboratory hydrothermal reaction experiments, show that these grains are nanometer-sized metal-free silicon-oxide, i.e., nano-phase silica (SiO_2, Figure CDA-12b), which is best explained as nm-sized colloidal silica stemming from hydrothermal interactions within Enceladus [Hsu et al. 2015; Sekine et al. 2015]. The instability of the nano-phase silica sets strong constraints on the internal conditions of Enceladus subsurface waters (see Figure CDA-13), including (a) a water-rock reaction temperature of >90°C; (b) a low salinity ocean region (<4%) and an alkaline pH value (8.5 to 10.5), in good agreement with [Postberg et al. 2009b]; (c) Enceladus' rocky core is likely undifferentiated and porous, with a primordial composition similar to carbonaceous chondrites;

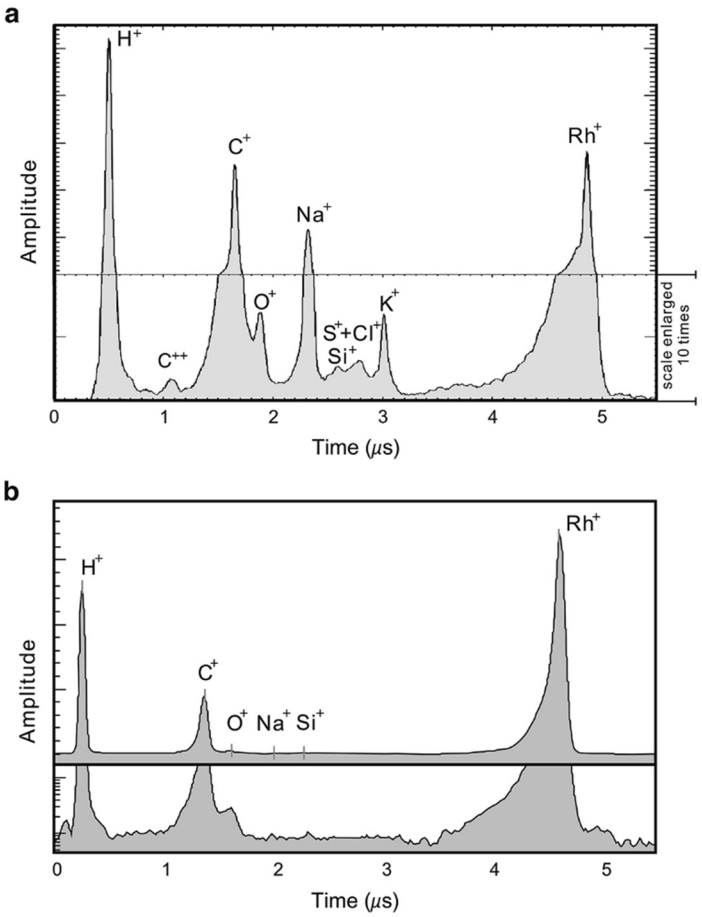

Figure CDA-12. CDA mass spectra of Jovian (*a*) and Saturnian (b) stream particles. Figure from Hsu et al. [2012b].

and (d) fast vertical transportation of the hydrothermal fluid from Enceladus' subsurface ocean to the plume within several years [Hsu et al. 2015; Sekine et al. 2015].

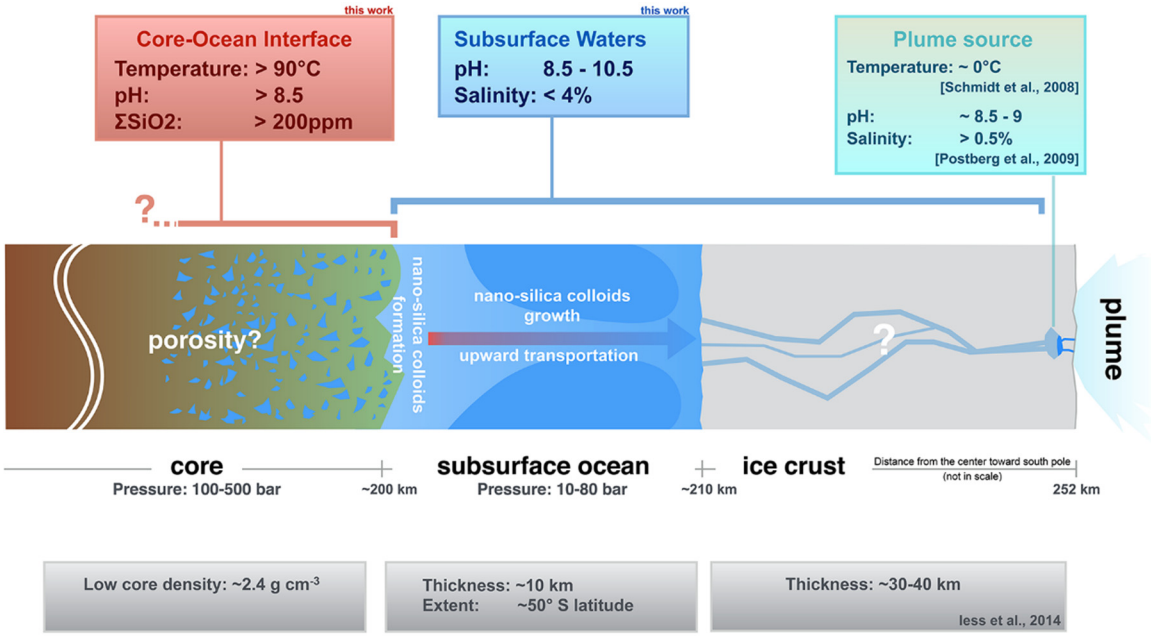

Figure CDA-13. A schematic of Enceladus' interior derived from the nano-phase silica results. Figure from Hsu et al. [2015].

Ejecta from Saturn's moons

As discussed in the section entitled Other Rings, the only major moon of Saturn around which an ejecta cloud was detected is Rhea [Jones et al. 2008]. The dusty rings associated with Pallene [Seiß et al. 2014], and Janus and Epimetheus [Buratti et al. 2019] were also explored in situ by CDA.

Magnetospheric and Plasma Science

Dust-magnetospheric plasma interactions

Grain charging, plasma sputtering, and plasma drag force

Magnetospheric plasma influences the charging, erosion, and dynamical processes of circumplanetary dust populations. In addition to the grain charge measurements in Saturn's E-ring [Kempf et al. 2006], as described in the section entitled E-ring, in situ E-ring characterization by CDA also provides constraints on the effects of the plasma sputtering erosion and the drag force. As illustrated in the modeling work by [Horányi et al. 2008], due to the plasma drag, grains from Enceladus can be transported from 4 to 20 R_S, and will arrive there with a few percentage of their

original radius due to sputtering losses, consistent with CDA measurements [Srama et al. 2006, 2011]. These calculations also indicate that the geysers on Enceladus have been supplying the E-ring material at an approximately constant rate for at least the last 300 years [Horányi et al. 2008].

Spacecraft charging

Strong interferences caused by dust impacts during the crossings of Enceladus' dusty plume have been reported from several instrument teams [Morooka et al. 2011; Ye et al. 2014; Krupp et al. 2018], likely caused by impact plasma produced from intense dust-spacecraft impacts. Because of the low plasma temperature of such an impact plasma cloud (~1 eV), this impact-generated plasma cloud may act as a buffer that reduces the spacecraft potential when traversing through a dust-rich region at high speed. The proposed effect has been examined by comparing the modeled spacecraft potential based on the CDA measurements to the Langmuir probe results during the plume and E-ring crossings [Hsu et al. 2012a, 2013a].

Nanodust dynamics in interplanetary space

CDA measurements also reveal the dynamical interactions of the Saturnian stream particles with the interplanetary magnetic field. After entering interplanetary space, the dynamics of the charged nanodust is governed by the IMF. CDA observed an identical detection pattern when the spacecraft crossed two similar solar wind compression regions associated with the Corotation Interaction Region (CIR), during the declining phase of solar activity in 2004 [Hsu et al. 2010b, 2011a]. These measurements illustrate that the nature of the dust stream phenomenon, first discovered by the Ulysses at Jupiter [Grün et al. 1993], is not in a form of collimated beams but a gust of electromagnetic acceleration of charged nanodust within a thick, warped dust sheet extending up to several astronomical units (AUs) from the source planets [Hsu et al. 2010a, 2010b].

Solar wind-magnetosphere interactions

The nanodust stream particle dataset is also relevant for studying the solar wind-magnetosphere interactions at Saturn. Serendipitous detections of a recurring pattern consisting of energetic stream particles coming from oblique directions are interpreted as the reentry of emitted stream particles back into their source magnetosphere due to the interaction with IMF [Hsu et al. 2013b]. Numerical simulation results show that this is simply due to the pick-up of the charged nanodust by the solar wind. The returning nanograins acquired kinetic energies higher than their initial kinetic energies gained from the magnetosphere, by being picked up in the compressed, high magnetic field strength solar wind regions. This means that this population can be easily identified and, more importantly, their directionality reflects the tangential component of the IMF. The latter provides additional information about the sector structure of the solar wind at Saturn's location. In other words, these measurements demonstrate an alternative method by which a single spacecraft can probe the solar wind conditions from within the magnetosphere [Hsu et al. 2013b; Hsu et al. 2016].

Instrument

In addition to the description of the CDA instrument [Srama et al. 2004], two publications provide information relevant for the CDA data analysis: (a) the DA dead time correction [Kempf 2008b] and (b) the contamination of the rhodium target of the integrated time-of-flight mass spectrometer [Postberg et al. 2009a].

Non-Saturn Science Results

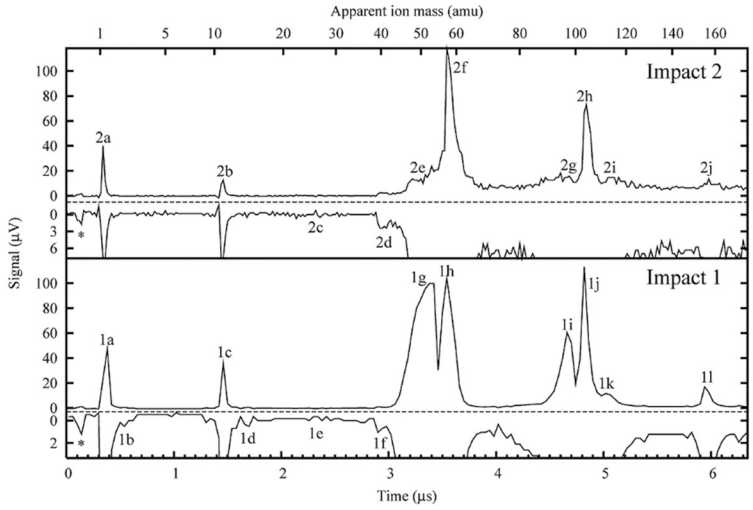
Jovian Nanodust Stream Particles

"Ashes" from the volcanic plumes of Io, having acquired sufficient electric charges, may be accelerated by Jupiter's powerful magnetosphere and ejected with speeds comparable to the solar wind [Horányi et al. 1993; Graps et al. 2000]. These so-called stream particles were discovered during the first Ulysses flyby of Jupiter in 1992 by the onboard dust detector [Grün et al. 1993]. The detection patterns as registered by the Galileo Dust Detection System [Grün et al. 1992] suggest that they are modulated by the structure of the Io plasma torus (IPT) [Krüger et al. 2003b] as well as the temporal variation of Io's volcanic activities [Krüger et al. 2003a]. The stream could be detected by Galileo and Ulysses many 100 Mkm away from Jupiter.

Cassini CDA performed the first composition measurement of the Jovian stream particles before and after its Jupiter flyby in 2000/2001.

Cassini CDA performed the first composition measurement of the Jovian stream particles before and after its Jupiter flyby in 2000/2001 [Postberg et al. 2006]. Figure CDA-14 shows that these ash particles are mainly composed of sodium chloride (NaCl). In contrast to the sulfur-rich environment of Io, sulfur or sulfurous components and potassium-bearing components are only identified as minor constituents. Trace amounts of silicates or rocky minerals are often found. It is suggested that sodium chloride particles are formed inside Pele-type plumes prior to the condensation of the volatile SO_2. The less refractory sulfur compounds, in particular SO_2, either do not condense abundantly onto the grains, or are lost in bow shock regions at the top of the plumes, before the grains acquire sufficient electric charges to escape into Io's exosphere [Postberg et al. 2006]. The proposed scenario is in good agreement with the New Horizons observation of plume particle condensation in the eruption of Tvashtar [Spencer et al. 2007].

The CDA measurements of Jovian stream particles lasted about 10 months, roughly from day of year (DOY) 240 of 2000 to DOY 170 of 2001. A qualitative analysis of the CDA impact rate shows a correlation with the Galileo measurements [Hsu et al. 2010a, 2012b; Krüger et al. 2003b], reinforcing the idea of using Jovian stream particles as a monitor of Io's volcanic activities [Krüger et al. 2003a].



Ion abundances for both impacts

Species (key in Fig. 1)	Time (μs)	$\int Q_M$	Ions
Impact 1			
H^+ (1a), H_2^+ (1b)	0.28–0.64	2.71×10^{-12}	52,200
C^+ (1c)	1.36–1.58	2.22×10^{-12}	42,800
O^+ (1d)	1.6–1.72	3.16×10^{-14}	600
K^+ (1f)	2.84–2.96	1.09×10^{-13}	2100
'Fast Fe^+' (1g)	2.96–3.44	2.61×10^{-11}	503,300
'Slow Fe^+' (1h)	3.44–3.84	1.24×10^{-11}	239,300
'Fast Rh^+' (1i)	4.00–4.72	1.06×10^{-11}	204,200
'Slow Rh^+' (1j)	4.72–4.96	9.92×10^{-12}	191,400
RhC^+/Fe_2^+ (1k)	4.96–5.20	1.92×10^{-12}	37,000
$RhFe^+$ (1l)	5.80–6.12	1.77×10^{-12}	34,100
Total			1,307,000
Impact 2			
H^+ (2a)	0.3–0.42	1.25×10^{-12}	44,700
C^+ (2b)	1.42–1.58	5.41×10^{-13}	19,300
K^+ (2d)	2.88-3.02	2.99×10^{-13}	10,700
'Fast Fe^+' (2e)	3.02–3.46	5.25×10^{-12}	187,400
'Slow Fe^+' (2f)	3.46–3.88	1.56×10^{-11}	557,800
'Fast Rh^+' (2g)	4.16–4.74	6.67×10^{-12}	238,100
'Slow Rh^+' (2h)	4.74–4.98	7.72×10^{-12}	275,600
RhC^+/Fe_2^+ (2i)	4.98–5.22	2.96×10^{-12}	105,600
$RhFe^+$ (2j)	5.88–6.12	2.10×10^{-12}	74,900
Total			1,514,100

Figure CDA-14. CDA IDP TOF mass spectra detected during the cruise phase. *Left*: The time-of-flight mass spectra of two interplanetary dust particles detected in 1999. *Right*: The table shows the identified cation of each corresponding mass peak. From Hillier et al. [2007b].

Interplanetary Dust

Cruise phase

The interplanetary dust environment in between the orbits of Earth and Jupiter was explored during the cruise phase, during 1999 to early 2000 when the spacecraft was around 1 to 2.5 AUs away from the Sun [Kempf et al. 2004; Hillier et al. 2007b]. The detections of bound IDPs and unbound ISD in between the Jupiter flyby (2000-365) and the Saturn Orbit Insertion (SOI, 2004-183) are reported by Altobelli et al. [2007a, 2007b]. While the CDA dataset is limited by the spacecraft pointing, the CDA IDP measurements are in general consistent with the Pioneer results from the 70s. However, due to spacecraft activities no dust measurements were possible during the asteroid belt crossing.

Two mass spectra of IDPs were registered on 1999-147 and 1999-314, at heliospheric distances of 0.89 and 1.87 AU, respectively. These grains are roughly 2 μm in radii and both have an iron-rich composition [Hillier et al. 2007b]. Surprisingly, silicates and magnesium do not feature predominantly in the spectra. They are likely to have originated from near-Earth asteroid families (Aten and Apollo family, respectively), or Jupiter-family comets.

Kempf et al. [2004] reported in total 37 registered IDP impacts between November 1999 and January 2000. Among them, 6 impacts were obtained whose QP signals identified show a clear feature caused by charged grains, corresponding to Q_d between 1.3 and 5.4 fC [Auer et al. 2002; Kempf et al. 2004]. Assuming a potential of $\varphi_d \approx +5$ V and spheroidal grain morphologies, the corresponding grain masses are found to be in excess of 10^{-13} kg. The detection rate reasonably matches the IDP flux prediction [Staubach et al. 1997].

Between the Jupiter flyby and SOI, 7 of the total of 17 impact events were identified as IDPs based on their directionality [Altobelli et al. 2007a, 2007b]. These grains show a large spread in mass, ranging from 2×10^{-16} to 10^{-11} kg, corresponding to grain radii of 3 to 11 μm assuming a bulk grain density of 2 kg m^{-3}. These grains are most likely in orbits with low inclination and low eccentricity and likely originate from the short-period external Jupiter family comets and Edgeworth-Kuiper Belt objects [Altobelli et al. 2007b].

Exogenous mass infall at Saturn

Grains migrating inwards from the Edgeworth-Kuiper belt are expected to be an important exogenous dust population entering the Saturnian system [Han et al. 2011; Poppe and Horányi 2012]. Recent modeling results suggest grains approach Saturn's Hill sphere with speeds lower than expected (<3 km s^{-1}), meaning that the IDP flux enhancement by the gravitational focusing of Saturn is significant and the exogenous flux highly depends on the location of the moons/rings [Poppe and Horányi 2012].

Interstellar Dust

ISD is the major ingredient in planetary formation. The flow of these charged grains is mainly shaped by the solar radiation pressure force and the IMF configuration [Grün et al. 2000; Sterken et al. 2012]. The interplanetary cruise of Cassini during the first half of year 1999 provided an ideal window to monitor these interstellar messengers as the spacecraft traveled upstream with respect to the ISD flow [Altobelli et al. 2003]. The mean interstellar flux measured during this period of time, corresponding to heliospheric distances between 0.7 and 1.2 AU, is $2.5 \pm 0.5 \times 10^{-5}$ m^{-2} s^{-1}, in the grain mass range of $5 \times 10e^{-17}$ kg to 10^{-15} kg [Altobelli et al. 2003], in good agreement with the ISD flux measured by Ulysses at 3 AU during the same time period [Landgraf et al. 2003]. These simultaneous measurements demonstrate that relatively large interstellar grains (radii > 0.4 μm) can penetrate deeply into the inner solar system.

At 5 to 9 AU from the Sun, corresponding to the time in between the Jupiter flyby and SOI, 6 out of the 17 events registered are consistent with interstellar origin [Altobelli et al. 2007b]. The grain sizes are around 0.4 μm and the upper limit value of the flux is estimated to be 2×10^{-5} m^{-2} s^{-1}, consistent with the previous results.

ISD composition has been studied based on measurements at Saturn during 2004 to 2013 [Altobelli et al. 2016]. The mass distribution of 36 interstellar grains, their elemental composition, and a lower limit for the ISD flux at Saturn were determined [Altobelli et al. 2016]. Mass spectra and grain dynamics suggest the presence of magnesium-rich grains of silicate and oxide composition, partly with iron inclusions. Major rock-forming elements (magnesium, silicon, iron, and calcium) are present in cosmic abundances, with only small grain-to-grain variations, but sulfur and carbon are depleted. The ISD grains in the solar neighborhood appear to be homogenized, likely by repeated processing in the interstellar medium (Figure CDA-15).

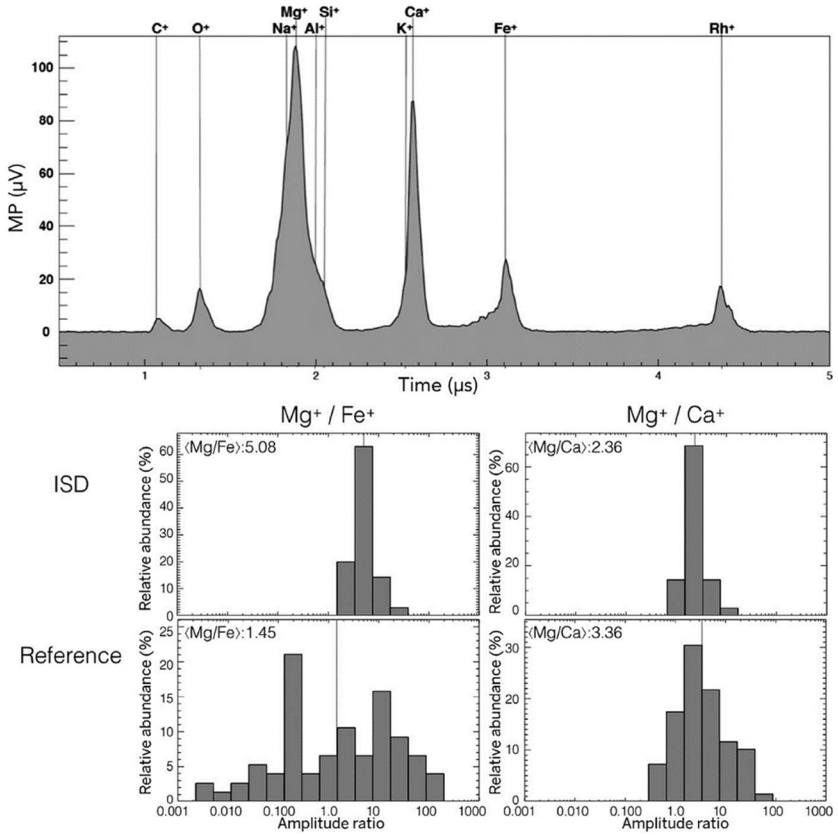


Figure CDA-15. Typical CDA ISD TOF mass spectrum and spectra comparison. *Top*: An example CDA time-of-flight mass spectrum of an ISD grain. *Bottom*: The comparison of cations from ISD spectra to that from the reference group spectra shows that ISD grains have a similar composition. From Altobelli et al. [2016].

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AO	Announcement of Opportunity
AU	astronomical unit
CA	chemical analyzer
CDA	cosmic dust analyzer
CIR	Corotation Interaction Region
DA	dust analyzer
DOY	day of year
FWHM	full-width-half-maximum
HMOC	high mass organic cation
HRD	high-rate detector
IDP	interplanetary dust particle
IID	impact ionization detector
IMF	interplanetary magnetic field
IPT	Io Plasma Torus
IR/UV	infrared/ultraviolet
ISD	interstellar dust
NaCl	sodium chloride
PVDF	polyvinylidene fluoride
RPWS	Radio and Plasma Wave Science
SOI	Saturn Orbit Insertion
TM	Traceability Matrix
TOF MS	time-of-flight mass spectrometry
VIMS	Visual and Infrared Imaging Spectrometer

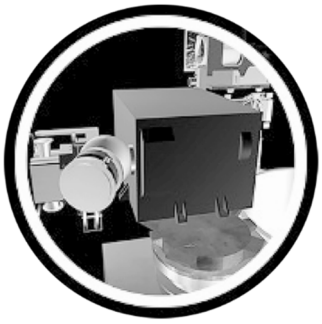
Ion and Neutral Mass Spectrometer



The Ion and Neutral Mass Spectrometer (INMS) was designed to determine the chemical, elemental and isotopic composition of the gaseous and volatile components of the neutral particles and the low energy ions in the Saturn system. The **science objectives** of INMS were to determine the composition and structure of Titan's ionosphere and upper atmosphere, to investigate the neutral and plasma environments of the rings and icy satellites and the interaction with the magnetosphere of Saturn. INMS directly sampled the gas in the Enceladus plume.

The instrument was a quadrupole mass spectrometer with two ion source inlets, a closed ion source for measurement of non-reactive neutral gas and an open ion source for the measurement of ions and reactive neutrals.

EXECUTIVE SUMMARY

The two primary scientific objectives of the Cassini Ion Neutral Mass Spectrometer (INMS) investigation were: 1) to characterize the composition, structure, and chemical behavior of Titan's upper atmosphere and its interaction with Saturn's magnetosphere; and 2) to investigate the neutral and plasma environments of the rings and icy satellites and their magnetospheric interactions [Waite et al. 2004]. Careful determination of the gas densities of the environment is necessary for the proper execution of these objectives. The ion density extraction process has been discussed in detail by Mandt et al. [2012b] for ram pointed flybys, and many other aspects of the INMS calibration and instrument response to ions and neutrals have been addressed in literature [Teolis et al. 2015; Cui et al. 2009a; Magee et al. 2009; Perry et al. 2010; Teolis et al. 2010b; Vuitton et al. 2008; Waite et al. 2004]. These include compositional extraction from mass spectra, wall adsorption of sticky gases such as H_2O and NH_3, thruster firing contamination, radiation background, high-pressure background effects, residual gas tails, high-sensitivity detector saturation, and on-going work to refine the instrument calibration with the ground-based refurbished engineering unit.

INMS produced results beyond expectation for all objects examined: Titan, Enceladus, Dione, Rhea, the inner magnetosphere, the rings, and the ring/atmosphere interaction in Saturn's equatorial atmosphere.

INMS produced results beyond expectation for all objects examined: Titan, Enceladus, Dione, Rhea, the inner magnetosphere, the rings, and the ring/atmosphere interaction in Saturn's equatorial atmosphere. The expectations at Titan were the measurement of the principal components of the atmosphere (nitrogen and methane) and their primary photochemical products (acetylene, ethane, hydrogen cyanide, and their ion counterparts). What emerged was the measurement of a plethora of organic compounds across the whole mass range of INMS that provided a window on a novel way to produce organics through ion neutral chemistry, perhaps an insight into the world of interstellar molecular clouds. There were no expectations for Enceladus, but in reality, this became the most compelling satellite in the system with INMS working in tandem with cosmic dust analyzer (CDA) to demonstrate the habitability of an internal ocean that no one even knew existed before the mission began. The crowning achievement was INMS measurements of molecular hydrogen in the plume that allowed the team to demonstrate that the interior ocean had the latent chemical energy to support methanogenic archea. Dione, Rhea, and the inner magnetosphere provided examples of sputtering of icy satellites, the first time this had been quantitatively investigated in the space environment. The Grand Finale proved *grand* indeed by providing the most complex spectra of the mission (Figure INMS-1) and uncovering a complex chemical interaction between the Saturn atmosphere and rings involving methane, water, carbon dioxide, and ammonia and a host of nanograin organic material—a truly amazing finish to an extraordinary mission.

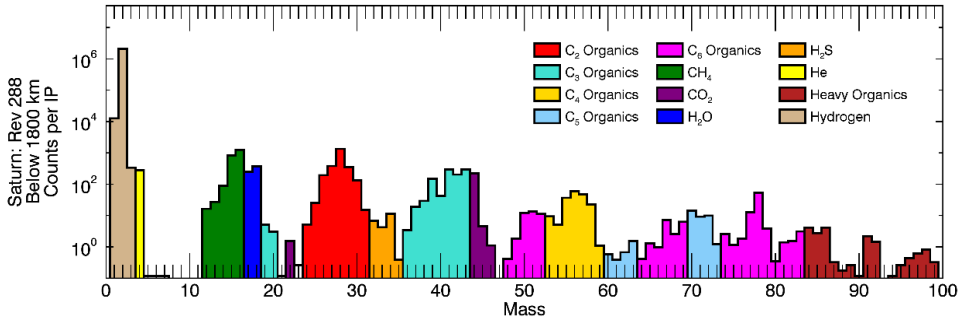

Figure INMS-1. INMS mass spectra of Saturn's upper atmosphere from the Grand Finale. Preliminary mass deconvolution of compounds measured by INMS on the last six orbits of the mission between 1700 and 1800 km at latitudes within 10° of the equator. The spectrum shown here is from the first of these orbits. The axis is in units of mass (u) and extends over the full mass range of INMS (1–99 u).

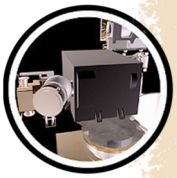
Instrument Summary

The INMS (Figure INMS-2) is a mass spectrometer described in detail by Waite et al. [2004]. The instrument is a quadrupole mass spectrometer (Figure INMS-3) with two source inlets: 1) a closed ion source (CS) for measurement of non-reactive neutral gas; and 2) an open ion source (OS) for the measurement of ions and reactive neutrals without wall collisions within the instrument interior (Figure INMS-4). The sources are housed in an Ion Source Enclosure (ISE). In flight, measurements alternate in a programmable fashion between the two sources. Gas enters the CS inlet through the entrance aperture as a well collimated molecular beam since the relative gas-spacecraft speed is typically much greater than the molecule thermal speeds. Molecule velocities are isotropized and slowed (thermally accommodated) by colliding (roughly 120 times) with the walls of the inlet's antechamber and antechamber-to-CS transfer tube [Teolis et al. 2015] before passing through the tube to the CS ionization region (Figure INMS-4, labeled with density n_s). The resulting density enhancement in the antechamber and CS is a function of the ram angle between the spacecraft velocity vector and the entrance aperture normal. A typical Titan flyby at 6 km/s produces a ram factor of ~71 for nitrogen relative to the density for a spacecraft at rest if one neglects the leakage paths out of the CS. Scaling the ram factor by $\sqrt{T_a/T_s}$ yields the CS to ambient density ratio at the CS and ambient gas temperatures T_s and T_a (see Teolis et al. [2015], Eq. A17). The side vent (Figure INMS-3 and Figure INMS-4) limits the accumulation of residual gas inside the instrument, and constitutes a major leakage pathway out of the instrument. Neutral gas is ionized in the CS using an electron beam (commandable to ~25 or 70 eV) generated by one of two redundant hot filaments. The OS inlet is located below the CS inlet, and consists of an entrance aperture and ion beam collimator. In-flight measurement of ambient ion densities is described by Mandt et al. [2012b]. In-flight measurement of ambient neutral densities is described by Teolis et al. [2015]. Positive ions from the CS or OS are extracted into the electrostatic quadrupole lens (Figure INMS-4), which is used as a deflector to switch ion trajectories between the two sources [Mahhafy and Lai 1990]. The quadrupole lens voltages are set to transfer the ions into the analyzer ion focus lenses and in turn into the quadrupole mass analyzer (QMA). The voltage setting on the ion focus lenses can increase or reduce the sensitivity by affecting how well the beam of ionized neutrals is focused into the mass analyzer.



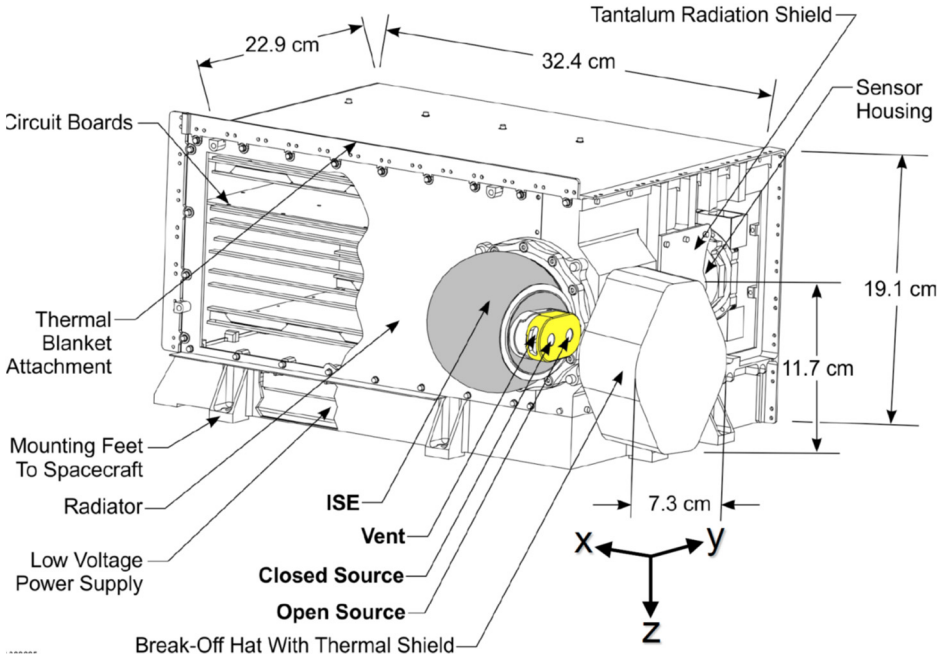


Figure INMS-2. Drawing of the INMS. Showing (*gray*) the ISE and CS and OS inlet apertures, and vent, in relation to (no color) the instrument and electronics housing. The Break-Off Hat was jettisoned after the launch of Cassini.

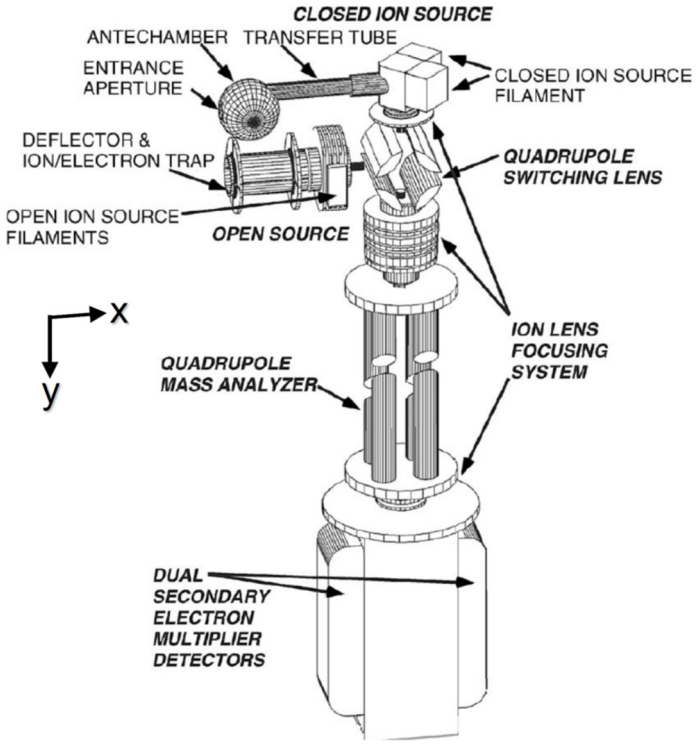

Figure INMS-3. Schematic showing the main components of the INMS. The ram factor model considers the sections above the quadrupole mass analyzer within the ISE (not shown).

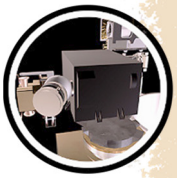

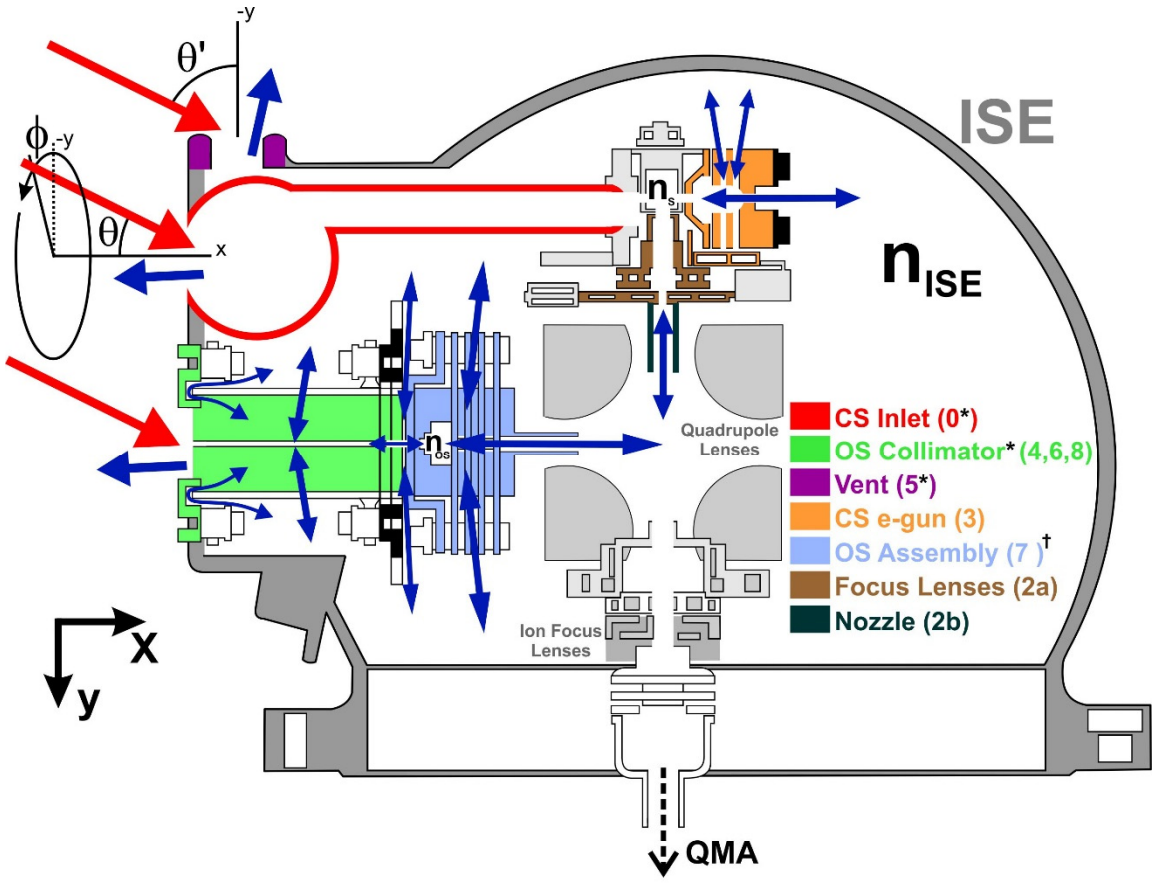

Figure INMS-4. Cross-section diagram (to scale) of the INMS ISE (shown in yellow in Figure INMS-2) with ion sources and gas inlet system shown, together with the azimuthal (ϕ), ram (θ) and vent ram (θ′) angles, spacecraft coordinates axes, gas flows (*Red arrows:* ram flux; *Blue arrows:* thermalized flows), and the approximate locations of densities n_s, n_{os}, and n_{ISE}. Conduction paths considered in the ram factor model are colored as indicated by the legend, with number-letter notation (detailed in Teolis et al. [2015], Appendix A) in parentheses. *Asterisks:* effective area estimated by Monte Carlo simulations. *Dagger:* effective area estimated by fit to Cassini T85 and T88 data. For remaining pathways, we estimated the effective areas analytically. For clarity, leakage through both CS electron guns is shown here as a single conduction pathway. See Teolis et al. [2015], Figure 4 for multiple pathways considered in the CS e-gun conductance calculation. *Grey components*: are neglected in the model, since these sections are treated as having either negligible (e.g., CS enclosure around n_s, ion focus lenses and QMA) or maximum (quadrupole lenses) conductance.

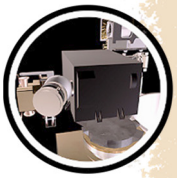
The QMA selects the mass-per-charge ratio (m/q) in the range of 0.5 to 8.5 and 11.5 to 99.5 u per charge, by way of a quadrupole radio frequency mass filter. The detector fore optics consists of three lenses: 1) the Einzel; 2) the Mask I; and 3) the Mask II, which together focus the ions into the detectors. The lens voltage settings can modify the INMS sensitivity depending on how well they focus the beam exiting the QMA into the detectors. Two secondary electron multipliers detect the resulting ion beam operating in a pulse counting mode. These detectors differ in effective sensitivity, with the lower sensitivity detector operating off of secondary electrons produced from the adjacent higher sensitivity detector [Waite et al. 2004]. INMS neutral species-dependent sensitivity factors s_f (for species f) are calibrated on the ground by seven factors: 1) the electron



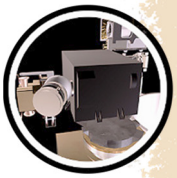
impact efficiency in the sources as determined by the ionization cross-sections of each neutral species; 2) the efficiency for extraction of ions from the CS or OS into the quadrupole lens; 3) the transmission band-pass of the quadrupole switching lens; 4) the degree of focusing in the ion focus lenses into the mass analyzer; 5) the QMA transmission; 6) the detector fore optics transmission; and 7) the detector efficiency.

The OS has three modes of operation: open source ion (OSI), open source neutral beam (OSNB), and open source neutral thermal (OSNT). In the OSI and OSNB modes the OS is used to analyze the ram flux (or molecular beam) of ambient ions and neutrals entering the OS at spacecraft speed, respectively. For more details on the OSNT, see Teolis et al. [2015]; for the OSI see, Mandt et al. [2012]; and for the OSNB, see Waite et al. [2004, 2017].

Over the course of the mission the INMS measurements of Titan's atmospheric neutral mass density were found to be systematically lower than that measured by the Cassini Attitude and Articulation Control System (AACS) and by Navigation (NAV), both of which use spacecraft drag data and aerodynamic models of the spacecraft to derive mass density, as reported by the Titan Atmospheric Working Group (TAMWG); Lee and Hanover [2005]. RPWS Langmuir probe (LP) electron densities can serve as a proxy for total ion densities, while ion densities can be retrieved from Cassini Plasma Spectrometer-Ion Beam Spectrometer (CAPS-IBS) data [Crary et al. 2009]. Comparisons of these sources of ion densities also show systematic differences with the ion densities measured by INMS. Teolis et al. [2015] traced the differences between INMS neutral density measurements and other spacecraft systems in part to gas escape from the CS through leakage pathways not accounted for in the original INMS calibration model. The escape competes with the ram dynamic pressure entering the INMS, yielding lower CS gas densities than indicated by the original calibration, and resulting in a lower INMS neutral gas sensitivity estimate. Therefore, the INMS original calibration model that assumed a sealed CS, used until 2015 to relate the CS density to the ambient density was replaced by a more accurate approach. Teolis et al. [2015] also re-analyzed the INMS detector gain, and found that the gain reduction that occurred during pre-launch characterization testing [Waite et al. 2004], had not been accounted for in the original calibration model. This gain reduction contributes to the reduced INMS sensitivity estimate in the model of Teolis et al. [2015]. The new calibration model brought Cassini INMS results into agreement within expected errors (30%) with the other Cassini systems on the Titan ion and neutral atmospheric densities, and enabled the extraction of Titan neutral density profiles from several previous flybys that yielded unusual and unreasonable densities using the original calibration model.

Key Objectives For INMS

The Announcement of Opportunity (AO) and Cassini Solstice Mission (CSM) objectives listed below have been drawn from the original documents and filtered for relevance to INMS. The objectives are given by key target or working group. Under each key target the AO objectives are first listed followed by the CSM objectives. The AO objectives are fairly general and, in most cases, apply to the overall mission. On the other hand, the CSM objectives largely pertain to new discoveries during the first half of the mission or to seasonal variation objectives during the CSM.



Saturn

The Grand Finale phase of the Cassini mission provided a unique opportunity to study the Saturn Ionosphere Magnetosphere interaction as anticipated. However, what was not expected was information on the equatorial composition and thermal structure (**S_AO1**), the variability of trace gases (**SN1c**), unique H/D and He/H_2 ratio measurements (**S_AO5**), and information on short time scale variations between the rings and the atmosphere (**SC2a**).

Saturn AO objectives

- **Saturn Temperature, Clouds, Composition (S_AO1)** - Determine temperature field, cloud properties, and composition of the atmosphere of Saturn.
- **Saturn Ionosphere-Magnetosphere Interaction (S_AO4)** - Study the diurnal variations and magnetic control of the ionosphere of Saturn.
- **Saturn Formation and Evolution (S_AO5)** - Provide observational constraints (gas composition, isotope ratios, heat flux …) on scenarios for the formation and the evolution of Saturn.

CSM objectives

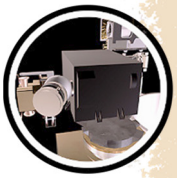
- *Priority 1* **SN1c** - Measure the spatial and temporal variability of trace gases and isotopes.
- *Priority 2* **SC2a** - Observe the magnetosphere, ionosphere, and aurora as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.

Rings

Once again, the Grand Finale phase of the mission allowed unique opportunities to address the rings composition (**R_AO2**) and the magnetosphere ring interaction (**R_AO5**) as anticipated, but also allowed unanticipated contributions in understanding ring structure and dynamics (**R_AO1, RN1a, RN1c,** and **RC1b**).

Rings AO objectives

- **Ring Structure and Dynamics (R_AO1)** - Study configuration of the rings and dynamical processes (gravitational, viscous, erosional, and electromagnetic) responsible for ring structure.
- **Ring Particle Composition and Size (R_AO2)** - Map composition and size distribution of ring material.



- **Ring Magnetosphere-Ionosphere Interactions (R_AO5)** - Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.

CSM objectives

- *Priority 1* **RN1a** - Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejecta trapped on field lines.
- *Priority 1* **RC1b** - Determine the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations.
- *Priority 1* **RN1c** - Determine structural and compositional variations at high resolution across selected ring features of greatest interest, using remote and in situ observations.

MAPS

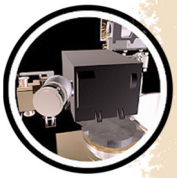
INMS was generally expected to address the MAPS AO and CSM objectives listed below (**M_AO2, M_AO4, M_AO5, MC1a, MN1b, MC2a,** and **MN2a**) and did indeed contribute in a meaningful way to all of the listed objectives.

MAPS AO objectives

- **Magnetosphere Charged Particles (M_AO2)** - Determine current systems, composition, sources, and sinks of magnetosphere charged particles.
- **Magnetosphere and Solar Interactions with Titan (M_AO4)** - Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.
- **Plasma Interactions with Titan’s Atmosphere and Ionosphere (M_AO5)** - Investigate interactions of Titan's atmosphere and exosphere with the surrounding plasma.

CSM objectives

- *Priority 1* **MC1a** - Determine the temporal variability of Enceladus’ plumes.
- *Priority 1* **MN1b** - Conduct in situ and remote sensing studies of Saturn’s ionosphere and inner radiation belt.
- *Priority 2* **MC2a** - Observe seasonal variation of Titan’s ionosphere, from one Solstice to the next.
- *Priority 2* **MN2a** - Determine the coupling between Saturn’s rings and ionosphere.



Icy Satellites

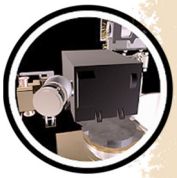
INMS was anticipated to contribute to AO objectives (**I_AO5** and **IN1c**). However, the plumes of Enceladus were not anticipated and thrust INMS into a fundamental role in addressing objectives (**I_AO1, I_AO3, I_AO4, IN1a,** and **IC1a**). INMS was unable to contribute to objectives (**IN2b** and **IN2e**) as a result of low satellite outgassing, proximity to the body, or a combination of both, which led to a very low signal to noise ratio in the measurements.

Icy Satellites AO objectives

- **Icy Satellite Geology and History (I_AO1)** - Determine the general characteristics and geological histories of the satellites.
- **Icy Satellite Surface Composition (I_AO3**) - Investigate the compositions and distributions of surface materials, particularly dark, organic rich materials and low melting point condensed volatiles.
- **Icy Satellite Interior Properties (I_AO4)** - Constrain models of the satellites' bulk compositions and internal structures.
- **Icy Satellite Magnetosphere and Ring Interactions (I_AO5)** - Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.

CSM objectives

- *Priority 1* **IN1a** - Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.
- *Priority 1* **IC1a** - Identify long-term secular and seasonal changes at Enceladus, through observations of the South Polar Region, jets, and plumes.
- *Priority 1* **IN1c** - Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.
- *Priority 2* **IN2b** - Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population.
- *Priority 2* **IN2e** - Understand the unusual appearance of Hyperion with remote sensing observations of the highest resolution possible.



Titan

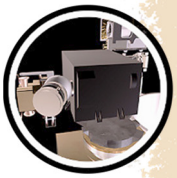
Titan was always a primary objective of interest for INMS (**T_AO1** and **T_AO5**). However, the importance of ion neutral chemistry in producing organic compounds that are connected to the aerosols and surface deposits (**T_AO2, TC1a, TC1b,** and **TN1c**) was an unanticipated objective. An unfortunate oversight of these processes in Phase B led to descoping the mass range of INMS during development, which in hindsight was a significant impediment in understanding the full extent of the ion neutral chemistry (**T_AO2** and **T_AO5**). Objective **TN2a** on resolving atmospheric density discrepancies between INMS, AACS, and NAV was discovered during the mission and was a direct result of descoping the calibration system for INMS during development.

Titan AO objectives

- **Titan Atmospheric Formation and Evolution (T_AO1)** - Determine abundances of atmospheric constituents (including any noble gases), establish isotope ratios for abundant elements, constrain scenarios of formation and evolution of Titan and its atmosphere.
- **Titan Atmospheric Composition and Distribution (T_AO2)** - Observe vertical and horizontal distributions of trace gases, search for more complex organic molecules, investigate energy sources for atmospheric chemistry, model the photochemistry of the stratosphere, study formation and composition of aerosols.
- **Titan Upper Atmosphere (T_AO5)** - Investigate the upper atmosphere, its ionization, and its role as a source of neutral and ionized material for the magnetosphere of Saturn.

CSM objectives

- *Priority 1* **TC1a** - Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport.
- *Priority 1* **TC1b** - Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex.
- *Priority 1* **TN1c** - Measure aerosol and heavy molecule layers and properties.
- *Priority 2* **TN2a** - Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission).



INMS Science Assessment

Rating of Relevant Cassini AO and Solstice Objectives

The Key Objectives for INMS detailed above provide some rationale for the color-coded ratings given in Table INMS-1 for summary purposes.

Table INMS-1. Science Assessment. Note: This table is an Assessment of Data collected to satisfy an objective. It is not an assessment of the status of data analysis/publications.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

INMS Science Objectives	AO and TM Science Objectives	INMS Science Assessment	Comments if yellow (partially fulfilled)
Saturn			
Saturn Temperature, Clouds, Composition	S_AO1		Measured temperatures and composition in the exosphere of Saturn near the equator.
Saturn Ionosphere-Magnetosphere Interaction	S_AO4		
Saturn Formation and Evolution	S_AO5		
Measure the spatial and temporal variability of trace gases and isotopes. *(Priority 1)*	SN1c		
Observe the magnetosphere, ionosphere, and aurora as they change on all time scales - minutes to years - and are affected by seasonal and solar cycle forcing. *(Priority 2)*	SC2a		Observed inner magnetospheric composition throughout the mission. Unable to sample in the auroral region close enough to the planet to see any atmospheric or ionospheric effects associated with the aurora.
Rings			
Ring Structure and Dynamics	R_AO1		Positively contributed to understanding the exchange of material between the C-ring and D-ring during the proximal orbits.
Ring Particle Composition and Size	R_AO2		
Ring Magnetosphere-Ionosphere Interactions	R_AO5		
Determine the temporal variability of ring structure on all timescales up to decadal for regions including Encke gap, D-ring, F-ring, and ring edges by substantially increasing the cadence and time baseline of observations. *(Priority 1)*	RC1b		Positively contributed to understanding the exchange of material between the C-ring and D-ring during the proximal orbits.
Constrain the origin and age of the rings by direct determination of the ring mass, and of the composition of ring ejecta trapped on field lines. *(Priority 1)*	RN1a		Positively contributed to understanding the exchange of material between the C-ring and D-ring during the proximal orbits. Also observed material infalling from the D-ring into the atmosphere and determined it to be an important source of ring decay.
Determine structural and compositional variations at high resolution across selected ring features of greatest interest, using remote and in situ observations. *(Priority 1)*	RN1c		INMS contributions limited to comparisons of material infall to Imaging Science Subsystem (ISS) brightness measurements of D68 ringlet during the proximal orbits.

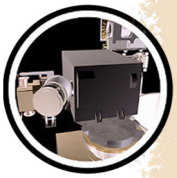


Table INMS-1. Science Assessment. Note: This table is an Assessment of Data collected to satisfy an objective. It is not an assessment of the status of data analysis/publications.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

INMS Science Objectives	AO and TM Science Objectives	INMS Science Assessment	Comments if yellow (partially fulfilled)
MAPS			
Magnetosphere Charged Particles	M_AO2		The INMS contribution to the magnetospheres studies was very limited due to the energy range covered by the open source ions.
Magnetosphere and Solar Interactions with Titan	M_AO4		
Plasma Interactions with Titan's Atmosphere and Ionosphere	M_AO5		
Determine the temporal variability of Enceladus' plumes. *(Priority 1)*	MC1a		
Conduct in situ and remote sensing studies of Saturn's ionosphere and inner radiation belt. *(Priority 1)*	MN1b		
Observe seasonal variation of Titan's ionosphere, from one Solstice to the next. *(Priority 2)*	MC2a		
Determine the coupling between Saturn's rings and ionosphere. *(Priority 2)*	MN2a		
Icy Satellites			
Icy Satellite Geology and History	I_AO1		Measured evolutional implications for Enceladus.
Icy Satellite Surface Composition	I_AO3		
Icy Satellite Interior Properties	I_AO4		
Icy Satellite Magnetosphere and Ring Interactions	I_AO5		
Identify long-term secular and seasonal changes at Enceladus, through observations of the south polar region, jets, and plumes.	IC1a		Measured variability but were unable to distinguish secular versus seasonal changes.
Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing. *(Priority 1)*	IN1a		
Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time. *(Priority 1)*	IN1c		
Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population. *(Priority 2)*	IN2b		INMS was unable to contribute as a result of low outgassing, proximity to the body, or a combination of both, which led to a very low signal to noise ratio in the measurements.

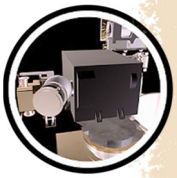

Table INMS-1. Science Assessment. Note: This table is an Assessment of Data collected to satisfy an objective. It is not an assessment of the status of data analysis/publications.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

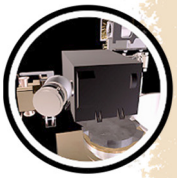
INMS Science Objectives	AO and TM Science Objectives	INMS Science Assessment	Comments if yellow (partially fulfilled)
Understand the unusual appearance of Hyperion with remote sensing observations of the highest resolution possible. *(Priority 2)*	IN2e		INMS was unable to contribute as a result of low outgassing, proximity to the body, or a combination of both, which led to a very low signal to noise ratio in the measurements.
Titan			
Titan Atmospheric Formation and Evolution	T_AO1		
Titan Atmospheric Composition and Distribution	T_AO2		
Titan Upper Atmosphere	T_AO5		
Determine seasonal changes in the methane-hydrocarbon hydrological cycle: of lakes, clouds, aerosols, and their seasonal transport. *(Priority 1)*	TC1a		
Determine seasonal changes in the high-latitude atmosphere, specifically the temperature structure and formation and breakup of the winter polar vortex. *(Priority 1)*	TC1b		Measurements at INMS in situ altitudes provided little information on processes in the stratosphere.
Measure aerosol and heavy molecule layers and properties. *(Priority 1)*	TN1c		
Resolve current inconsistencies in atmospheric density measurements (critical to a future Flagship mission). *(Priority 2)*	TN2a		

Alternative Science Performance Assessment – Mapping of Refereed Publications

An alternative way to assess INMS science performance is to take the science performance requirements compiled prelaunch and match them with the complete list of INMS refereed publications. A relationship between the science performance and functional requirements for INMS was spelled out in the Cassini Orbiter Functional Requirements Book Ion and Neutral Mass Spectrometer (INMS), Rev. A, CAS-4-2074, dated July 4, 1997 prepared just before launch. The performance is encapsulated in a series of science objectives spelled out in Section 3.3.1 of Functional Requirements Book and repeated below in summary assessment form with references of related published INMS papers.

Titan – atmospheric structure

1. What gases (and isotopes) are present besides the N_2, CH_4, and C_2H_2 detected by the Voyager UltraViolet Spectrometer (UVS)?



2. What is the extent of diffusive separation (or, where is the homopause)? This may require a comparison with Cassini Probe data.

RELEVANT PAPERS

There are 31 refereed papers listed below that discuss the bulk structure and composition of Titan's atmosphere. The methane homopause was located at ~1100 km above the surface. The papers range in topics from major species structure to isotope and minor species structure in altitude, longitude, and latitude. The quality and quantity of papers far exceeds performance expectations. Solar cycle variability was also examined.

Titan – thermal structure and energetics

1. What is the exospheric temperature and how does it vary (diurnally, spatial, or long term)?

2. What energy sources and sinks determine the heat balance of the exosphere and lower thermosphere?

3. What role do radiatively active species play in the upper atmospheric heat balance and the coupling of the lower and upper atmosphere thermal processes?

RELEVANT PAPERS

There are 10 papers listed below that report the thermal structure of the atmosphere including solar heating, particle precipitation, and gravity wave forcing. Solar heating was found to be the primary energy source and hydrogen cyanide rovibrational emissions the major cooling process. The papers met expectations for the performance noted prior to the mission.

Titan – ionospheric structure

1. What are the sources of ionization? What is the chemistry of positive ions? How important are vertical and horizontal transports of ions and electrons?

2. What are the energy sources and sinks for ions and electrons? What ions and neutrals are escaping from Titan? What is the environment in which the intense airglow (aurora?) is produced?

RELEVANT PAPERS

There are 51 papers listed below that deal with the ionosphere—its formation and chemistry, especially the complex ion neutral chemistry that forms the heavy organic compounds found on the Titan surface. This work far exceeds the pre-flight expectations.

Titan – unanticipated findings

There are five papers listed below that detail unanticipated findings by INMS. The complex nature and complexity of the ion neutral chemistry was totally unanticipated, as was our overall characterization of the formation of the Saturn system through compositional measurements.

RELEVANT PAPERS

Rings and icy satellites

There are 11 papers listed below that discuss Saturn's rings and icy satellites. INMS allowed a characterization of the E-ring and F-ring as expected. The sputtered atmospheres of Dione and Rhea were well characterized, including the unexpected seasonal variations associated with those atmospheres. The D-ring interaction with Saturn's atmosphere during the Grand Finale exceeded all expectations.

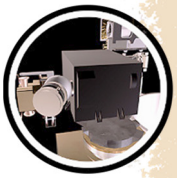
Magnetosphere

There is one paper listed below that discusses the magnetosphere. The INMS contribution to the magnetospheres studies was limited due to the energy range covered by the open source ions.

RELEVANT PAPERS

Southwood, J. H. Waite Jr., D. T. Young, (2002), Magnetospheric and plasma science with Cassini-Huygens, Space Science Reviews, 104, 1, 253–346.



Enceladus

The most startling and unanticipated contribution from INMS was the characterization of the gas composition of the Enceladus plume. The 18 papers listed below discuss the composition, structure, and dynamics of the plume. Most noteworthy were the discovery that the water in the plumes has the same D/H ratio of some Oort cloud comets, and that the plume contained molecular hydrogen that showed a positive chemical affinity to the reaction for methanogenesis $[4\ H_2 + CO_2 \rightarrow CH_4 + 2\ H_2O]$. There is food for microbes in the global ocean.

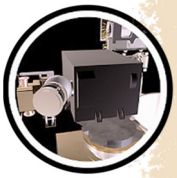
INMS Saturn System Science Results

Titan Science

Titan highlights

- **Complex Ion Neutral Chemistry:** Existence demonstrated of a complex ionospheric chemistry on Titan dominated by hydrocarbon and nitrogen-bearing species.
- **Solar Radiation as the Primary Ionospheric Source:** Demonstration that solar radiation dominates as the global source of Titan's ionosphere but that locally on the nightside particle precipitation from Saturn's magnetosphere is an important source.
- **Atmospheric Escape:** Early studies by Yelle et al. [2006, 2008] and Strobel [2008, 2010] demonstrated possible need for enhanced methane escape from Titan to explain the data. Later studies by Bell et al. [2014] and Tucker et al. [2013] that combined thermal balance, dynamical, and chemical calculations reproduced INMS without hydrodynamic escape of methane. The New Horizons mission also demonstrated that hydrodynamic escape is not likely at Pluto and by extension, Titan. However, the possibility remains that high escape rates could be possible due to other non-thermal mechanisms. Definite implications for evolution of Titan [Mandt et al. 2012a].
- **Thermosphere Temperatures:** Rapid changes in upper atmosphere temperatures could be due to a combined effect of upward propagating gravity waves (see Müller-Wodarg et al. [2006a, 2008]; Strobel [2006]; Snowden et al. [2013a, 2013b]) and downwelling plasma from Saturn's co-rotating magnetosphere [Westlake et al. 2011; Bell et al. 2011a]. Thus, this is a thermosphere driven from above and below in unique ways in the solar system.



Summary of Titan science

Instruments on the Cassini Orbiter carried out extensive measurements of the upper atmosphere and ionosphere of Titan over a 12-year period of time, starting in 2005. The first INMS neutral measurements were made during the TA pass and the first ion composition were made on Titan's nightside during the T5 pass. The INMS measured densities of ion species up to a mass number of 99 throughout the main and topside ionosphere, on the dayside and nightside, the ramside and wakeside (with respect to the external flow of magnetospheric plasma), and when Titan was in different regions of Saturn's magnetosphere. The measured ion composition and densities provided insight into several aspects of Titan's ionosphere and its linkage between the neutral atmosphere and the external environment including the Sun (solar ionizing radiation), Saturn's magnetosphere, and the solar wind. In particular, ionospheric processes were shown to play a critical role in how external particles and radiation, combined with a nitrogen and methane neutral atmosphere, in driving photochemistry in the upper atmosphere that leads to complex organic composition and also to aerosol growth.

TITAN UPPER ATMOSPHERE/IONOSPHERE MAJOR FINDINGS (NEUTRAL)

- INMS made first in situ measurements of the major constituents of Titan's upper atmosphere and ionosphere, discovering an unexpectedly complex and rich ion and neutral chemistry occurring above 1000 km. **(T_AO2, T_AO1,** and **T_AO5)**.
- The INMS measurements of the $^{12}C/^{13}C$ and $^{14}N/^{15}N$ isotopic ratios have allowed for assessments of Titan's evolutionary history. **(T_AO1)**.
- INMS observations have revealed significant variations in thermal structures that suggest a combination of magnetospheric and wave/tide energy deposition. **(T_AO5)**.
- INMS observations over time have revealed that the atmospheric content of methane above 1000 km is sensitive to the solar cycle.
- INMS measurements over time demonstrated that solar ionizing radiation is the dominant source of the ionosphere and correlated with solar activity, although ionization by energetic particle precipitation from Saturn's magnetosphere is important on the nightside **(T_AO5)**.

Table INMS-2 shows the INMS Titan objective, the AO and TM/CSM science objective, and the color-coded rating assessment.

Figure INMS-5 shows the inferred neutral temperatures from INMS nitrogen density measurements.

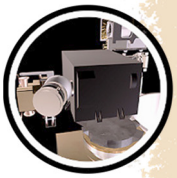


Table INMS-2. Final Report INMS – Titan Science.

Fully/Mostly Accomplished: Partially Accomplished: Not Accomplished:

INMS Objectives	AO and TM/CSM Science Objectives	Assessment
Titan Objectives		
Titan Atmospheric Formation and Evolution	T_AO1	
Titan Atmospheric Composition and Distribution	T_AO2	
Titan Upper Atmosphere	T_AO5	

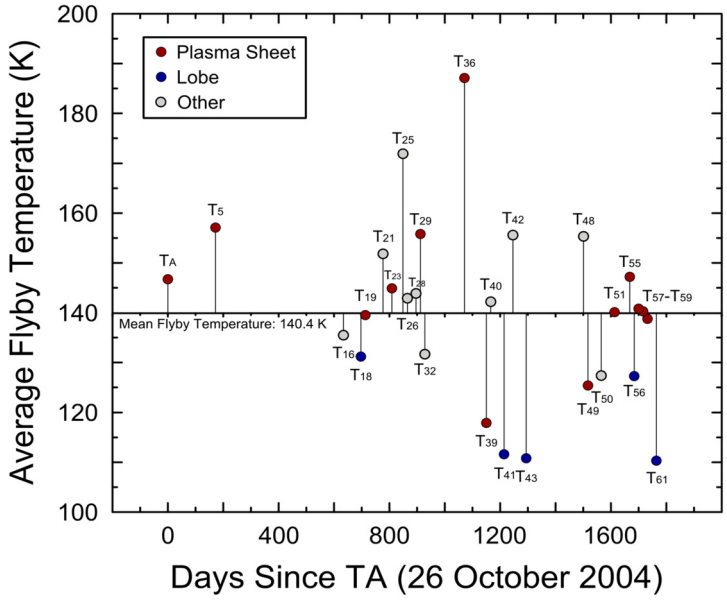

Figure INMS-5. Inferred neutral temperatures (vertical axis) from INMS nitrogen density measurements over time since the TA.

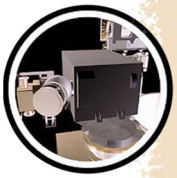
Titan's neutral atmosphere

Observations of neutral densities (mainly N_2), have allowed us to make inferences into the thermal structure of Titan's upper atmosphere [cf. Müller-Wodarg et al. 2006a, 2008; Cui et al. 2008, 2009a; Magee et al. 2009; Westlake et al. 2011; Snowden et al. 2013a]. The average thermospheric temperature derived from INMS data is around 150 K, which is in good agreement with pre-Cassini estimates [Müller-Wodarg et al. 2000, 2003; Müller-Wodarg and Velle 2002a]. However, the temperature of Titan's thermosphere exhibits a high degree of variability that was not predicted prior to Cassini—see, for example, Müller-Wodarg et al. [2000, 2003]; Müller-Wodarg and Velle [2002a]. Pre-Cassini models calculated day-night variations on the order of 10–15 K. Cassini has observed temperature variations much larger than this over the course of a single Titan day, even when observing the same region of atmosphere at a similar local time. The variations in



temperature are not correlated with solar input, indicating there are additional heating/cooling mechanisms with magnitudes that are similar to solar insulation. The short-timescales associated with the large variations in temperature has led some to postulate that the magnetosphere may provide sporadic and localized inputs [Westlake et al. 2011] or internal gravity waves may be depositing significant energy into the upper atmosphere [Müller-Wodarg et al. 2006a; Snowden et al. 2013a]. Atmospheric escape may also significantly alter the temperature of the upper thermosphere [Tucker et al. 2013] as can spatial and temporal variation of minor species that are strong sources of radiative cooling such as HCN and CH_4.

INMS data indicates that, similar to other atmospheres, waves are a persistent feature in Titan's thermosphere. Wave characteristics derived by fitting INMS data (Figure INMS-6) indicates vertical wavelengths are the order of several hundred kilometers, amplitudes are on the order of 10%, and wave periods are on the order of several hours [Müller-Wodarg et al. 2006a; Snowden et al. 2013a; Cui et al. 2013]. The persistence of waves in Titan's thermosphere indicates that the zonal wind speed must exceed 100 m/s [Snowden et al. 2013a]. Super rotating winds around 100 m/s have also been employed to explain day-night variation in short and long-lived ions observed by INMS in Titan's upper atmosphere [Cui et al. 2009b].

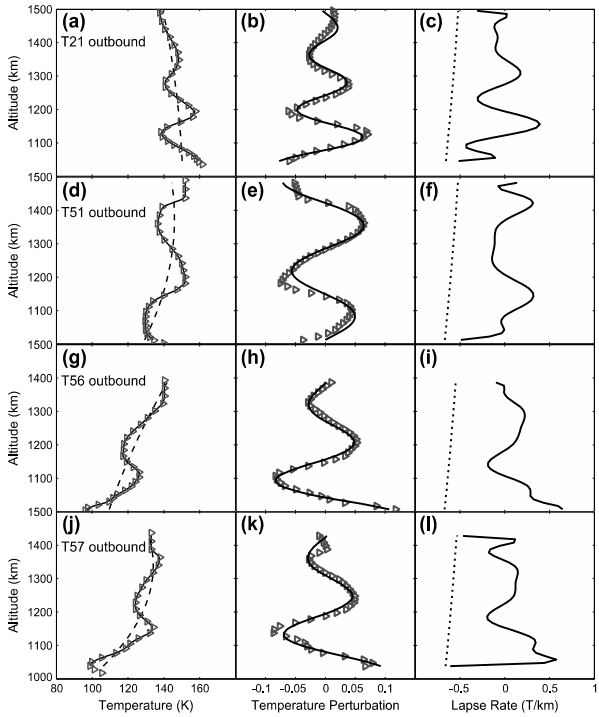


Figure INMS-6. The panels show how wave properties are determined by fitting the vertical temperature profiles derived from INMS data from four flybys. Panels on the right compare the vertical gradient in temperature to the adiabatic lapse rate to show that waves of this scale can be stable in Titan's thermosphere. [Snowden et al. 2013a].

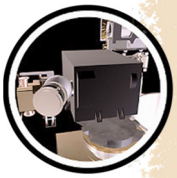
Not only has INMS revealed the nature of Titan's upper atmospheric thermal structure, but it has also shown that the methane in the upper atmosphere can exhibit significant solar cycle



variations. As seen in Figure INMS-7, the methane densities (abundances) during the extended solar minimum remained relatively stable and consistent relative to the major background species N_2. However, as the solar activity levels increased (Figure INMS-7, panels 4 and 5), methane was significantly reduced relative to N_2. This occurred despite the fact that, as shown by the panel 3 in Figure INMS-7, Titan was moving farther away from the Sun, and all things being equal, should have experienced reduced solar insolation. These observations demonstrated that methane is a chemically active species, responding relatively quickly to increases in solar insolation, again highlighting the surprisingly dynamic nature of Titan's upper atmosphere.

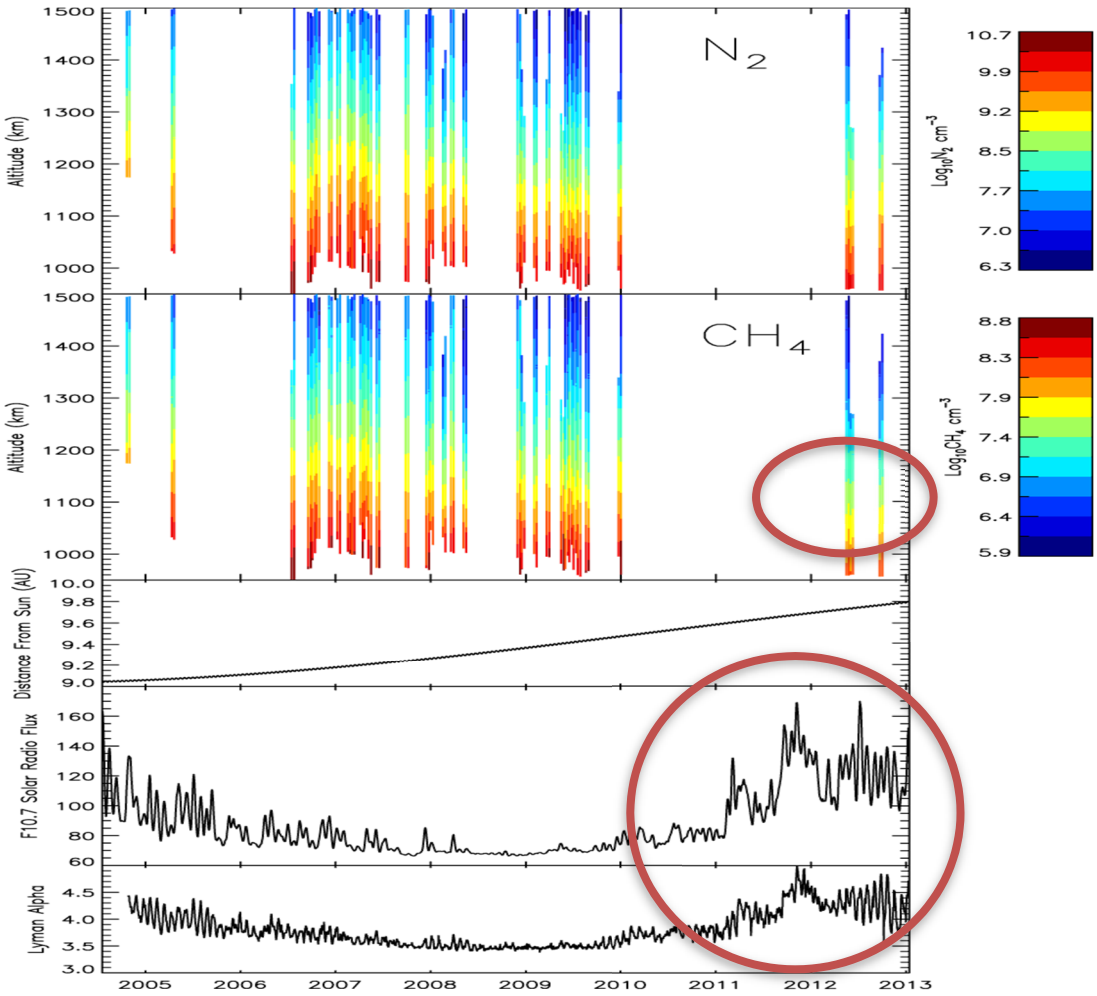


Figure INMS-7. Titan's upper atmospheric thermal structure shows that the methane in the upper atmosphere can exhibit significant solar cycle variations. Multipanel plot showing N_2 densities (*panel 1*), CH_4 densities (*panel 2*), Titan-Saturn orbital distance (*panel 3*), Solar $F_{10.7\text{-cm}}$ radio flux (*panel 4*), and Lyman-alpha fluxes at Titan's orbit (*panel 5*) as a function of time (horizontal axis). The circles point to the time periods of significantly reduced methane measured by INMS that correlates with high solar activity [Westlake et al. 2012a].

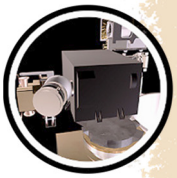
While no direct thermosphere wind measurements could be made with the INMS or any other Cassini or Earth based instrumentation, the horizontal density variations in the thermosphere as



measured by the INMS were used in conjunction with balance of forces calculations as well as more sophisticated General Circulation Model (GCM) simulations to infer horizontal wind speeds reaching around 150 m/s [Müller-Wodarg et al. 2008]. These calculations also determined the important influence of thermospheric winds on the distribution of atmospheric gases such as CH_4. More recent calculations with the Titan thermosphere GMC [Müller-Wodarg et al. 2003] demonstrated that much of the significant variability in densities and temperatures observed by the INMS [Snowden et al. 2013a] could be explained by variability in the stratosphere which strongly affected the thermosphere.

Titan's ionosphere

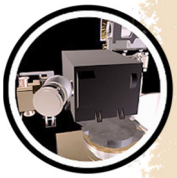
Voyager measurements, both in situ of the magnetotail and radio occultation of the main ionosphere, showed the existence of an ionosphere at Titan [Neubauer et al. 1984; Bird et al. 1997]. Subsequent theoretical modeling suggested that the ionospheric composition could be quite complex, largely due to the presence of hydrocarbons associated with dissociation and ionization of methane [Nagy and Cravens 1998; Keller et al. 1992, 1998; Fox and Yelle 1997]. But the series of Cassini measurements by INMS, CAPS, and the Radio and Plasma Wave Science (RPWS) LP quantified the ionospheric densities and the extent of the ionosphere. The INMS science of Titan's ionosphere is organized into 3 sub-sections: 1) sources, 2) chemistry, and 3) dynamics.

Sources of Titan's ionosphere

The major ion species produced is N_2^+, since N_2 is the major neutral species. However, chemical considerations told us that the main ion species at mass 28 is not N_2^+ but $HCNH^+$, so another ion species, CH_3^+, was used to almost directly deduce ion production rates [Richard et al. 2015a, 2015b; Vigren et al. 2015; Sagnières et al. 2015]. The rapid chemical reaction of N_2^+ with CH_4 produces CH_3^+ (mass 15). The ionization rate of CH_4 can be deduced by the measured CH_4^+ ions at mass 16 [Richard et al. 2015a, 2015b].

It was found that solar ionizing radiation is the dominant source of the dayside ionosphere, not surprisingly, and the quantification of the source rate was largely as expected given the solar flux and the relevant photoionization cross-sections for N_2 and CH_4. Given that Cassini spanned a large part of a solar cycle, the INMS-deduced ion production rates were shown to increase with increasing solar activity [Madanian et al. 2016].

Sources of ionization deep on the nightside were also studied by Cassini and INMS. Globally, solar radiation accounts for 90% of total ionization, but precipitation of energetic electrons and ions leading to ionization is obviously locally important on the nightside [Ågren et al. 2007; Cravens et al. 2008a, 2008b; Cravens et al. 2009b; Vigren et al. 2015; Snowden and Yelle 2014a, 2014b; Edberg et al. 2013a, 2013b; Robertson et al. 2009; Galand et al. 2014]. As on Venus and Mars, the two possible sources of the nightside ionosphere are local/direct ionization from precipitation (i.e., a diffuse aurora) and transport of plasma from the dayside. Evidence for the precipitation source was provided by INMS by measurements of primary or almost primary ion species (CH_3^+,



CH_4^+, CH_5^+…), which have short chemical lifetimes and could only be produced locally. On T5 a correlation between secondary auroral electron fluxes measured by CAPS ELS correlated with the CH_5^+ densities [Cravens et al. 2008a]. Longer-lived ion species (e.g., $HCNH^+$) can also be transported from day to night and both sources can operate [Cui et al. 2009a]. Modeling combined with INMS, CAPS, and RPWS data determined that the precipitation ionization source depend on magnetic topology and on the location of Titan in Saturn's magnetosphere. Incident magnetospheric electron fluxes, and the associated nightside ionosphere, were more robust when Titan was located in the plasmasheet region as opposed to the magnetic lobes of Saturn's magnetosphere [Richard et al. 2015a; Rymer et al. 2009].

Chemistry of the Upper Atmosphere and Ionosphere

The chemistry of Titan's upper atmosphere and ionosphere is complex due to the presence of a large number of organic species extending up to high mass numbers. The neutral and ion chemistry is linked together [Waite et al. 2007]. The INMS has played a key role in improving our understanding of this chemistry. Photodissociation and photoionization of N_2 and CH_4 form ion and neutral species that are very reactive and that initiate a series of reactions producing increasing larger species, up to aerosol-sized particles [Waite et al. 2007]. Primary N_2^+ ions react with CH_4 to produce CH_3^+, which again reacts with CH_4 to produce $C_2H_5^+$. $C_2H_5^+$ reacts with HCN to produce the very abundant species $HCNH^+$. Reactions of $C_2H_5^+$ and $HCNH^+$ with C_2H_2, C_2H_4, and C_4H_2 drive a chain of reactions leading to families of $C_nH_m^+$ species, including protonated benzene ($C_6H_7^+$), and up to masses exceeding 99 Da [Anicich and McEwan 1997; Cravens et al. 2006; Vuitton et al. 2006, 2007, 2009; Westlake et al. 2014b; Cui et al. 2009a; Mandt et al. 2012a] (Figure INMS-8 and Figure INMS-9). Figure INMS-10 shows INMS ion density profiles versus neutral density (i.e., altitude). CAPS measurements, albeit at low mass resolution, indicated the presence of species up to at least 1100 Da [Crary et al. 2009; Coates et al. 2010]. For example, CH_2NH_2, CH_3CN, and other nitrogen-bearing species react with lower mass ion species to produce protonated ion species [Vuitton et al. 2007].

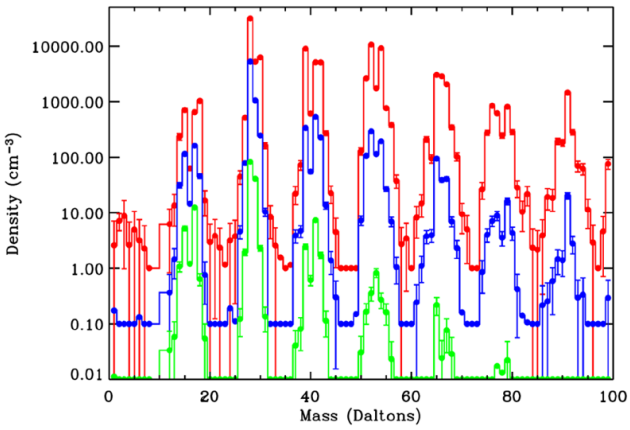


Figure INMS-8. Shown are the first INMS measurements of ion densities versus mass number at three different altitudes for the T5 nightside ionosphere [Cravens et al. 2006]. *Red:* 1027–1200 km. *Blue:* 1200–1400 km. *Green:* 1400–1600 km. Chemical complexity increases with decreasing altitude.

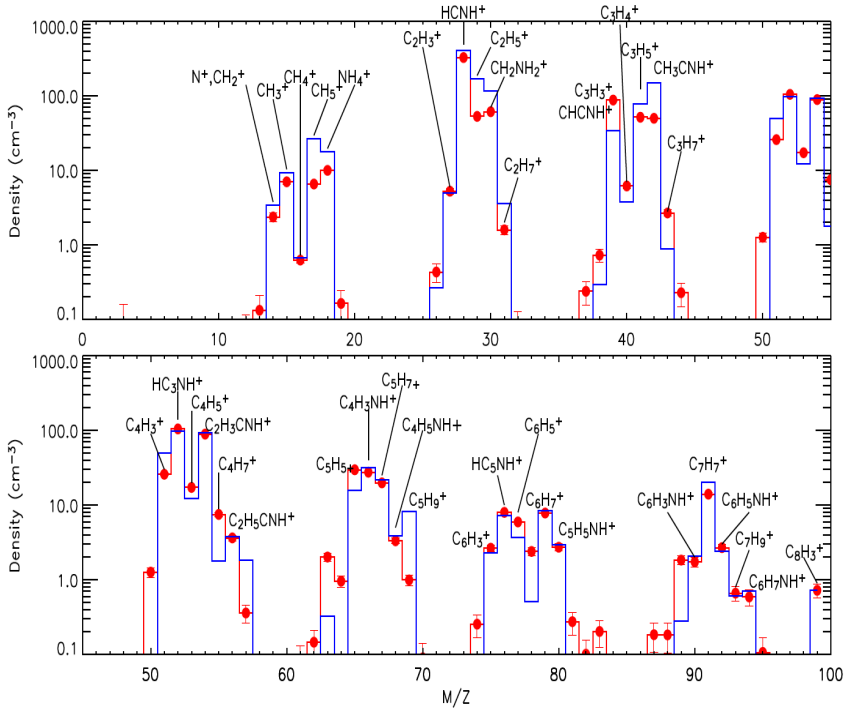

Figure INMS-9. INMS T5 data compared with a photochemical model which put forward the presence of protonated nitrogen ion species. The *blue line* is the modeled mass spectrum [Vuitton et al. 2007].

INMS data for 4 ion species. *Ion Density vs. neutral density*.

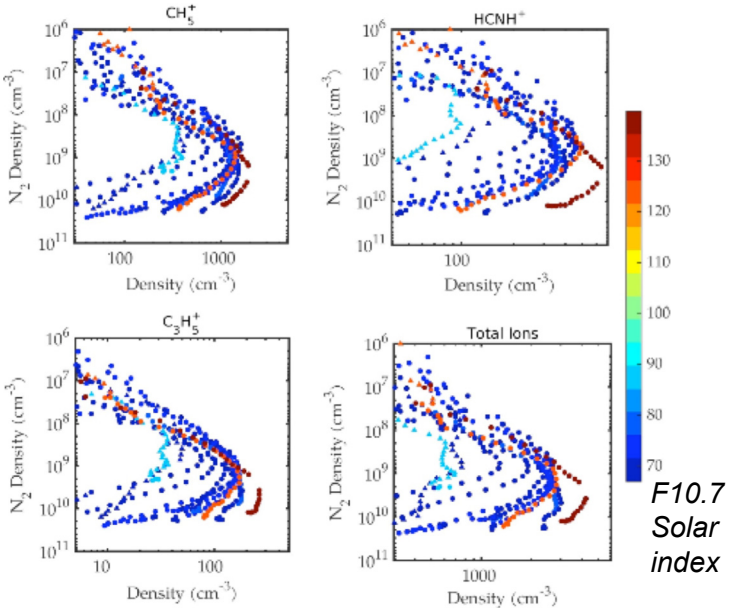

Figure INMS-10. INMS ion density profiles versus neutral density measured throughout the mission with different solar activity levels (as given by the solar extreme ultraviolet (EUV) proxy F10.7—*color bar*). Total ions denote the total INMS ion density. In general, higher solar activity correlates with higher density. [Madanian et al. 2016].

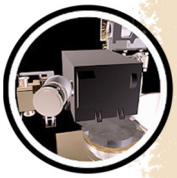
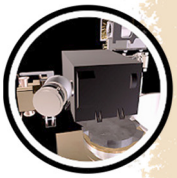


Titan's ionosphere consists of positive and negative ions, some of which have masses of up to and possibly beyond 1000s u [Waite et al. 2007; Coates et al. 2007]. The study of Vuitton et al. [2007] identified over 100 ions in the INMS spectrum including several N-bearing species such as protonated ammonia (NH_4^+), $CH_2NH_2^+$, and CH_3CNH^+. Titan's atmosphere is a reducing atmosphere (little or no oxygen species are present) and as such the ionization will flow from species whose parent neutral molecules have low proton affinities (PA) to those whose parent neutral molecules have greater PAs. The proton affinity of a molecule is a measure of the gas-phase basicity or its propensity to undergo a reaction in which a proton is gained. In general, molecules containing unsaturated carbon bonds (those which have double or triple covalent bonds between adjacent molecules) have larger proton affinities.

The hydrocarbon chemistry at Titan has been shown to lead to the production of benzene [Waite et al. 2007; De La Haye et al. 2008b; Vuitton et al. 2008]. There have been several attempts by the modeling community to reproduce the INMS observed benzene abundances including those based solely on radical neutral and termolecular processes [Lebonnois 2005], some ion-molecule reactions coupled with neutral processes [Wilson et al. 2003], and intricately coupled ion-molecule chemical schemes [De La Haye et al. 2008b; Vuitton et al. 2008]. The INMS measured molar fraction of benzene was found to be about 2×10^{-6} at 1050 km altitude [Magee et al. 2009]. The study of Vuitton et al. [2008] argues that most of the observed benzene is a product of reactions between phenyl radicals (C_6H_5) and hydrogen within the INMS instrument's antechamber yielding a benzene abundance that contributes one-third of the total observed peak level. This implies significant amounts of the phenyl radical are present in Titan's upper atmosphere. Further analysis of the INMS data revealed that it is difficult to disentangle heterogeneous surface chemistry of radicals from adsorption/desorption of the parent molecule [Cui et al. 2009b]. Regardless of interpretation, the Cassini INMS data shows that the mixing ratio of benzene or benzene and phenyl is a few times 10^{-6} indicating that the chemistry is efficient in producing not only unsaturated hydrocarbons but also aromatic hydrocarbons.

Although NH_3 and CH_2NH were not directly detected on Titan, we have shown that the mass spectra obtained by Cassini indicate the presence of NH_4^+ and $CH_2NH_2^+$. This implies quantities of NH_3 and CH_2NH close to 10 ppm in the upper atmosphere, because the NH_4^+/NH_3 and $CH_2NH_2^+/CH_2NH$ couples are connected to each other by proton exchange and electron recombination reactions. However, the presence of such an amount of NH_3 in the upper atmosphere of Titan was not predicted by photochemical models.

In order to tackle this problem, we have proposed a new way for the formation of NH_3, by reaction of the radical NH_2 with H_2CN, the latter being also the precursor of HCN. To confirm this hypothesis, we calculated the kinetic constant and showed that it is indeed fast (7.5×10^{-11} cm^3 s^{-1} at 150 K). The calculated NH_4^+ and $CH_2NH_2^+$ densities are then in agreement with the densities measured for the entire altitude range for which observations are available, which leads to the conclusion that the main mechanisms of production and loss of NH_3 and CH_2NH have been properly identified. More generally, we have shown that ammonia and methanimine are formed from a complex network of reactions involving both neutral and charged species, which, as for



C_6H_6, shows the importance of ion chemistry for the composition of the neutral atmosphere [Yelle et al. 2010].

Below about 1200 km in Titan's atmosphere positive ions with masses greater than 100 u have been found [Waite et al. 2007; Crary et al. 2009]. A sample spectrum obtained by the CAPS-IBS instrument during the T26 flyby is shown in Figure INMS-11. The composition of the high mass ions has been suggested to primarily consist of polycyclic aromatic hydrocarbon (PAH) that are multi-ringed molecules built from benzene [Crary et al. 2009]. PAH ions are likely the precursors to the tholins observed in the haze layer at about 500 km [Waite et al. 2007; Lavvas et al. 2008a, 2008b]. Models have shown that the most efficient pathway for production of the haze layer is through PAHs [Wilson et al. 2003]. Several theoretical models have also been developed to describe the process of producing PAHs from benzene through neutral chemistry in the context of flame chemistry [Wang and Frenklach 1997; Richter and Howard 2000], and interstellar environments [Bohme 1992; Snow et al. 1998]. Computational models have been developed to describe the energy required to build PAHs through neutral chemistry [Bauschlicher and Ricca 2000], cation chemistry [Bauschlicher et al. 2002], as well as, the efficiency for incorporating nitrogen into PAHs [Ricca et al. 2001a, 2001b].

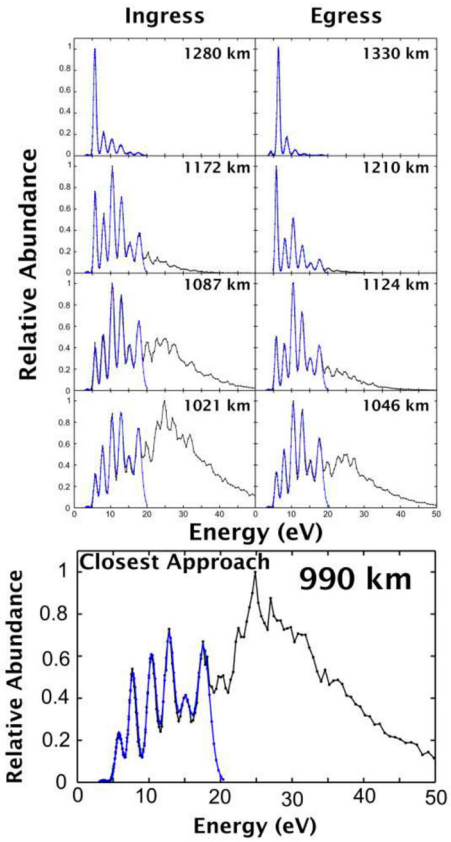


Figure INMS-11. Shown are nine ion mass spectra obtained by the CAPS-IBS instrument at various altitudes during the T26 flyby. The *blue lines* show the INMS data converted using the CAPS-IBS instrument response model.

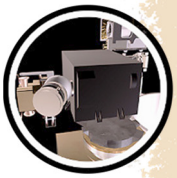

The Cassini INMS measures positive ions with masses up to 100 u. The CAPS-IBS can be used to measure positive ions with much larger masses at lower resolution. The CAPS-IBS measures the energy per charge of incident ions with an energy resolution of 1.4% [Young et al. 2004]. The energy per charge spectrum can be converted to a mass per charge spectrum by fitting the CAPS-IBS and INMS measurements using the spacecraft potential, ion temperature, and crosstrack winds as free parameters [Crary et al. 2009]. The high mass ion densities were found to increase exponentially with altitude down to the lowest observed Cassini altitudes [Crary et al. 2009]. An analysis of the chemical production mechanisms studied by Wilson et al. [2003] was compared to the peak spectrum, and it was found that the most likely compounds were aromatic in character. This further supports that aromatic chemistry is efficient in Titan's ionosphere, and that it is likely to proceed past benzene.

Westlake et al. [2014b] analyzed the T57 flyby in detail between the CAPS and INMS observations to determine the characteristics of the processes responsible for the production and loss of the large hydrocarbons observed at Titan. Altitude profiles (Figure INMS-12) of heavy ions

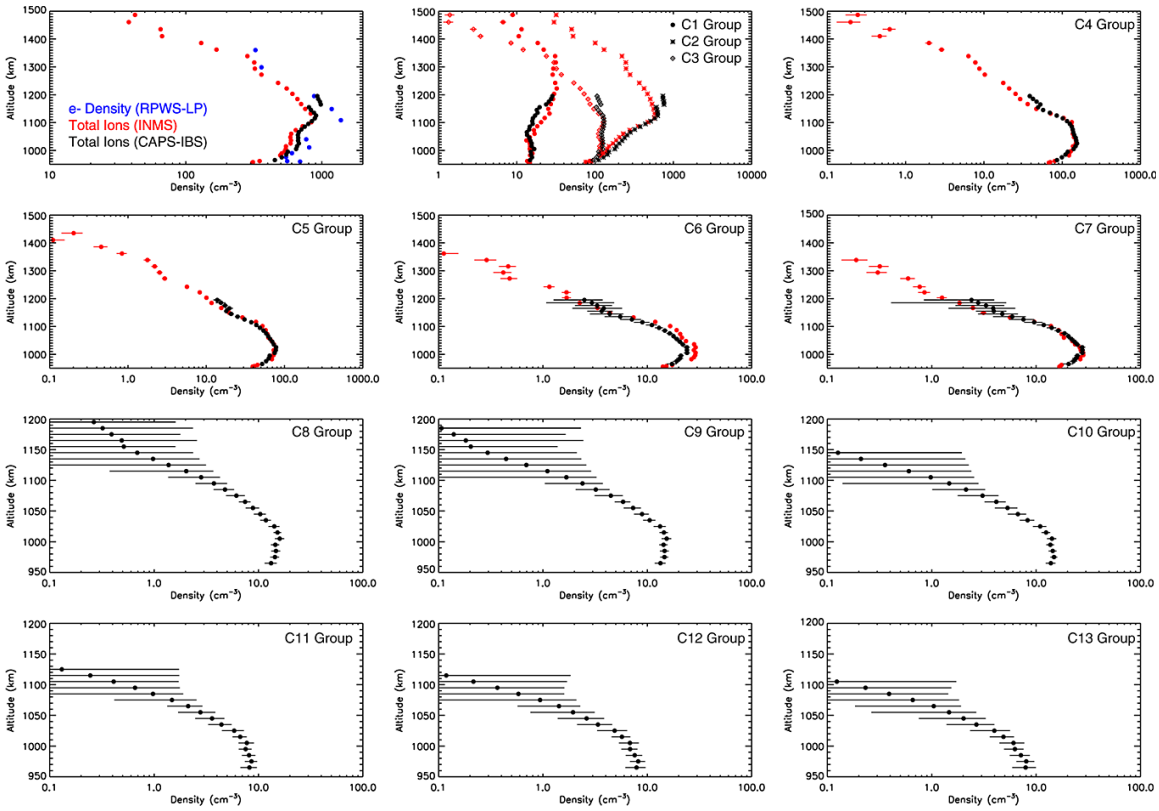

Figure INMS-12. Hydrocarbon group densities from the C1 to the C13 groups for the T57 flyby. A group density is simply the integrated density between the minima in the mass spectrum. The labeling using carbon number (C_i) indicates the number of heavy atoms (carbon, nitrogen, oxygen, etc.) expected within this mass grouping. The *black points* represent CAPS-IBS data, the *red points* give the INMS data, and the *blue points* give the RPWS-LP total electron density. The CAPS-IBS data are both summed within carbon groups and 10 km height bins. The *error bars* in the CAPS-IBS and INMS data represent the statistical counting errors.

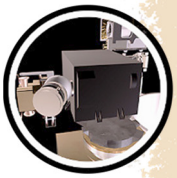

from the C6–C13 group (C_i indicates the number, i, of heavy atoms in the molecule) using a CAPS-IBS/INMS cross calibration reveal structure that indicates a region of initial formation and growth at altitudes below 1200 km followed by a stagnation and dropoff at the lowest altitudes (1050 km). Westlake et al. [2014b] suggested that an ion-molecule reaction pathway could be responsible for the production of the heavy ions, namely reactions that utilize abundant building blocks such as C_2H_2 and C_2H_4, which have been shown to be energetically favorable and that have already been identified as ion growth patterns for the lighter ions detected by the INMS. This growth scenario, in contrast with alternative growth scenarios, has implications for the densities of the source heavy neutrals in each scenario. Westlake et al. (2014b) showed that the high-mass ion density profiles are consistent with ion-molecule reactions as the primary mechanism for large ion growth and derived a production rate for benzene from electron recombination of $C_6H_7^+$ of 2.4×10^{-16} g cm^{-2} s^{-1} and a total production rate for large molecules of 7.1×10^{-16} g cm^{-2} s^{-1}.

Magnetosphere – Titan Interactions Science

The INMS and other Cassini instruments including RPWS, Magnetospheric Imaging Instrument (MIMI), CAPS, and Magnetometer (MAG) provided data, that with associated modeling (including global magneto-hydrodynamic (MHD) and hybrid models) has increased our understanding of Titan's plasma interaction with Saturn's magnetosphere and, rarely, with the solar wind plasma [Ledvina et al. 2012a, 2012b; Ulusen et al. 2010, 2012]. As alluded to earlier, the precipitation of energetic particles can lead to the ionization and heating of the neutral atmosphere. The pressure (thermal and magnetic) of the external plasma affects the dynamics [Cui et al. 2010; Cravens et al. 2010] and energetics [Richard et al. 2011; Vigren et al. 2013] of the ionosphere. Magnetic fields are induced in the ionosphere by this interaction, which then acts to help constrain and control the plasma motion. Put simply, plasma flows in response to magnetic forces and thermal pressure forces. INMS data contributed to our understanding of these processes. For example, INMS measurements show that chemically complex species (e.g., $HCNH^+$) flow out the wake (i.e., downstream of the external magnetospheric flow) of Titan eroding Titan's atmosphere [Westlake et al. 2012a, 2012b].

Data from the open source supra thermals mode from Titan showed ions escaping from Titan. In this mode, we tuned the quadrupole switching lens to look for ions with velocities above the spacecraft ram velocity. We fine-tuned these sweeps to look for ions of mass 2, 15, 16, 17, 28, 29, and 30 to characterize Titan's ion outflow and determine the actual velocity of these ions, looking for changes in their apparent temperature, understanding their spatial distribution, looking for acceleration mechanisms, and understanding the instrument response. We have included a Figure INMS-13 that shows these observations for several ions during the T100 flyby.

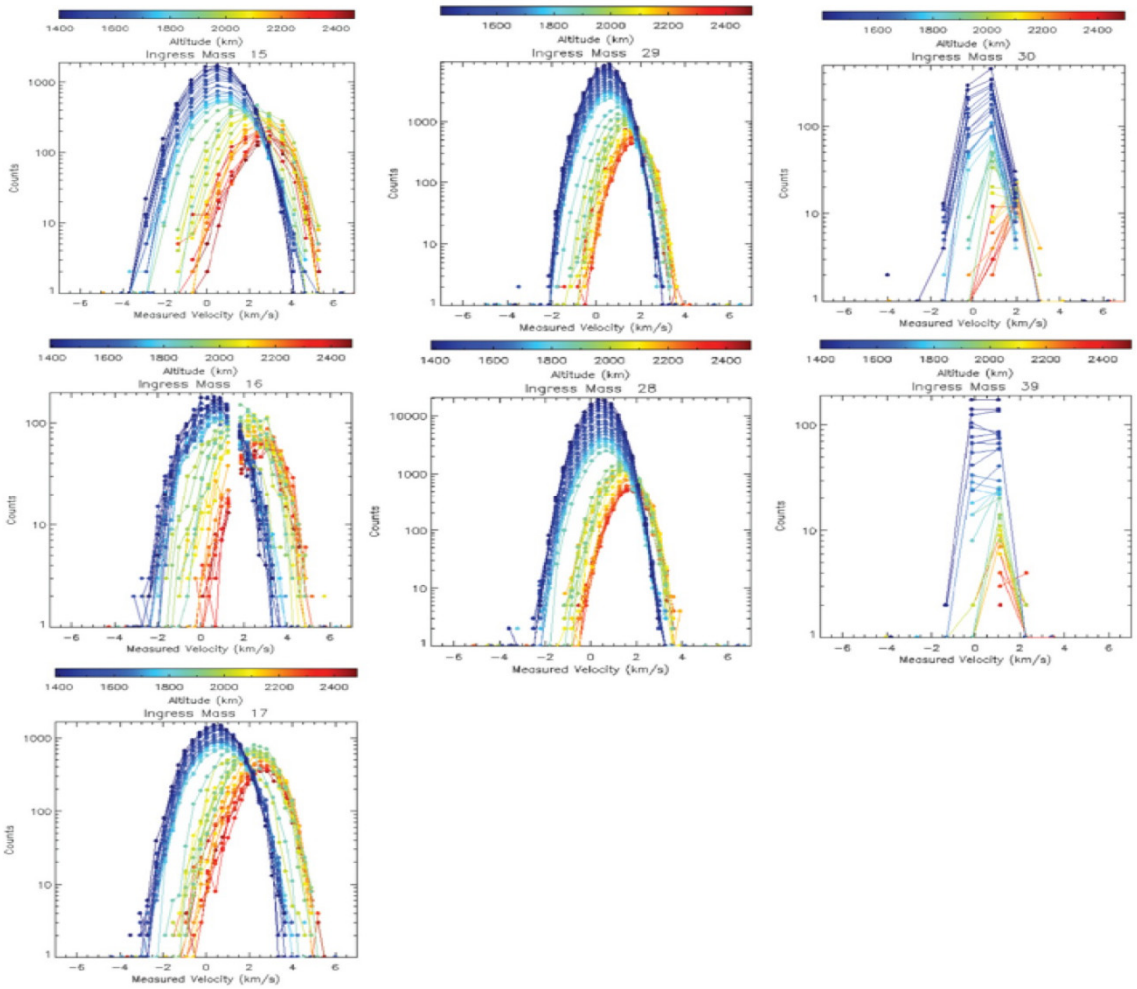

Figure INMS-13. INMS ion measurements from the T100 flyby.

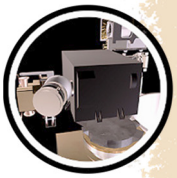
Titan open questions

1. INMS discovered a new regime for organic chemistry in the solar system in Titan's upper atmosphere. Observations indicated the presence of large organic molecules with masses greater than 100 u. This could include biological precursors such as amino acids and nucleotide bases, but the mass range and resolution were insufficient for unique identifications. Thus, detailed knowledge of the organic composition, including the extent of nitrogen incorporation into the large organic molecules, and the associated chemistry remains an open question.

2. INMS found that the thermal structure of Titan's upper atmosphere was highly variable both in space and time. The mean temperature is ~150 K but pass-to-pass variability can be as large as 50 K and there may be long term trends. The variability has been poorly characterized and the cause of the variability has not been



definitively identified. The high level of variability has stymied studies of the dynamics of Titan's upper atmosphere.

3. We have numerous examples of the effect of Titan's interaction with Saturn's magnetosphere on the structure of Titan's upper atmosphere, but insufficient data to thoroughly characterize the interaction.

    a. Why is there no Titan torus about Saturn?

    b. What is the energetic ion environment along Titan's orbit?

    c. How do the upstream plasma conditions affect Titan?

    d. What is the energy and momentum deposited into Titan's atmosphere as a result of the different bulk plasma conditions?

    e. What effect do the deposition of energetic ions have on Titan's atmosphere and its plasma interaction?

    f. How do the different upstream plasma conditions affect ion loss from Titan?

    g. How do the answers to these questions vary along Titan's orbit about Saturn?

    h. How does re-configurations of Saturn's magnetosphere effect Titan's plasma interaction?

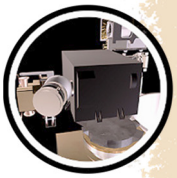
    i. How does Titan respond to changes in the upstream conditions and how long does it take those changes to occur?

    j. What role do negative ions play in each of these situations?

4. INMS measured the structure of Titan's ionosphere but a factor of 2–3 disagreement between the observed and modeled electron densities has not yet been fully resolved. What explains the difference between the modeled ionospheric electron densities and the observed ionospheric electron densities? Is there a missing loss process? Are new recombination rates needed? Might ion transport be an answer?

5. There is evidence for both in situ ionization on the nightside of Titan and transport of ions from the dayside, but the relative contributions and characteristics of these two sources remain an open question.

6. How does the coupled neutral and ion dynamics in the ionosphere affect the magnetic structure that is observed? In fact, ionospheric dynamics at Titan was not well-described with Cassini data.



7. The variability of major gasses in the upper atmosphere as a response to solar input? Are there differing variations across species?

8. What are the large volatiles in Titan's upper atmosphere and how are they created?

    a. What is the extent of nitrogen in the larger organic compounds?

    b. What is the relative importance of day/night transport and in situ ion production on the nightside ionosphere?

    c. What is the role of day to night transfer in maintaining the ionosphere.

9. How does the system change with the solar cycle?

10. How does the system change throughout the Saturn year?

11. What are the boundary conditions at Titan? Is there a subsurface ocean and could it be detectable from the Cassini data?

12. What controls the magnetic field signatures below 1200 km? What role does the ionosphere and atmosphere play?

    a. How does the magnetic field topology around Titan and in its ionosphere effect ion and electron transport within Titan's ionosphere and linking them to Saturn's magnetosphere?

    b. What is the role of the Hall and Pederson conductivities in controlling Titan's ionospheric dynamo region? What role do the resulting ion and electron current have in heating Titan's ionosphere/atmosphere?

    c. What are the time constants of the remnant magnetic fields in Titan's ionosphere?

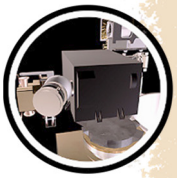
    d. How might atmospheric processes (such as gravity waves) effect Titan's ionosphere and its' resulting plasma interaction?

    e. What is the day to night ion transport rate in the ionosphere?

    f. How do the above processes affect the ion loss rate from Titan?

    g. What happens during morning energetic neutral atom (ENA) storms?

    h. Why is there no Titan torus about Saturn?



Enceladus Science

The initial INMS planning considered Enceladus as another small icy satellite albeit of some additional interest due to the fact that it was embedded in the E-ring. This perception soon changed. The Cassini MAG measurements on the first flyby of Enceladus redirected flyby E2 close to the satellite and thus began the important compositional exploration of Enceladus by INMS that culminated in a startling assessment that the internal global ocean was habitable; there was food for the microbes.

The first close flyby of Enceladus with a ram pointing orientation for INMS occurred on the July 14, 2005 when Cassini passed within 168.2 km of the flank of Enceladus. The presence of water vapor emanating from the south polar cap was noted over 4000 km before the encounter. Water, carbon dioxide, methane, and a mass 28 compound (carbon dioxide and molecular nitrogen were suggested) were observed during the flyby. Trace detections of ammonia, acetylene, and propane were noted. Figure INMS-14 shows a reproduction of the integrated mass spectra during the E2 flyby (~8 km/s relative velocity) taken from Waite et al. [2006], Figure 2.

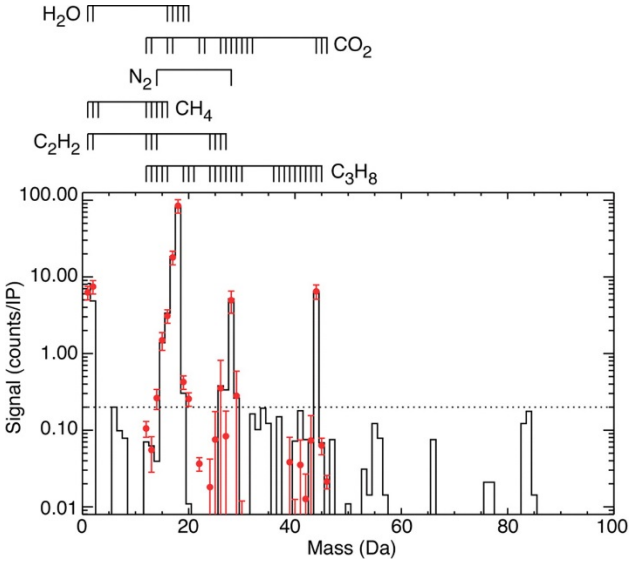


Figure INMS-14. Average mass spectrum for altitudes below 500 km. (Reproduced from Waite et al. [2006], Figure 2). The solid *black line* indicates the measured average spectrum and the *red symbols* represent the reconstructed spectrum. The *error bars* displayed are the larger of the 20% calibration uncertainty or the 1σ statistical uncertainty. The *dotted line* is indicative of the 1σ noise level. The dissociative ionization products produced by the electron ionization source for each constituent are also shown in the figure. Legend: Da = Daltons; IP = integration period.

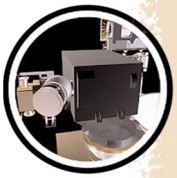
Enceladus highlights

1. Determination of the major composition of the Enceladus plume gas.

2. Measurement of the deuterium/hydrogen ratio of water in the Enceladus plume.



3. Discovery of organic molecules in the Enceladus plume. From fragmentation we know that there are large organic molecules.

4. Discovery of molecular hydrogen in the Enceladus plume.

5. Dynamics of the plume—speed of the gas measured with the open source and more evidence of it with the closed source. Also, angular structure told us about the dynamics. See very narrow jets that suggest that some jets have very high-Mach numbers.

6. Discovery of grains in an intermediate size range between CDA and CAPS.

7. The ion composition measured in Enceladus's plume by INMS confirms the strong interaction between the plume and the external Saturnian magnetosphere and was strongly dominated by H_3O^+.

Velocity-dependent mass spectra and impact fragments

The next major milestone occurred during the E5 flyby that occurred at a much higher relative velocity of ~18 km/s, approached from the Northern hemisphere and flyout along the south polar axis. This produced the highest signal to noise mass spectra of Enceladus of the entire mission due to the long outbound duration in the plume. The integrated mass spectra in Figure INMS-15 (reproduced from Waite et al. [2009], Figure 1) shows a much more complex spectrum extending out to the limits of the INMS mass range (99 u).

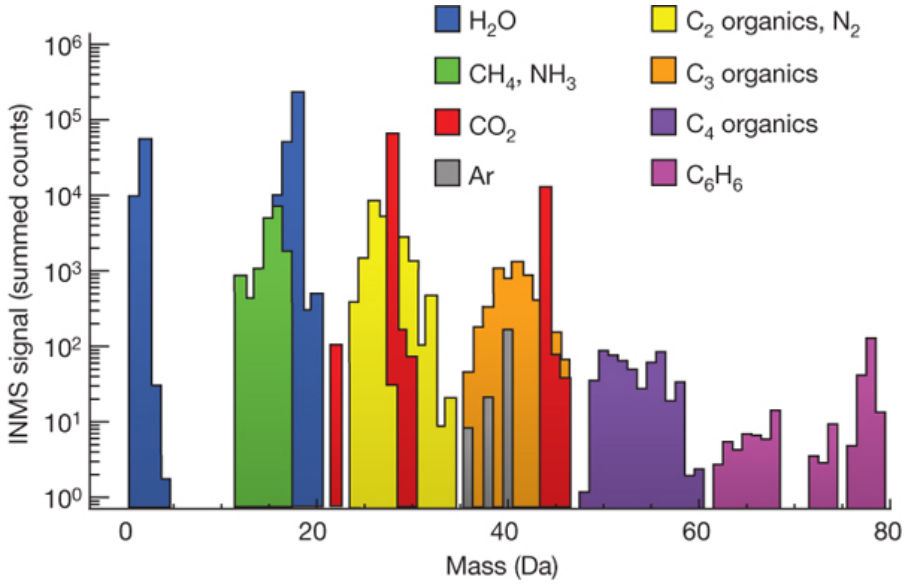


Figure INMS-15. A complex spectrum extending out to the limits of the INMS mass range (99 u). From Waite et al. [2009], Figure 1.

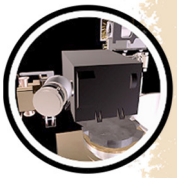

A mass deconvolution of the E5 integrated mass spectra is given in Table INMS-3 indicating a host of complex organic compounds, as well as, the compounds previously cited on flyby E2: water, carbon dioxide, methane, mass 28, ammonia, acetylene, and propane. Of particular note was that water seems to be converted into molecular hydrogen and some other compounds abundance altered due to the high flyby speed. This conversion was interpreted and later verified [Walker et al. 2015] as due to raw titanium vapor from ice grain impacts reacting with water to form TiO and TiO_2 and leaving behind the H_2. The serendipitous side effect of this reaction allowed the INMS team to determine the D/H ratio in water from Enceladus, which was found to be similar to comet Halley ($2.9\ (+1.5/-0.7) \times 10^{-4}$) suggesting that Enceladus had never come into chemical equilibrium with the protoplanetary nebula of Saturn otherwise the ratio would have been much closer to the protoplanetary value of 2×10^{-5}.

The first INMS measurements of the plume's composition were made in the plume's outer edge on July 15, 2005 (E2 encounter), and revealed that the plume consists predominantly of water vapor, with small amounts of carbon dioxide, methane, a species of mass 28, and trace quantities of acetylene and propane. During the October 9, 2008 (E5) encounter, favorable spacecraft pointing and the high spacecraft velocity relative to Enceladus significantly increased the neutral gas density in the closed source antechamber. This density enhancement, together with the proximity of the measurements to the center of the plume, enabled a considerably improved signal-to-noise ratio compared with that obtained during the earlier four encounters. (The y-axis shows counts summed over the period of plume influence.) With their higher signal-to-noise ratio, the E5 measurements provide the first clear evidence of the presence of higher-order (C_4^+) hydrocarbons in the plume, including benzene, and allow the tentative identification of individual species within each hydrocarbon group and of other organics, such as methanol and formaldehyde (Table INMS-3). As described in the Supplementary Information of Waite et al. [2009], interpretation of the INMS spectra requires careful deconvolution of a complex pattern of mass peaks representing both parent species and dissociative ionization products. Fractionation by energetic impact as well as interaction of the gas with the titanium antechamber walls must also be taken into account. Owing to the low mass resolution of INMS, overlapping mass peaks cannot in a number of cases be uniquely separated, resulting in some ambiguity in the interpretation of the data.

The mixing ratios shown for CO and H_2 (values in parenthesis) are included in the mixing ratios for H_2O and CO_2 (first two rows). Analysis of the data from all five encounters shows that the ratios of mass 44 (CO_2) to mass 28, and mass 18 (H_2O) to mass 2 (H_2) decrease with increasing spacecraft velocity, suggesting that H_2 and CO are produced by the dissociation of H_2O and CO_2 through hypervelocity impact on (and reaction with) the walls of the INMS antechamber, see supplementary information of Waite et al. [2009]. We estimate that 40–80% of the signal in mass channel 28 is due to CO produced in this way. A small contribution of CO from Enceladus is also possible, but cannot be distinguished from the dissociation product. The residual mass 28 signal is attributed to N_2, C_2H_4, or a combination of both, with either HCN or the ethene dissociation product C_2H_3 contributing to the signal in mass channel 27. The values given for these species are upper limits based on the two alternative scenarios (N_2 + HCN versus C_2H_4). Neither scenario can be given preference over the other on the basis of the present INMS data set.

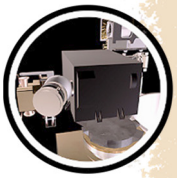

Table INMS-3. With higher signal-to-noise ratio, E5 measurements provide the first clear evidence of the presence of higher-order hydrocarbons in the plume, including benzene, and allow the tentative identification of individual species within each hydrocarbon group and of other organics. From Waite et al. [2009], Table 1.

Species	Volume Mixing Ratio
H_2O	0.90 ±0.01
CO_2	0.053 ±0.001
CO	(0.044)
H_2	(0.39)
H_2CO	$(3.1 \pm 1) \times 10^{-3}$
CH_3OH	$(1.5 \pm 0.6) \times 10^{-4}$
C_2H_4O	$< 7.0 \times 10^{-4}$
C_2H_6O	$< 3.0 \times 10^{-4}$
H_2S	$(2.1 \pm 1) \times 10^{-5}$
^{40}Ar	$(3.1 \pm 0.3) \times 10^{-4}$
NH_3	$(8.2 \pm 0.2) \times 10^{-3}$
N_2	< 0.011
HCN†	$< 7.4 \times 10^{-3}$
CH_4	$(9.1 \pm 0.5) \times 10^{-3}$
C_2H_2	$(3.3 \pm 2) \times 10^{-3}$
C_2H_4	< 0.012
C_2H_6	$< 1.7 \times 10^{-3}$
C_3H_4	$< 1.1 \times 10^{-4}$
C_3H_6	$(1.4 \pm 0.3) \times 10^{-3}$
C_3H_8	$< 1.4 \times 10^{-3}$
C_4H_2	$(3.7 \pm 0.8) \times 10^{-5}$
C_4H_4	$(1.5 \pm 0.6) \times 10^{-5}$
C_4H_6	$(5.7 \pm 3) \times 10^{-5}$
C_4H_8	$(2.3 \pm 0.3) \times 10^{-4}$
C_4H_{10}	$< 7.2 \times 10^{-4}$
C_5H_6	$< 2.7 \times 10^{-6}$
C_5H_{12}	$< 6.2 \times 10^{-5}$
C_6H_6	$(8.1 \pm 1) \times 10^{-5}$

Later, subsequent orbits at relative flyby velocities of < 8 km/s E14, E17, and E18 also helped establish that much of the organic content beyond the C_3 (> mass 40 u) were likely fragments of a heavier organic compound CDA identified in E-ring ice grains. This is the subject of a paper in Science [Postberg et al. 2018]. Figure INMS-16 shows the differences of the combined E14, E17, and E18 relative to the E5 spectra.

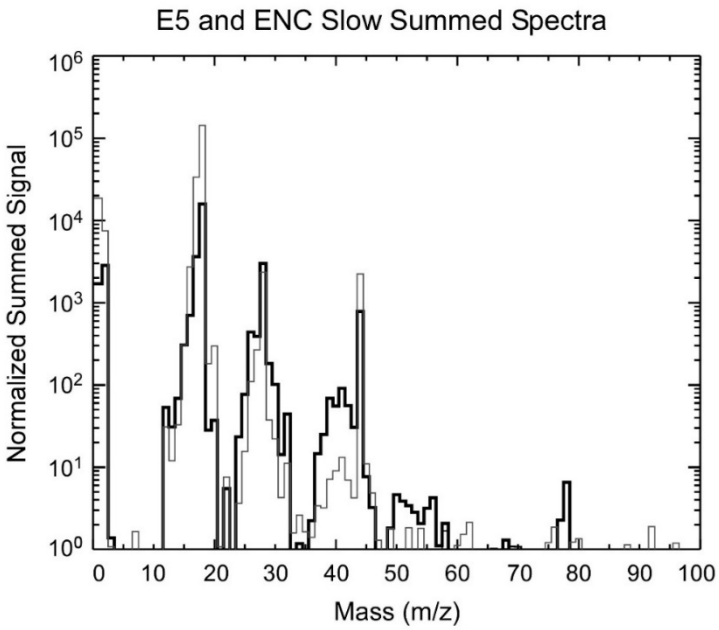

Figure INMS-16. The effects of impact fragmentation of organics within the ice grains and the effect of Titanium vapor on the water signal can be seen in this comparison mass spectra. The E5 spectra are the bold lines, and the summed E14, E17, and E18 spectra are the light lines. The normalization is performed by setting the spectra equal at mass 15 u.

The composition of plume vapor

The data obtained during the E14, E17, and E18 flybys all at relative flyby speeds of 7–8 km/s and all along or in parallel tracks near the Baghdad tiger stripe provide a consistent and repeatable depiction of the mass spectra at relative speeds low enough that fragmentation effects are minimized. These spectra are shown in Figure INMS-17. The spectra above 50 u (not shown) were near the noise level and further reinforce the point that the relative speeds above 8 km/s can lead to significant fragmentation of heavy organics buried in ice grains that complicate the interpretation of the mass spectra from E3 (~14 km/s) and E5 (~18 km/s). One can mass deconvolve the combined spectra from the slower flybys (E14, E17, and E18). The detailed analysis of this data set is the subject of Magee and Waite [2017]. A preliminary deconvolution is shown in Table INMS-4 taken from Magee and Waite [2017].

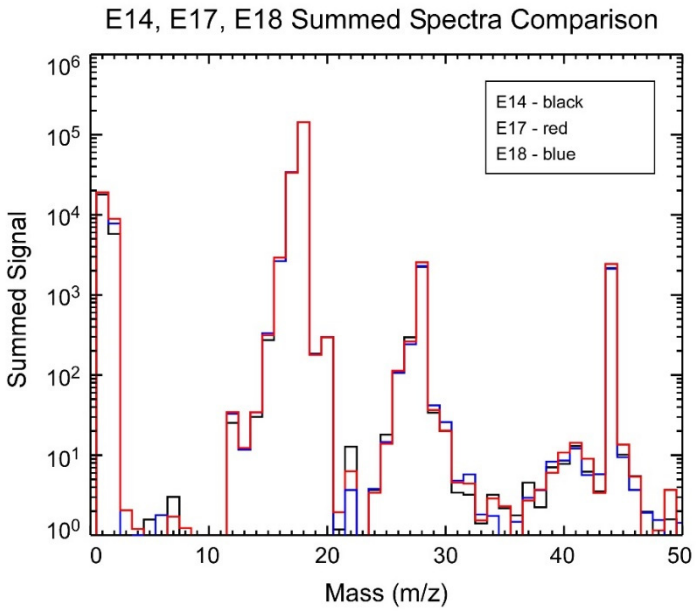

Figure INMS-17. Overlaid mass spectra for flybys E14, E17, and E18. Note the consistency of the spectra.

Table INMS-4. Preliminary mass deconvolution of mass spectra from E14, E17, and E18.

Minor Species I	Minor Species II				
Moderate Ambiguity	High Ambiguity				
< 0.2% and > 100 ppm	< 100 ppm				
	Hydrocarbons	**N-bearing**	**O-bearing**	**NO-bearing**	**Others**
C_2H_2 (26)	C_3H_4 (40)	CH_5N (31)	O_2 (32)	C_2H_7NO (61)	H_2S (34)
HCN (27)	C_3H_6 (42)	C_2H_3N (41)	CH_3OH (32)	$C_2H_5NO_2$ (75)	PH_3 (34)
C_2H_4 (28)	C_3H_8 (44)	C_2H_7N (45)	C_2H_2O (42)	$C_3H_7NO_2$ (89)	Ar (36, 38, 40)
CO (28)	C_4H_8 (56)	$C_2H_6N_2$ (58)	C_2H_4O (44)		C_3H_5Cl (76)

			$C_2H_6O_2$ (62)		
			$C_4H_{10}O$ (74)		
			$C_4H_6O_2$ (86)		

INMS measurement of ice-grain composition

Another serendipitous data product that INMS obtained from the Enceladus plume was a record of the ice grain composition. When an ice grain impacted the antechamber, a burst of material passed through the instrument creating a spike in the data [Perry et al. 2015; Teolis et al. 2010b]. Since

material flowed through the instrument in 2–3 milliseconds, these bursts occurred within one sampling period (i.e., one mass step), which had a dwell time of 31 milliseconds. Compiling the spikes from the E14, E17, and E18 data sets produces a mass spectrum of the portion of the ice grain material that does not chemically interact with the walls of the antechamber. This spectrum is shown in Figure INMS-18 (reproduced from Postberg et al. [2018], Figure 10).

The ice grain spectrum is related but distinct from the spectrum of the plume vapor. If present, C_2H_4 is limited to less than approximately 6% of the 28-u signal, and N_2 has an upper limit of approximately 10% due to the low signal at 14 u. This leaves a requirement for CO as the dominant species at 28 u, which matches well the signal at 12 u and 14 u (C^+ and CO^{++} dissociative peaks). Acetonitrile (C_2H_3N) also appears to be present. The signal pattern of 39–42 u suggests a species with its highest signal peak at 41 u and lower signal in the surrounding masses. C_2H_3N is the best candidate as it matches this stairstep pattern.

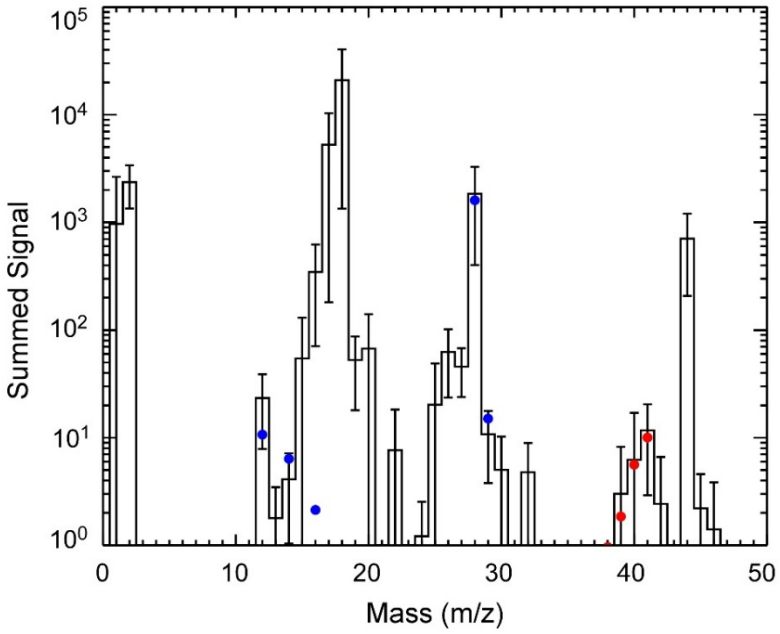

Figure INMS-18. Co-added INMS ice grain spike spectrum from three plume encounters. *Error bars* are derived from the dispersion of the count rate from the three encounters. The spectrum proves the presence of CO fragments (*blue circles*) as an oxygen bearing species: N_2 has very low abundance and contributes < ~10% of the 28 u signal. CO_2 and C_2H_4 collectively contribute < ~10% of the 28 u signal. CO (*blue circles*) is required to fit the rest of the 28 u signal and matches its other dissociative peaks well. The spectrum also indicates the presence of nitrogen bearing species: the stairstep pattern around 41 u matches best to the C_2H_3N spectrum (*red circles*). From Postberg et al. [2018], Figure 10.

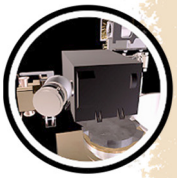
Velocity of plume vapor

During four Enceladus encounters between November 2009 and October 2015, INMS operated in its seldom-used OSNB mode. In the OSNB mode, INMS makes direct measurement of the



velocities of the neutrals. Although the velocity data from OSNB measurements are coarse, they provide strong constraints on the speed distribution of H_2O molecules within and surrounding the plumes.

In the OSNB mode, the velocity of the neutrals measured by INMS are determined by the angle of the INMS boresight, which sets the direction of the molecules, and the INMS compensation velocity parameter (V_{COMP}), which sets the speed of the molecules. The vector addition of this velocity with Cassini's velocity provides the neutrals' velocity relative to Enceladus. During E8, E11, and E16, V_{COMP} was fixed, but Cassini rotated so that INMS scanned the velocity of neutrals. (E21 operations were different: Cassini's attitude was fixed and V_{COMP} was scanned throughout the encounter to purposely sample the velocity distribution of the plume multiple times.) For each encounter, Cassini's rotation produced a single velocity scan, where the measured molecules had velocities that were radial from Enceladus with speeds increasing from 0 to 2 km/s. Figure INMS-19 shows the results of the velocity scan for E8. The fitted shape peaks at 1.25 km/s, but reduces to 1.1 ±0.2 after correction for INMS pointing calibration. The width of 300 m/s corresponds to a temperature of 65 K, which is similar to the low temperatures predicted by the models of Yeoh et al. [2015].

The ultimate velocity of adiabatic expansion for water at its triple point reflects the energy available per molecule of H_2O and is equivalent to 1.0 km/s, which is within the uncertainty of the measurement for the bulk velocity of E8. These results are reconciled with a previous higher-velocity estimate due to the modeling that shows the observed high-Mach jets have lower temperatures than previously assumed. INMS measured molecules leaving Enceladus at both high and low velocities.

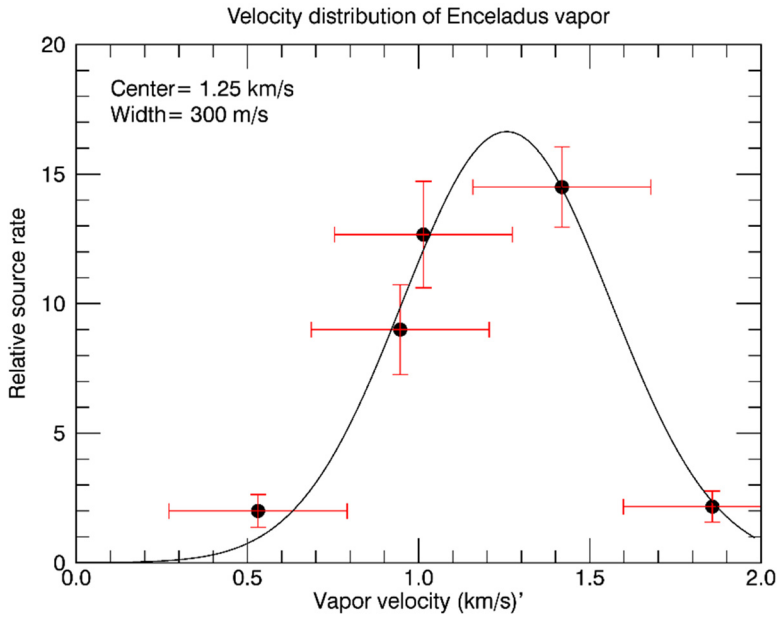


Figure INMS-19. Results of the E8 OSNB velocity scan. After adjustment for pointing calibration, the distribution peaks at ±0.2 km/s.

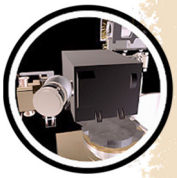

The measurements from the other OSNB encounters show a range of speeds that reflect the different environments surrounding Enceladus (Figure INMS-20).

- E8 had the highest velocities, and was sampling the strong jets.
- E11 velocities are slower and may represent the broader plume, outside of the dense, fast jets. E11 velocities are also consistent with early modeling of data from the higher-altitude encounters where the jets had merged with lower-velocity sources such as the tiger stripes, and the broad distribution of E11 may indicate a combination of multiple sources.
- E16 measured the neutral cloud that surrounds Enceladus and is fed by the plumes.

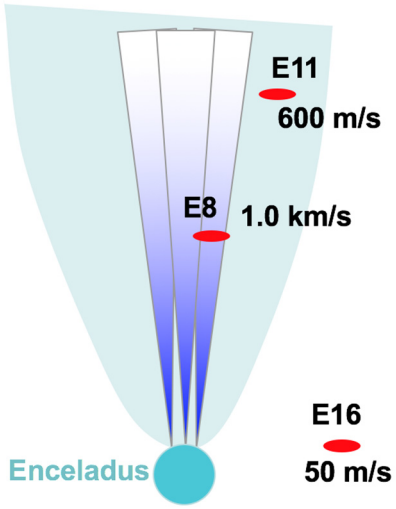

Figure INMS-20. The vertical speed of H_2O molecules measured during the E8, E11, and E16 encounters, showing several different velocity regimes.

The vapor-density structure of the Enceladus plumes

During six encounters between 2008 and 2013, the Cassini INMS made in situ measurements deep within the Enceladus plumes (Table INMS-5). Throughout each encounter, those measurements showed density variations that reflected the nature of the source, particularly of the high-velocity jets. Since the dominant constituent of the vapor, H_2O, interacted with the walls of the INMS inlet, changes in the external vapor density are tracked by using more-volatile species that responded promptly to those changes. To understand the plumes requires examination of each of the three components of Enceladus ejecta, fast and dense jets, slower diffuse gas, and ice grains.

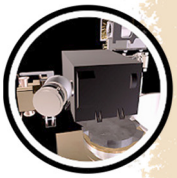

Table INMS-5. Information on the Enceladus encounters with the best INMS data. Perry et al. [2015] contains plume-structure data for the six un-shaded encounters. The last three encounters follow nearly identical trajectories but are offset several kilometers from each other.

Encounter	Features
E2	Relatively far from ejected vapor; minimal data useful for plume structure; first INMS identification of H_2O.
E3, E5	Steeply inclined, fast (14, 17 km/s) north-south trajectories, following the plume.
E7	Horizontal, slow pass (7 km/s) at 100 km min altitude, perpendicular to stripes, outbound from Saturn.
E8	Horizontal, slow pass south of Enceladus 1,200 km below the equatorial plane. Includes vapor velocity measurements from OSNB data. Minimal closed source neutral (CSN) data.
E14	Horizontal, slow pass at 100 km, high res, parallel to stripes, inbound to Saturn.
E17	Horizontal, slow pass at 75 km, high res, parallel to stripes, inbound to Saturn.
E18	Horizontal, slow pass at 75 km, high res, parallel to stripes, inbound to Saturn.

When INMS operated in the Closed Source Neutral (CSN) mode, Teolis et al. [2010b] described H_2O adsorption onto the walls of the INMS inlet system and the consequential delayed passage of H_2O through INMS. The delays can be tens of seconds to hours, depending on the amount of water already adsorbed onto the walls, and measurements of H_2O do not represent the conditions at the time and location of the measurement. Molecules with higher volatility respond to external flux in a tenth of an IP, 34 milliseconds, the temporal resolution of INMS [Waite et al. 2004], and these volatile gases (referred to as volatiles) are used to track changes in density.

The ice grains entering the INMS aperture add complexity and uncertainty to the physical interpretation of the data because the grains modified the INMS measurements. On entering the CSN aperture, an ice grain causes a high count or spike for a single measurement. The larger grains cause spikes that mask the gas density, confuse interpretation of INMS measurements, and add uncertainty. Since the resident time for volatiles in the INMS CSN inlet system is 2−3 milliseconds, the grain usually affects the measurement of only one IP.

The size of ice grains spans a range from molecular clusters to several microns in radius [Spahn et al. 2006; Jones et al. 2009; Coates et al. 2010]. Only grains that cause count rates much larger than the neighboring measurements can be clearly identified, and these were removed from the vapor-density data. Slightly smaller grains can cause two types of ambiguity in the INMS measurement: small spikes may be misinterpreted as local increases in vapor density, and rapid density variations may be misinterpreted as grain spikes. Grains that are still smaller cannot individually cause a noticeable change in count rate, but nanometer-scale grains are so plentiful that many enter the INMS aperture during a single IP, and these combine to create a background. Figure INMS-21 shows an example of INMS data with ice-grains spikes removed.

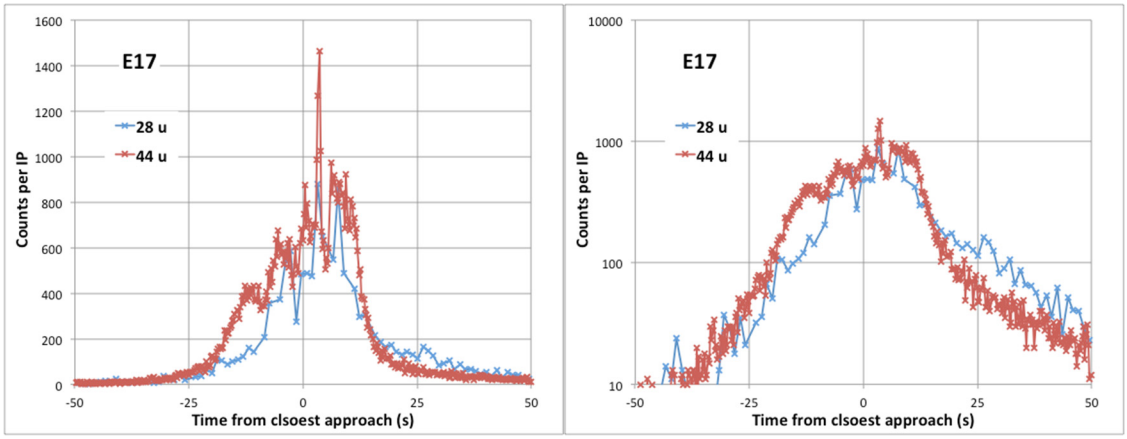

Figure INMS-21. Linear and log-plot profiles for the E17 Enceladus encounters. (Perry et al. [2015] has the profiles for all Enceladus encounters before 2016 with structure data.) The plots contain count rates for species with masses of 28 u and 44 u. Measurements that were clearly affected by ice grains have been removed.

For molecules emitted at the same supersonic velocity and in thermal equilibrium with each other at the time they are emitted, the cone angle or spreading of the molecules depends on mass (Figure INMS-22). This behavior causes differences in spatial composition that are measured by INMS and are independent of variations in source composition. Depending on the temperature, bulk velocity and mass, spreading angles vary from 10 to 45 degrees for Mach numbers from 1 to higher than 5, see Teolis et al. [2017].

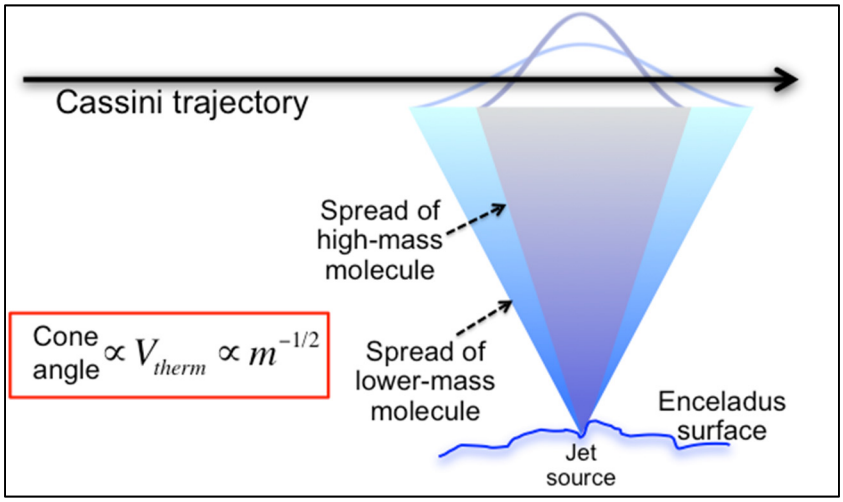

Figure INMS-22. Illustration of the mass-dependent behavior of high-velocity molecules emitted by the jets.

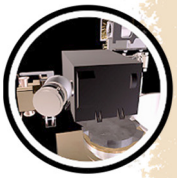
Based on ground [Waite et al. 2004] and flight calibration at Titan [Teolis et al. 2015], each INMS count during E7, E14, E17, and E18, corresponds to 2,100 molecules/cm^3 for the 28 u mass channel and 1,500 molecules/cm^3 for the 44 u channel (25% uncertainty). For E3 and E5, which had higher velocities, the calibration factors are 890 and 660 molecules/cm^3 for 28 u and 44 u



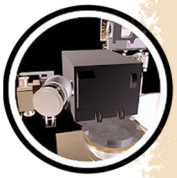
channels, respectively. Since high-velocity fragmentation products of molecules with masses greater than 100 u increase the counts of lower masses, E3 and E5 counts are higher than they would be without the added molecular fragments. Consequently, the actual 28 u and 44 u densities for E3 and E5 are a factor of two-to-five lower than the values based on the calibration factor provided for E7, E14, E17, and E18 [Teolis et al. 2015].

In lieu of modeling each individual molecule separately to account for mass-dependent behavior, the total-count ratios between the 18 u mass channel and the volatile masses provide an approximate density for H_2O. For the later, lower-velocity encounters, the total counts summed over the flyby for the 28 u and 44 u channels were each 0.5 % to 1% of the total 18 u counts after adjusting for the higher measurement frequency of the 44 u channel. At the high velocity of E3 and E5, larger molecules dissociate on impact with the INMS inlet, modifying the measurements for lower masses. This increased the counts for the measured volatiles and the ratio to water counts increased to 2–5% for each species [Teolis et al. 2015].

The vapor plumes show variability that was first reported by Hedman et al. [2013]. A comparison of data from the last three encounters, E14, E17, and E18, are consistent with the Visual and Infrared Imaging Spectrometer (VIMS) observation of variability in jet production and a slower, more diffuse gas flux from the four sulci or tiger stripes. Teolis et al. [2017] used data from all INMS and Ultraviolet Imaging Spectrograph (UVIS) encounters to constrain a time-dependent and high-resolution model of the plumes.

Two-component and multi-component models of INMS plumes

During the final low-altitude flybys of Enceladus, the most abundant, non-sticky species in the plume, CO_2 at 44 u, was sampled at a higher rate, to enable higher-resolution measurements of local density variations along Cassini's trajectory, achieving resolution of 0.25 s temporal and 1.9 km spatial. As shown in Figure INMS-24, CO_2 data from E17 clearly resolved density variations, indicative of gas jets, along Cassini's trajectory. Hurley et al. [2015] suggested on the basis of Monte Carlo models (Figure INMS-23) that the plume source may be continuously distributed, albeit variable, along the tiger stripes. These models included one lower-velocity component for the tiger stripes and a second, higher-velocity component for the jets. The complete plume three-dimensional structure is difficult to uniquely constrain solely on the basis of the few INMS flybys as multiple combinations of jet pointing directions and intensities can fit the data, and temporal variability further increases the potential solutions.



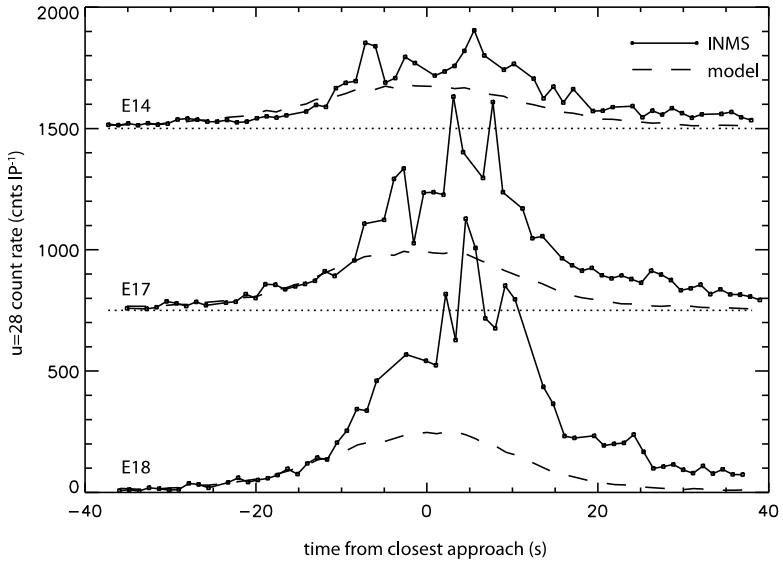


Figure INMS-23. Using the model described in Hurley et al. [2015], the *dashed lines* are simulated count rates with a continuous source along the tiger stripes as the only source of vapor. The temperature (270 K) and velocity (500 m/s) of the emitted tiger-stripe vapor were chosen to fit the rise and fall of the INMS data for mass 28 u. The best fit to the data is for E14, which occurred during a phase that corresponds to lower activity in the jets according to Hedman et al. [2013]. E17 and E18 occurred near Enceladus' apoapsis, when VIMS observed higher ice-grain emissions, and the higher, variable measurements in E17 and E18 may be due to more-active jets.

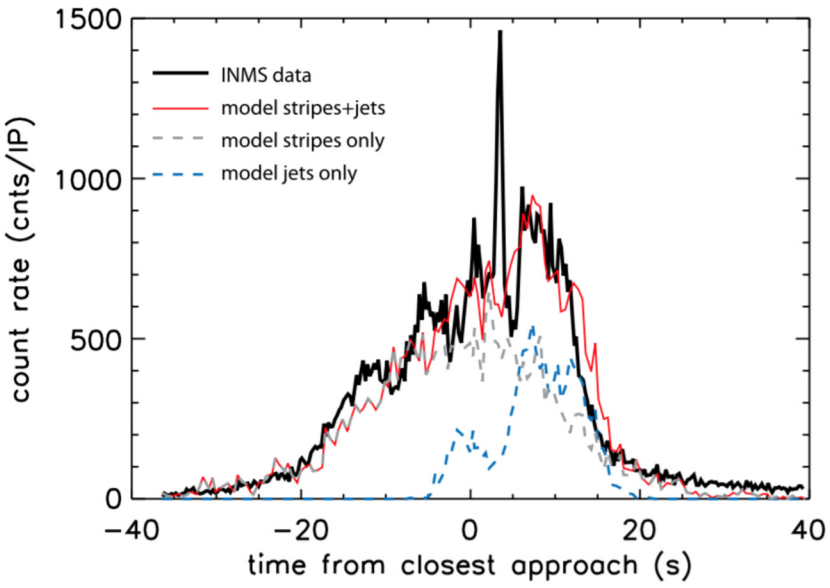

Figure INMS-24. INMS measurements of mass 44 u species during the E17 flyby are shown in *black*. Model [Hurley et al. 2015] predictions using constant emission along the tiger stripes at 500 m/s and 270 K (*gray dashed line*) are selected to match the rise and fall on the outskirts of the plume. The jet model using Mach 4 (1500 m/s and 270 K) are included (*blue dashed line*) to reproduce the overall enhancement near closest approach. The sum of the two models (*red line*) reproduces the overall structure of the plume, but misses some of the fine structure.

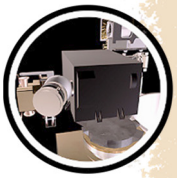
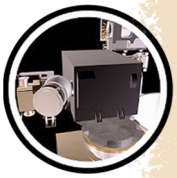


Alternate Enceladus plume structure

During Cassini's close (99, 74, 74 km) E14, E17 and E18 flybys through the Enceladus gas/dust plume on October 1, 2011, March 27, 2012, and April 14, 2012, the INMS measured in situ the detailed spatial structure of the neutral gas along the trajectories. These encounters were the first to fly close enough to the plume sources with the required pointing and sufficient data acquisition rate, to enable resolution of individual gas jets within the broad plume by INMS. During these flybys two INMS objectives were to: 1) constrain the locations, magnitudes and gas velocity from the plume surface sources, and 2) extrapolate the three-dimensional structure of the plume, including the diffuse plume and individual major jets. Since these flybys, the INMS team have carried out detailed plume modeling, combining the along-track densities measured at different times/dates by INMS, with and occultation, surface temperature, and imaging data from UVIS, Composite Infrared Spectrometer (CIRS) and ISS. The goals were to constrain the physics of the jet sources, i.e., the nozzle dimension and gas thermodynamic properties including temperature, density, flow and expansion rate, and provide necessary inputs for future modeling of the plume interaction with the Saturn system, i.e., the E-ring and magnetospheric sources and mass loading.

The results of our studies are now published in the papers by Perry et al. [2015] and Teolis et al. [2017]. Teolis et al. [2017] describes a detailed comparison of several plume source scenarios. The findings indicate that a time variable source, consisting of a source continuously (but non-uniformly) distributed along the tiger stripes, and sharp gas jets as inferred from ISS data [Porco et al. 2014], provide the best fit to the INMS and UVIS data. Figures INMS-26–INMS-30 compare the results of plume modeling for several different plume source models, considering both a curtain source with upward (normally) directed emission continuously distributed along the tiger stripes, and a source consisting of discrete gas jets with locations and pointing direction matching the grain jets identified by Porco et al. [2014] in ISS data.

In both the curtain and jet cases, the model suggests that a gas source with a Mach number distribution, containing a slow (with thermal velocity, Mach 0) isotropic emission, and a super-sonic (high velocity) component, was required to fit the broad distribution, and the fine structure, respectively, observed in the UVIS/INMS data. The fits use a 4-point Mach number distribution ranging from zero (gas at rest) to 16 (the fast component), as necessary to best fit the shapes of the features in the INMS and UVIS data. The curtain model considered three cases: 1) a uniform emission along the tiger stripes; 2) emission correlated to the tiger stripe temperature from CIRS data (Figure INMS-25); and 3) emission optimized to fit the INMS and UVIS data. For jets, the model considered two cases: 1) jets with equal intensities; and 2) jet intensity optimized to fit the data. The optimized models typically give multiple solutions, corresponding to reductions/enhancements in different combinations of jets, or different vapor source distributions along the tiger stripes. Figures INMS-26–INMS-30 show the averages over these solution families to compare and contrast the quality of the fits in the cases of continuous distributed emission and of discrete gas jets. It is clear on the basis of the plots, that neither the thermal plume cases, nor the cases of uniform curtains or jets, provide very good fits to the data. Both optimized curtains and jets yield rough agreement with the data but, as shown in the plots, some features of the data are better matched by the jets. The models could not fit all of the INMS and UVIS data simultaneously



with a unique model solution. Therefore, given the curtain and [Porco et al. 2014], jets as a modeling constraint, an assumption of time variability of plume source distribution and/or individual jets between the Cassini flybys, is required to fit the data. The changes over time of the individual jets appears to be chaotic, exhibiting no obvious correlation to the Enceladus mean anomaly, as seen (for the plume as a whole) in VIMS data [Hedman et al. 2013].

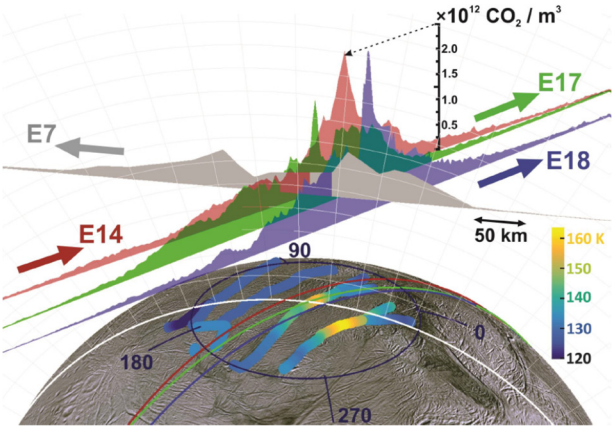


Figure INMS-25. Emission correlated to the tiger stripe temperature from CIRS data. To scale 3-D representation of the E14, E17, E18, and also (lower resolution) E7 INMS data with vertical areas representing (in linear scale) the density, and the flat base of the areas corresponding to the Cassini trajectories. Lines across the surface are the ground tracks. The Tiger stripes are colored according to the temperature estimated by CIRS. Figure from Teolis et al. [2017].

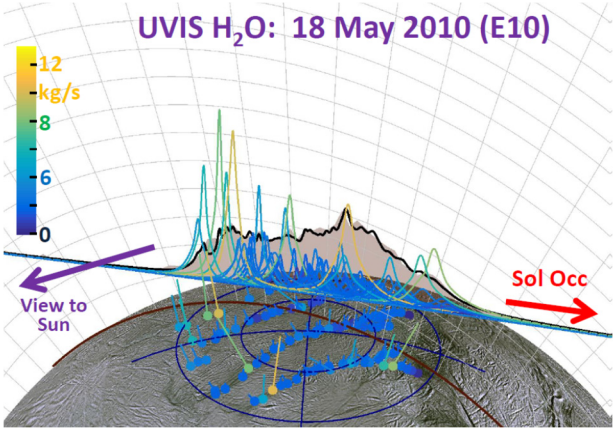

Figure INMS-26. Results of plume modeling. To scale 3-D representation of the 2010 Enceladus plume UVIS Solar Occultation with vertical areas representing (in linear scale) the occulted intensity fraction (corresponding to the water vapor column density), and the flat base of the area corresponding to the line of minimum ray height (*brown line* on surface is the ground track of this ray). For example, Cassini's viewpoint onto the plume is from the upper right of the figure, and UVIS is scanned from left to right as shown by the *arrow*. *Dots on surface:* [Porco et al. 2014] jet source locations, with *straight lines* showing jet directions. The colors and jet line lengths are given by the optimized jet strength; i.e., *orange* (*blue*), long (short) jets represent high (low) intensity jets. Colored curves: line height from min ray height line gives the estimated column density profile of each jet along the UVIS line of sight. *Black curve:* the best fit total column density of all jets across the UVIS line of sight: the colored curves sum to yield the *black curve*. Figure from Teolis et al. [2017].

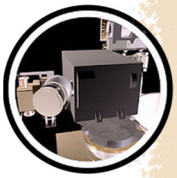

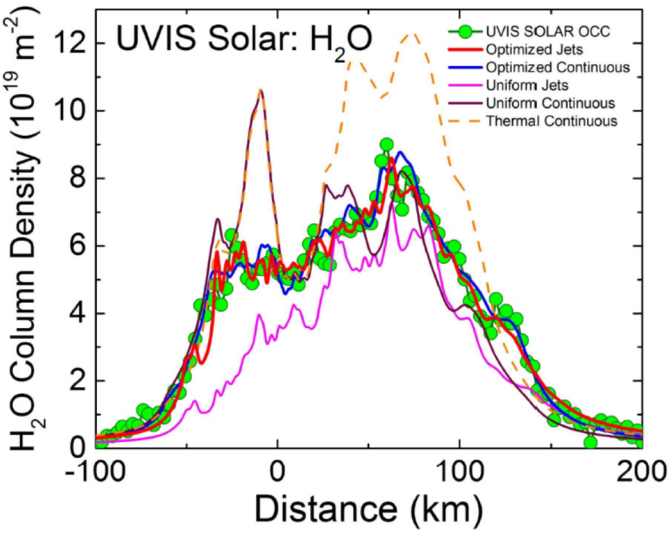

Figure INMS-27. Results of plume modeling. Enceladus plume water vapor column density measurement from the UVIS 2010 solar occultation (*Green circles*), plotted versus distance across the plume along the occultation line of sight minimum ray height. *Red line:* Average model solution for the optimized [Porco et al. 2014] jets. *Blue line:* Average solution for continuous emission along the tiger stripes. *Magenta line:* Jets with equal intensity. *Brown line:* Uniformly distributed continuous emission along the tiger stripes. *Orange dashed line:* Continuous emission with emission strength dependent on tiger stripe temperature (proportional in this example to Tn, with n = 7). Figure from Teolis et al. [2017].

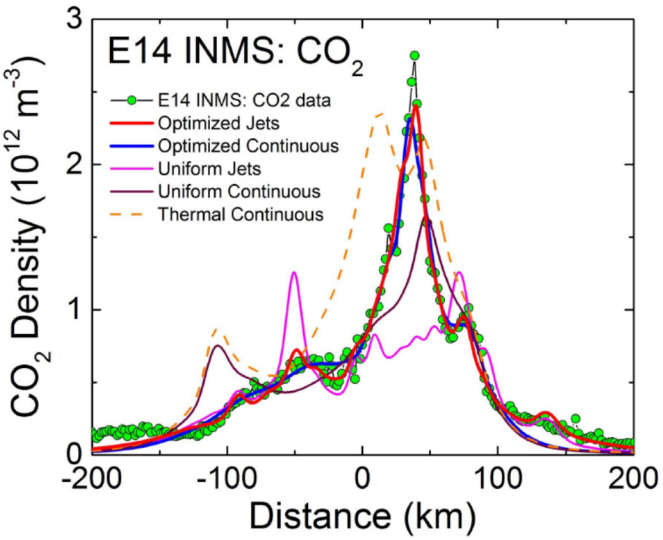

Figure INMS-28. Results of plume modeling. INMS CO_2 density measurement (*Green circles*) along the E14 flyby trajectory showing structure in the plume density along trajectory. *Red line:* Average model solution for the optimized (Porco et al., 2014) jets. *Blue line:* Average solution for continuous emission along the tiger stripes. *Magenta line:* Jets with equal intensity. *Brown line:* Uniformly distributed continuous emission along the tiger stripes. *Orange dashed ine:* Continuous emission with emission strength dependent on tiger stripe temperature. Figure from Teolis et al. (2017).

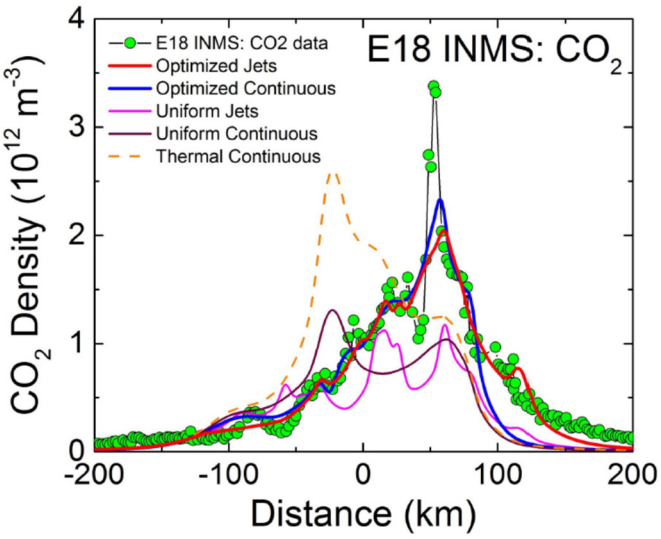

Figure INMS-30. Results of plume modeling. Same as Figures INMS-28 and INMS-29 for the E18 flyby. Figure from Teolis et al. [2017].

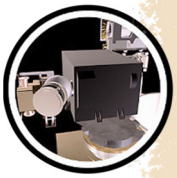
Confirmation of H_2 in the plume vapor and hydrothermal activity

Finally, one of the most important findings of the Cassini mission by INMS was the open source detection of molecular hydrogen within the plume. Previous observations by the closed source had indicated the presence of molecular hydrogen, but were fraught with ambiguity due to the unearthing of fresh titanium from the walls of the antechamber from ice grain impacts as noted in the E5 discussion in the section entitled Velocity-Dependent Mass Spectra and Impact Fragments. E21 used the open source to measure molecular hydrogen and then after a lengthy and careful



study of the instrumental background this result was verified and published in Science [Waite et al. 2017]. Figure INMS-31 data (reproduced from Waite et al. [2017], Figure 2) indicates a two sigma detection of molecular hydrogen in the plume and an indication of the other important minor constituents, see Table INMS-6 (reproduced from Waite et al. [2017] Table1). The important implications of this measurement are shown in Figure INMS-32 (reproduced from Waite et al. [2017], Figure 4), which illustrates that a positive chemical affinity for the reaction that represents methanogenesis in Earth's ocean can be shown to be present on Enceladus. This constitutes evidence that food for microbes is present Enceladus' ocean, the crowning achievement for demonstrating habitability at Enceladus.

Comparison of OSNB measurements of mass 2 (H_2) with the estimated total mass 2 instrumental background

The detected count rates and estimated background rates are plotted (Figure INMS-31) as a function of time from closest approach to Enceladus. The bottom panel of the plot is on a linear scale showing all the data points at or below ten counts. The top panel, plotted on the common log scale, shows the remaining data points that are above ten counts. Data points are color-coded according to the statistical uncertainties and background estimation: **open black circles** - no distinguishable separation from the background signal; **light blue circles** - at least one sigma separation; **dark blue diamonds** - at least two sigma separation; **purple triangles** - at least three sigma separation.

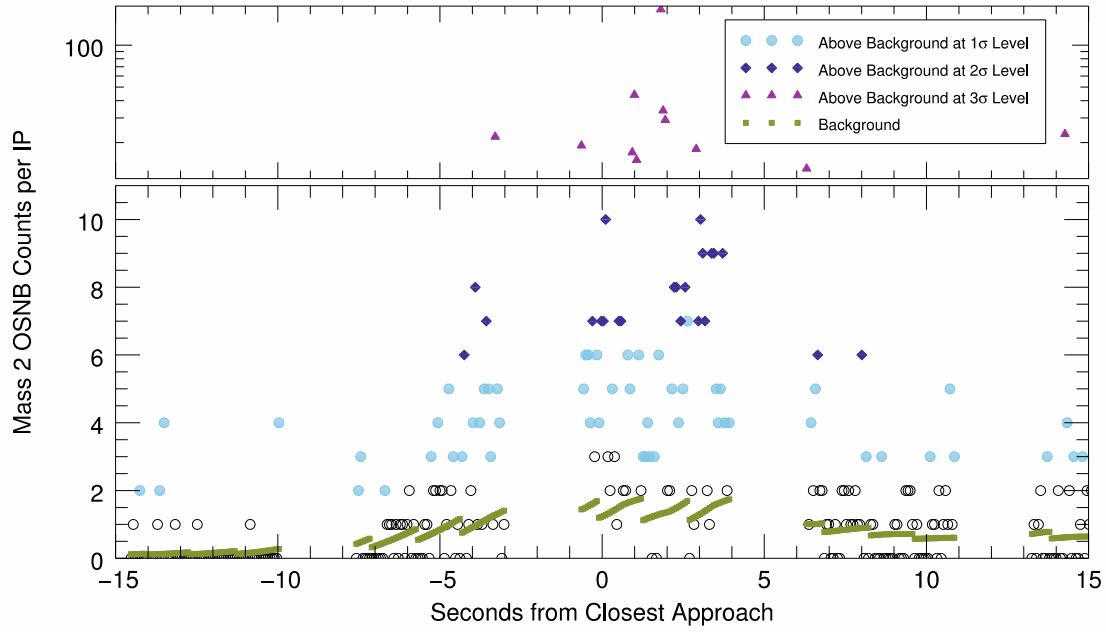


Figure INMS-31. Detection of molecular hydrogen in the plume. Figure from Waite et al. [2017].

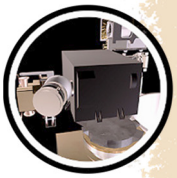

Table INMS-6. Other important minor constituents. Table from Waite et al. [2017]*.

Constituent	Mixing Ratio (%)
H_2O	96 to 99
CO_2	0.3 to 0.8
CH_4	0.1 to 0.3
NH_3	0.4 to 1.3
H_2	0.4 to 1.4

* Waite et al. [2017], Table 1. The major species composition of Enceladus' plume gas. Volume mixing ratios are derived from Cassini INMS measurements—supplementary materials [20], sections 2.4 and 3.2.

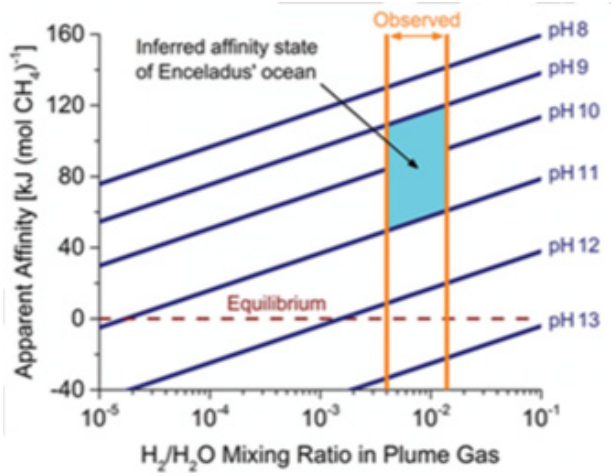

Figure INMS-32. A positive chemical affinity for the reaction that represents methanogenesis in Earth's ocean can be shown to be present on Enceladus. (Reproduced from Waite et al. [2017] Figure 4.) Apparent chemical affinity for hydrogenotrophic methanogenesis in Enceladus' ocean (273 K, 1 bar). The *orange lines* bracket the observed range in the mixing ratio of H_2 in the plume gas (Waite et al. [2017], Table 1). The *blue lines* are contours of constant ocean pH, a key model parameter. The *cyan region* indicates affinities for a pH range that may provide the greatest consistency between the results of (13, 15, 25). The *dashed red line* designates chemical equilibrium, where no energy would be available from methanogenesis. These nominal model results are based on CH_4/CO_2 = 0.4 (Waite et al. [2017], Table 1), a chlorinity of 0.1 molal, and 0.03 molal total dissolved carbonate (*25*). Reported ranges in these parameters propagate to give an uncertainty in the computed affinities of ~10 kJ (mol CH_4)$^{-1}$.

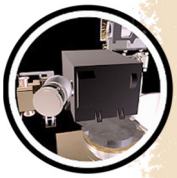
Detection of a plume ionosphere by INMS

As will be discussed later, the INMS (and CAPS) measured plasma in the Enceladus torus that mainly consisted of H_2O^+, OH^+, and O^+. In addition to closed source measurements of neutrals, INMS during the E3 flyby of Enceladus also made measurements in its open source ion mode [Cravens et al. 2009c]. The mass spectrum primarily showed a species with a mass of 19 u, and localized to the region of the neutral plume. Almost no signal at mass 18 was detected. Mass 19 corresponds to H_3O^+. We interpret the INMS measurements of cold H_3O^+ ions and the almost complete absence of cold H_2O^+ ions as being a consequence of ion-neutral chemistry taking place



in a plume "ionosphere" where the H_3O^+ is produced by reaction of H_2O^+ ions (incident from outside or locally from phototionization of water) with H_2O [Sakai et al. 2016].

Enceladus Open Questions

1. Extremely narrow vapor jets with Mach numbers as high as ten were sampled by INMS along Cassini's E14, E17 and E18 trajectories. What is the temperature and speed of the gas in the jets?

2. Drastic stochastic time variability in the vapor jets detected by INMS between Cassini's plume traversals. How does the time variability relate to subsurface tidal stresses and fluid flow in the tiger stripes?

3. What chemistry produces a mass 28 species in the closed source of INMS?

4. What is the isotopic composition of non-water plume gases?

5. Are there noble gases in the plume?

6. Is the methane detected by INMS abiotic or biotic in origin?

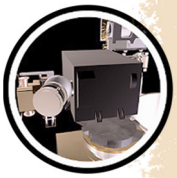
7. What is the relationship between plume gas abundances and the concentrations of dissolved species in Enceladus's ocean?

8. What is the composition of those large organics that are outside the mass range of the instrument?

Icy Satellite Science

> INMS results provide essential clues regarding the origin of O_2 and CO_2 at Dione and Rhea, and invaluable insight into the physics of icy satellite exospheres generally.

A major original objective of the Cassini mission, and of the INMS in particular, was to measure the abundance and composition of atmospheric gases around Saturn's large icy moons. Unlike Enceladus, which has insufficient gravity to retain an appreciable bound exosphere, sputtered and/or cryovolcanic emissions from Saturn's other large airless moons may fall back to their surfaces, and more volatile molecules can accumulate in the exosphere, adsorbing and desorbing to and from the surface many times before escaping to space. The ability of INMS to capture and analyze exospheric ions (with the OS) and/or neutrals (with the CS) is a strong function of Cassini's distance from these moons, with close flybys most likely to encounter detectable exospheric densities. Of Saturn's five large airless moons Mimas, Tethys, Dione, Rhea, and Iapetus, Cassini only flew close enough to



two, Dione and Rhea, to enable the detection of neutral O_2 and CO_2 exospheres by INMS at both moons (Figure INMS-33 and Figure INMS-34). INMS found evidence that the exospheres of Dione and Rhea exhibit complex structure, and observed drastic changes in the exosphere over time during the mission, as the Saturn system transitioned between equinox and solstice.

Owing to the diversity of multiple flyby dates and geometries (altitude, latitude, local time) the INMS was able to carry out exospheric density measurements over different geographic regions of Dione and Rhea, and at different flyby dates throughout the Saturnian year. The constraints provided by these INMS data, provide critical context and interpretation for the exospheric pickup ions detected by Cassini CAPS, and paint a highly detailed picture of the exospheric structure and time evolution. These data, together with high fidelity exospheric modeling, reveal highly seasonal exospheres at both Dione and Rhea, and inform interpretation of the exospheric measurements reported by Cassini's other instruments at these two moons [Simon et al. 2011; Tokar et al. 2012]. INMS results provide essential clues regarding the origin of O_2 and CO_2 at Dione and Rhea, and invaluable insight into the physics of icy satellite exospheres generally. For these reasons, INMS exploration of Saturn's large icy moons must be judged a spectacular success, meeting and in fact exceeding the original science objectives.

Icy satellites highlights

1. Discovery of oxygen and carbon dioxide exospheres at Dione and Rhea.
2. The exospheres change with time seasonally.
3. The exospheres have complex structure.
4. The measurements of the INMS place limits on the exospheric density that allowed aspects of the magnetometer data to be interpreted such that new types of current systems were discovered.

The Rhea and Dione flybys

Table INMS-7 summarizes Cassini's close flybys of Dione and Rhea, and the flybys for which INMS (and CAPS) had priority. At Rhea, Cassini carried out five major flybys ranging in speed from 6.8 to 9.3 km/s: the high altitude R1 and R1.5 flybys through the plasma wake, the low altitude R2 and R3 flybys approximately over the north and south poles, and the high altitude R4 flyby over the northern hemisphere. At Dione, five 6.5–9.0 km/s flybys were performed: the high altitude D1 flyby over the south, the high-altitude D2 flyby through the plasma wake, the low altitude D3 flyby near the dusk terminator, and the high altitude D4 and D5 flybys over the north. Cassini's traversal across the solar terminator, from night to day on all of the low altitude flybys (R2, R3, D3, see Figure INMS-33, Figure INMS-35, Figure INMS-36), was fortunate and essential, enabling INMS to detect the drastic differences of exospheric density between the night and day hemispheres. This constraint is key to the interpretation and understanding of the INMS data as discussed in the rest of this section.

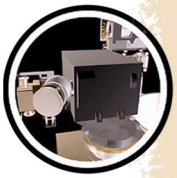


Table INMS-7. Dione and Rhea flyby observations.

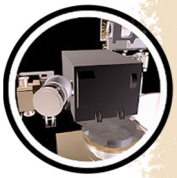
Flyby	Body	Date	UTC	Speed	Alt	Detection	Species	References	Description
D1	Dione	11-Oct-05	17:52:00	9.12 km/s	500 km	MAG	-	Simon et al. 2011	Upstream southern flux tube, Saturn inbound.
R1	Rhea	26-Nov-05	22:37:38	7.28	500	CAPS	CO_2^+, O^-	Teolis et al. [2010a]; Teolis and Waite [2016]	Equatorial Wake, toward night side, Saturn inbound.
R1.5	Rhea	30-Aug-07	01:18:55	6.76	5725	CAPS	CO_2^+	Teolis and Waite [2016]	Northern Wake, toward night side, Saturn outbound.
R2	Rhea	2-Mar-10	17:40:36	8.58	100	INMS	O_2, CO_2	Teolis et al. [2010a]; Teolis and Waite [2016]	Low altitude, north polar, toward day side, Saturn inbound.
D2	Dione	7-Apr-10	05:16:11	8.34	500	CAPS	O_2^+	Tokar et al. [2012]	Equatorial Wake, toward day side, Saturn inbound.
R3	Rhea	11-Jan-11	04:53:25	8.05	72	INMS	O_2	Teolis and Waite [2016]	Low altitude, south polar, toward day side, Saturn outbound.
D3	Dione	12-Dec-11	09:39:23	8.73	99	INMS	O_2, CO_2	Teolis and Waite [2016]	Low altitude, equatorial wake, toward day side, Saturn outbound. CAPS offline.
R4	Rhea	9-Mar-13	18:17:26	9.29	996	-	None	Teolis and Waite [2016]	South-to-north, over anti-Saturn night side. CAPS offline. Altitude too high, and pointing poor, for INMS: Non-detection.
D4	Dione	16-Jun-15	20:11:52	7.32	516	INMS	O_2	Teolis and Waite [2016]	North polar, toward night side, Saturn outbound. CAPS offline.
D5	Dione	17-Aug-15	18:33:25	6.45	476	-	None	Teolis and Waite [2016]	North polar, toward night side, Saturn inbound. CAPS offline.

Detection of exospheric oxygen and carbon dioxide

Figure INMS-33 and Figure INMS-34 show the densities of exospheric O_2 and CO_2 at Rhea and Dione as they were measured by the INMS closed source along Cassini's flyby trajectories [Teolis et al. 2010a; Teolis and Waite 2016]. While O_2 is an expected product of sputtering, produced by radiolysis of highly abundant water ice on the surfaces of many icy satellites, the detection of exospheric CO_2 at a high relative abundance compared to O_2 was not expected.



Before addressing the origin of CO_2, we first point to several other extraordinary aspects of these INMS data sets that are key to their interpretation:

- Exospheric densities, as measured during the R2, R3 and D3 flybys, were higher over the dayside than the night side (Figure INMS-33).
- The day-night asymmetry is in all cases far more pronounced for CO_2 than for O_2 (Figure INMS-33).
- Despite the lower altitude of the R3 flyby (minimum 72 km) relative to R2 (minimum 100 km), ten times less O_2, and no CO_2 was detected on R3 (Figure INMS-33).

The observation of higher exospheric densities over the daysides of Dione and Rhea is consistent with higher exospheric scale heights over that hemisphere, as exospheric gas interacts and thermally accommodates to the warmer dayside surface temperatures. However, the day-night exospheric asymmetry is far more pronounced for CO_2 than for O_2 at both Dione and Rhea (Figure INMS-33, Figure INMS-35, Figure INMS-36), suggesting that the less volatile CO_2 molecules may, unlike O_2, actually freeze out onto the night sides of both moons.

However, the detection of far less O_2, and non-detection of CO_2 at R3 was entirely unexpected at the time of the flyby, since the R3 trajectory was at a lower altitude than the previous R2 flyby. This raised the question of whether the drastically different O_2 and CO_2 densities between R2 and R3 were the result of exospheric spatial structure (a gas source in the north), or changes in the exospheric structure with time?

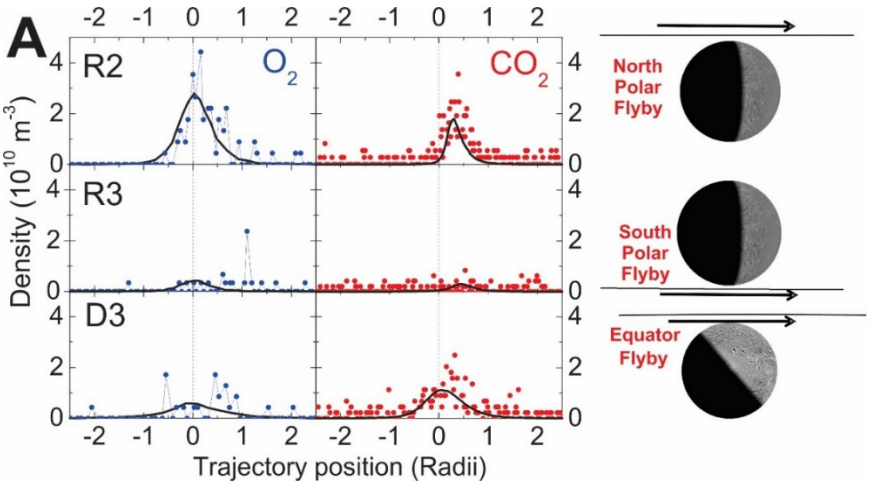


Figure INMS-33. Densities of exospheric O_2 and CO_2 at Rhea and Dione as they were measured by the INMS closed source along Cassini's flyby trajectories. The Dione and Rhea O_2 and CO_2 exospheric densities measured by Cassini INMS versus distance (in planetary radii) from closest approach (*dashed line*) along the night-to-day R2, R3 and D3 trajectories (*shown on right*). The data are un-binned, such that single counts are visible. Time increases left to right in the plots, with Cassini moving from the night to the dayside hemisphere on all flybys. As shown, the exospheric profiles are concentrated (especially for CO_2) over the dayside when equivalent inbound-outbound altitudes are compared. Lines: exosphere model results, see Figure INMS-35 and Figure INMS-36. Figure from Teolis and Waite [2016].

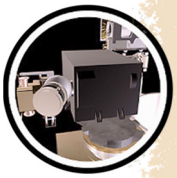

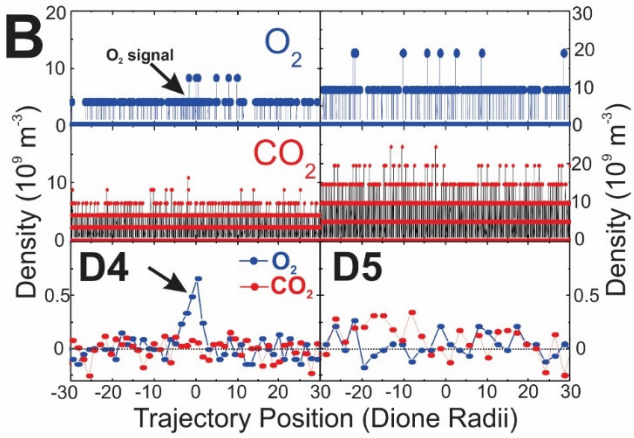

Figure INMS-34. Densities of exospheric O_2 and CO_2 at Rhea and Dione as they were measured by the INMS closed source along Cassini's flyby trajectories. Exospheric data (*top-center:* raw counts converted to density; *bottom:* binned/background subtracted) from the recent Dione northern high (516 km) altitude (day-to-night) D4 and D5 flybys, showing the detection of O_2 but not CO_2 at D4 and the non-detection of either species at D5. Time increases left to right with Cassini moving from the day to the night side hemisphere on both flybys. Figure from Teolis and Waite [2016].

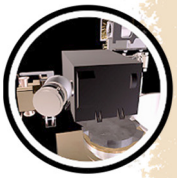
Exospheric structure and seasons at Dione and Rhea

To address this puzzle Teolis et al. [2010a] and Teolis and Waite [2016] created a state-of-the-art icy satellite exospheric model code that specifically takes into account the effects of surface thermal accommodation and sticking observed by INMS. The model considers the rotation of Dione and Rhea, the variability of surface temperature between day and night, and the change in the solar declination with Saturn's seasons, which varies from between ±26.7 degrees over the 29.5 (Earth) year Saturn orbit. Molecules of O_2 and CO_2 are ejected into the simulated exosphere uniformly from all points on the surface to approximate a surface sputtered source, but can stick (transiently) to the night side and (for much longer periods) at the winter latitudes.

The exospheres of Dione and Rhea are, according to the models, highly seasonal with exospheric O_2 and CO_2 freezing onto the cold terrain in the winter latitudes, which remain in shadow drop as low as 20 Kelvin over the 14 year Saturn system winter [Howett et al. 2016]. However, with the approach of spring equinox the solar terminator advances across the polar terrain resulting in the rapid desorption of condensed gasses and a drastic ramp up of the exospheric gas density. In fact, the Rhea R2 flyby over the north occurred shortly after northern equinox and thus the exospheric O_2 and CO_2 were still desorbing from the northern terrain as previously shadowed areas were coming into sunlight. The main exospheric gas source was in the north at the time of the R2 and R3 flybys, due to desorption of condensed O_2 and CO_2 (built up over the prior winter) from that region. This can be seen in Figure INMS-35 and Figure INMS-36 where we plot the modeled exospheric CO_2 and O_2 densities at Rhea and compare predicted with measured densities along the R2 and R3 flyby trajectories. For CO_2 it can be seen (Figure INMS-35) that Rhea's exospheric gas density was higher over the north than the south according to the model, since CO_2 was



desorbing from the north at that time. This interpretation, shown in Figure INMS-35, successfully accounts for INMS non-detection of CO_2 on R3 in the south.

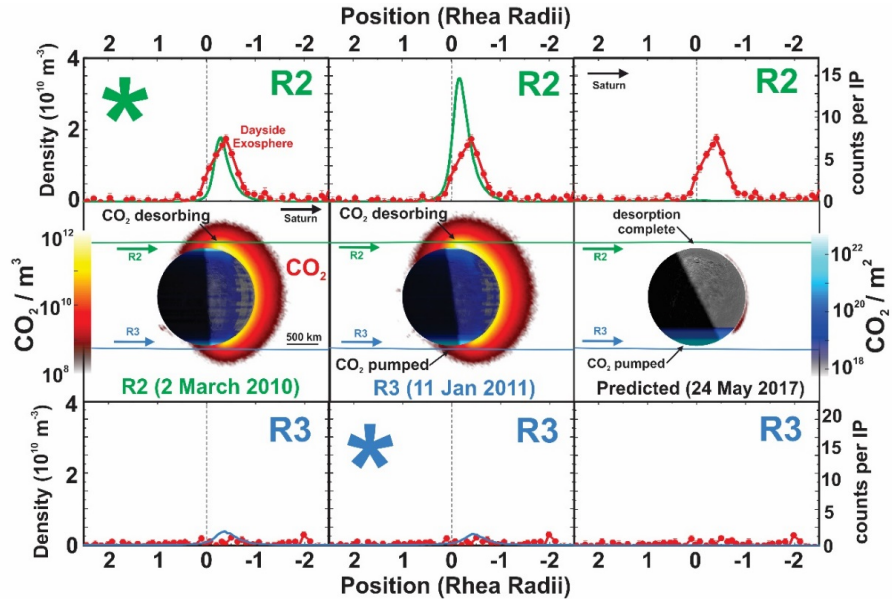


Figure INMS-35. Plot of the modeled exospheric CO_2 and O_2 densities at Rhea, and the comparison of predicted with measured densities along the R2 and R3 flyby trajectories. Rhea CO_2 exospheric model results, showing (*center row*) the surface solar illumination (dawn terminator as viewed over the equator), and predicted gas density cross-sections and surface frost column density at the R2 (*left*) and R3 (*center column*) flyby dates and times, and prediction (*right*) for the 2017 Saturn solstice. *Top*: comparison of the observed (*red points*, data binned) and predicted (*green line*) CO_2 densities versus position from closest approach along the R2 trajectory (x-axis, in Rhea radii, *dashed line:* closest approach). *Bottom*: same for the R3 flyby trajectory. *Asterisks* denote model-data comparisons with the same flyby date; all other plots show model projections to different dates. The model assumed a 3.7×10^{21} CO_2/s source rate as required to match the observed peak density on both flybys. The observation of CO_2 concentrated on the dayside is consistent with the modeled exospheric structure due to night side and polar cryopumping. CO_2 was desorbing from the north, and cryopumping onto the southern polar surface during the flybys. Accordingly, as anticipated by the model (*bottom center*), CO_2 was undetectable in the south on R3. As shown (*right*) exhaustion of the northern frost cap should result in the collapse of the CO_2 exosphere by the time of the 2017 solstice. Figure from Teolis and Waite [2016].

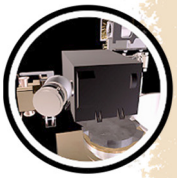
Surprisingly the O_2 data has a somewhat different interpretation than CO_2 according to the model, owing to the greater volatility of O_2 as compared to CO_2. The less volatile CO_2 (unlike O_2) is was beginning to freeze out onto the south polar terrain at the time of the R2 flyby according to the model, even before its desorption from the north had completed. For CO_2 (unlike O_2) the adsorption of exospheric gas onto one pole overlaps in time with its desorption from the opposite pole, meaning that CO_2 exhibited a more drastic difference of density between north and south at the time of the R2 and R3 flybys than O_2. Therefore, as can be seen in Figure INMS-36, the drop in O_2 between R2 and R3 is indicative of a rapid collapse of the entire exosphere in the ten months between R2 and R3. The exosphere's collapse occurs as all of the O_2 frozen onto the northern terrain is depleted, having fully desorbed off of the northern surface. The CO_2, being less volatile, takes longer to desorb from the north, and therefore CO_2 exosphere is predicted to have collapsed



only after the R3 flyby took place. In this way exospheric O_2 and CO_2 desorb and re-freezing, moving from pole to pole every equinox, in a repeating seasonal cycle, leading to changing exospheric densities at Dione and Rhea that are minimal near Saturn's solstices and maximal near the its equinox's. The model of a seasonal exosphere not only accounts for the INMS data, but also the spatial distribution, composition, flux of pickup ions observed by CAPS discussed by Teolis and

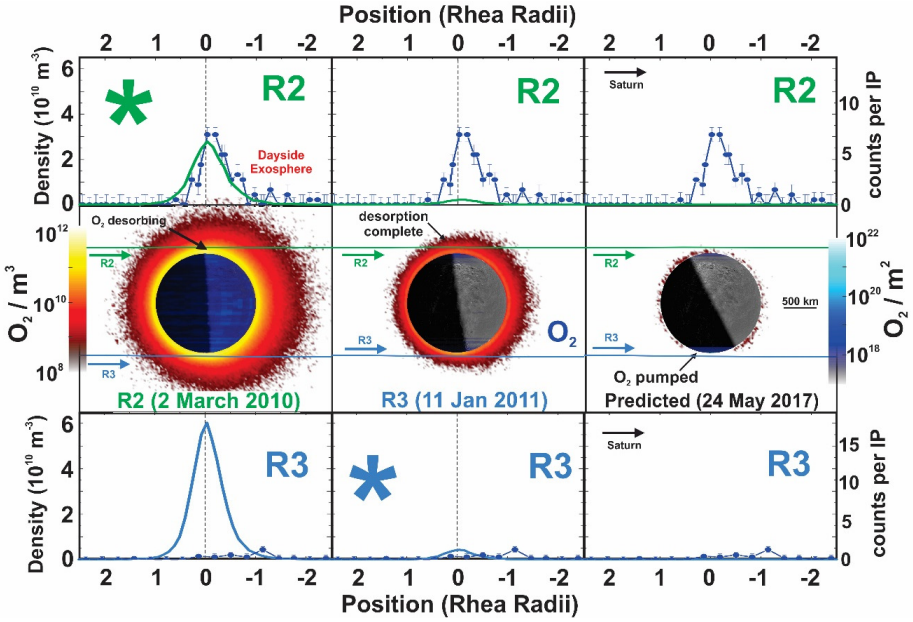


Figure INMS-36. Plot of the modeled exospheric CO_2 and O_2 densities at Rhea, and the comparison of predicted with measured densities along the R2 and R3 flyby trajectories. Rhea O_2 exospheric model results, showing (center row) the surface solar illumination (dawn terminator as viewed over the equator), and predicted gas density cross-sections and surface frost column density at the R2 (left) and R3 (center) flyby dates and times, and prediction (right) for the 2017 Saturn solstice. (Top) comparison of the observed (data binned) and predicted O_2 densities versus position from closest approach along the R2 trajectory (x-axis, in Rhea radii, dashed line: closest approach). (Bottom) same for the R3 flyby trajectory. Asterisks denote model-data comparisons with the same flyby date; all other plots show model projections to different dates. The model assumed a 7.2×10^{21} O_2/s source rate as required to match the observed peak density on both flybys. An O_2 tail is detected on the dayside, consistent with the anticipated greater dayside scale height. Unlike CO_2, the southern latitudes are not yet cold enough to cryopump O_2 from the southern exosphere on the R2 and R3 flybys dates. However, the modeled O_2 frost cap is exhausted between the R2 and R3 flybys, resulting in an anticipated collapse of the global exosphere, consistent with the reduced O_2 detection on R3. Figure from Teolis and Waite [2016].

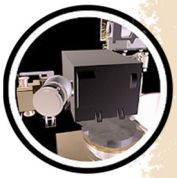
Waite [2016]. CAPS observed 50% more CO_2^+ pickup ions during the distant 2007 R1.5 flyby than the 2005 R1 flyby, consistent with the expected ramp up of Rhea's exospheric CO_2 densities as the 2009 Saturn system equinox was approaching. See the publication by Teolis and Waite [2016] for a much more detailed description of these (and other) aspects of the analysis.

The source of O_2 and CO_2 at icy satellites

Another spectacular facet of these INMS data and models is that, together, they fully constrain the source rates O_2 and CO_2 to the exospheres of Dione and Rhea. Since both the exospheric density



and ionization/escape rates are constrained by INMS and CAPS, the O_2 and CO_2 source rates can be directly estimated by fitting the exospheric model to obtain agreement with the INMS and CAPS data—as Teolis and Waite [2016] have done. These source rates can, in the case of O_2, be compared to known yields of sputtered radiolytic O_2 from water ice measured in the laboratory [Teolis et al. 2017a] to infer the composition and radiation chemistry of the surface material on Rhea and Dione subject to magnetospheric sputtering.

The results of this analysis are remarkable—the O_2 source rates at Dione and Rhea are lower, by approximately two orders of magnitude, than that expected from water ice subject to sputtering by Saturn's magnetospheric plasma [Thomsen et al. 2010]. Teolis and Waite [2016] concluded that, if pure water ice were present on their surfaces, Dione and Rhea ought to have two orders of magnitude more O_2 in their exospheres than observed.

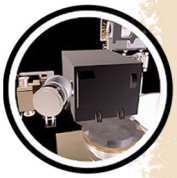
A clue to this puzzle may be the high CO_2 abundance CO_2 (relative to O_2) in the exospheres of Dione and Rhea. Teolis and Waite [2016] proposed that preferential sputtering and removal of radiolytic volatile water products such as O_2 and H_2, and of H_2O itself, may enrich the topmost nanometers of surface material of these moons in carbonaceous sputter-resistant refractory material. As a result, the surfaces of surface regolith grains, composed in bulk of water ice and (likely) small amounts of carbon-bearing organic species, may be coated with a nanometer thick rind of radiolytically processed refractory material, for example, graphitic oxide, which is carbon-rich and yields small amounts of O_2 and CO_2 when sputtered. Recent composition analysis [Desai et al. 2018] of negative pickup ions detected by Cassini CAPS during the Rhea R1 flyby [Teolis et al. 2010] also supports the interpretation of a carbonaceous material on Rhea's surface ice. Thus, by constraining the source rates of O_2 and CO_2 to the exospheres of Dione and Rhea, the findings of Cassini INMS at these two Saturnian icy satellites have provided fundamental clues about the physics of surface sputtering and radiolysis, and of exospheric gas production, at icy bodies generally.

… the findings of Cassini INMS at these two Saturnian icy satellites have provided fundamental clues about the physics of surface sputtering and radiolysis, and of exospheric gas production, at icy bodies generally.

ICY SATELLITES OPEN QUESTIONS

1. O_2 and CO_2 exospheres at Rhea and Dione confirmed by INMS. Is CO_2, like O_2, a sputtered surface radiolysis product?

2. Exospheric seasonal variability, and complex spatial structure, in the exospheres of Dione and Rhea, suggests that diurnal and seasonal adsorption and desorption play a major role in exospheric structure and dynamics. What is the effect of regolith porosity on the exospheric gas adsorption, desorption and diffusion rates on the surfaces of Dione, Rhea, and other solar system icy satellites?



3. Lower than expected O_2 exospheric densities at Dione and Rhea O_2 suggest surface sputtering rates two orders of magnitude less than those measured from water ice in the laboratory. Do surface refractory impurities suppress sputtering from ice satellites, and do carbonaceous refractories contribute radiolytic CO_2 to their atmospheres?

4. Rhea's INMS-measured exospheric densities are insufficient to account for strong magnetic perturbations in Rhea's vicinity, leading to the conclusion that Cassini's Magnetometer measured two new electric current systems never before observed at a plasma absorbing planetary body. These are an Alfvenic current system generated by Rhea's plasma wake, and a thermo-electric flux-tube current system which maintains electric charge balance on Rhea's surface. How widespread are these newly discovered current systems at other plasma absorbing planetary bodies in the solar system?

Magnetosphere–icy satellite Interactions science

Saturn inner magnetosphere highlights

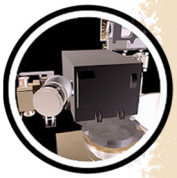
1. INMS measured the individual ions and determined the fractional abundance within the water group (O^+, H_2O^+, OH^+, H_3O^+) and derived those fractions relative to the various parameters (velocity phase space and distance from Saturn).

2. INMS measured neutral water and was able to derive an azimuthal distribution with respect to Enceladus via in situ measurements.

Current systems at Rhea

The constraints provided by INMS on the exospheric gas abundances at Dione and Rhea have been essential to the interpretation of the Magnetometer (MAG) readings from these two moons, resulting in the discovery of two previously unknown current systems at inert plasma absorbing planetary bodies. These discoveries a fantastic demonstration of the power of a diverse instrument payload; in this case Cassini’s INMS, CAPS and MAG; to reveal new and previously unknown fundamental physics operating in planetary systems.

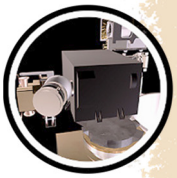
MAG has been a powerful tool for the detection of exospheres in the Saturn system, having been in part responsible for the initial discovery of the Enceladus plume. Exospheric neutral gas disrupts the flow of Saturn’s co-rotating magnetosphere plasma by contributing new pickup ions to magnetosphere, generating electric currents and draped magnetic field perturbations, which can be measured by MAG to infer the presence of an exosphere. In addition to Enceladus, a major effort was made to detect the exospheres of Saturn’s other large icy satellites with the magnetometer, and to compare these data with the in situ measurements from CAPS and INMS. In fact, MAG did detect field-aligned currents at both Dione [Simon et al. 2011] and Rhea [Khurana



et al. 2017; Santolik et al. 2011; Simon et al. 2012] which appeared, initially, to be consistent with exospheres at these moons as found by INMS. Remarkably, after taking into consideration the rates of pickup ion generation and the electrical conductivity, it became clear that the exospheres measured by CAPS [Tokar et al. 2012] and INMS [Teolis et al. 2010] at Dione at Rhea (Chapter 1.4) were two orders of magnitude too tenuous to account for the Magnetometer data. At Rhea these limits on the exospheric abundances from INMS spurred a fundamental new re-interpretation of the MAG data which, together with new modeling approaches, resulted in the discovery of two new current systems. In the next few paragraphs we briefly summarize these current systems at Rhea, but we refer the reader to papers by [Khurana et al. 2017; Simon et al. 2012; Teolis et al. 2014] for a much more detailed analysis.

The first current system, detected by MAG in Rhea's plasma wake, results from the combination of ion kinetic effects in a hot plasma, and relative motion between the plasma and an inert plasma absorbing body like Rhea. As the wake is refilled with plasma in the downstream co-rotation flow [Roussos et al. 2008], the plasma pressure gradient directed back toward Rhea results in diamagnetic current closure across the wake and perpendicular to the co-rotation flow. The pressure gradient exerts a force directed towards Rhea and mimics a real exosphere by generating a field-aligned Alfvénic current system, which extracts momentum from the co-rotating plasma outside the wake and transfers it to the wake. The Alfvén wings from the wake [Khurana et al. 2017] produce flow-directed magnetic field perturbations north and south of Rhea's equatorial plane, detected by MAG at the locations of R2 and R3 and also during two distant (102 R_H and 54 R_H away from Rhea on June 3 and October 17, 2010 [Khurana et al. 2012] downstream flybys. However, MAG also found indications of a second field aligned current system in Rhea's flux tube which, remarkably, is not generated by Rhea's motion relative to the plasma. Evidence for this current system comes from sharp magnetic field perturbations detected during Cassini's R2 and R3 flybys through Rhea's northern and southern flux tubes [Teolis et al. 2014]. The perturbations point in opposite directions on opposite sides of the flux tube, indicating a field twisting about the flux tube, consistent with a wire of flux tube current flowing away, north and south, from Rhea [Santolik et al. 2011; Simon et al. 2012]. The small ~100 km thickness of these field perturbations, much less than the ~500 km ion inertial length, makes them too small to be Alfvénic.

This current system, investigated by [Teolis et al. 2014], results from the requirement to balance ion and electron currents at Rhea's non-conductive surface, and the difference of gyroradius between the positive (ion) and negative (electron) charge carriers. The ions which (owing to their larger gyroradius) discharge into the plasma absorber's surface from all directions are balanced by the electrons, which are constrained to flow along the magnetic field lines. More magnetic field lines connect to the planetary equator due to the oblique angle and, therefore, the electron current is most intense at the edge of the flux tube. The resulting magnetic field perturbation circles about the flux tube and is maximal at the edges, as observed by the Cassini spacecraft. A fundamental property of this flux tube current system is its proportionality only to the ion flux into Rhea, i.e., the plasma density times the ion thermal speed, and its independence of the motion of the moon's conductive atmosphere through the magnetosphere. This spectacular, albeit unexpected outcome of Cassini's magnetic field data at Rhea, would not have been possible



without the exospheric abundance limits provided by Cassini CAPS [Tokar et al. 2012] and INMS [Teolis and Waite 2016].

Inner magnetosphere science

INMS has extracted the water-group ion fractions from OSI measurements in Saturn's inner magnetosphere. These fractions are sensitive probes of the source, transport, and loss mechanisms that govern Saturn's magnetosphere. INMS samples only a small portion of velocity space at a time (Figure INMS-37), which enables investigation of the distributions within velocity space but also limits sensitivity and complicates the separation of various factors that affect the relative ion fractions. Densities and count rates can be low, sometimes requiring the sum of 10,000 IPs for a two-sigma result. Figure INMS-38 shows that ion fractions depend on distance from the orbit of Enceladus. Models show that the water-group fractions depend most strongly on the local fraction of neutrals. In contrast to CAPS results, INMS data show H_3O^+ fractions less than 0.1 except for measurements taken directly in the plumes. These fractions are now being used to calibration ion and neutral models of Saturn's magnetosphere.

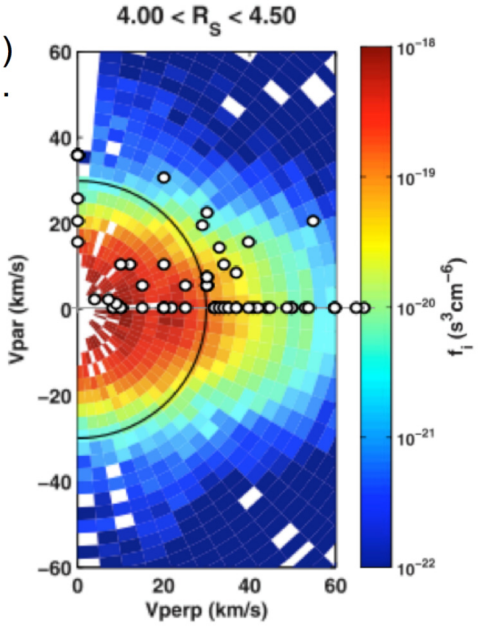


Figure INMS-37. INMS samples only a small portion of velocity space at a time. The *small white circles*, displayed on the CAPS distribution of ion density in velocity space [Tokar et al. 2008], show the location of the INMS measurements of water-group fractions. Although coverage is sparse, the INMS measurements take spot samples of a wide region of velocity space.

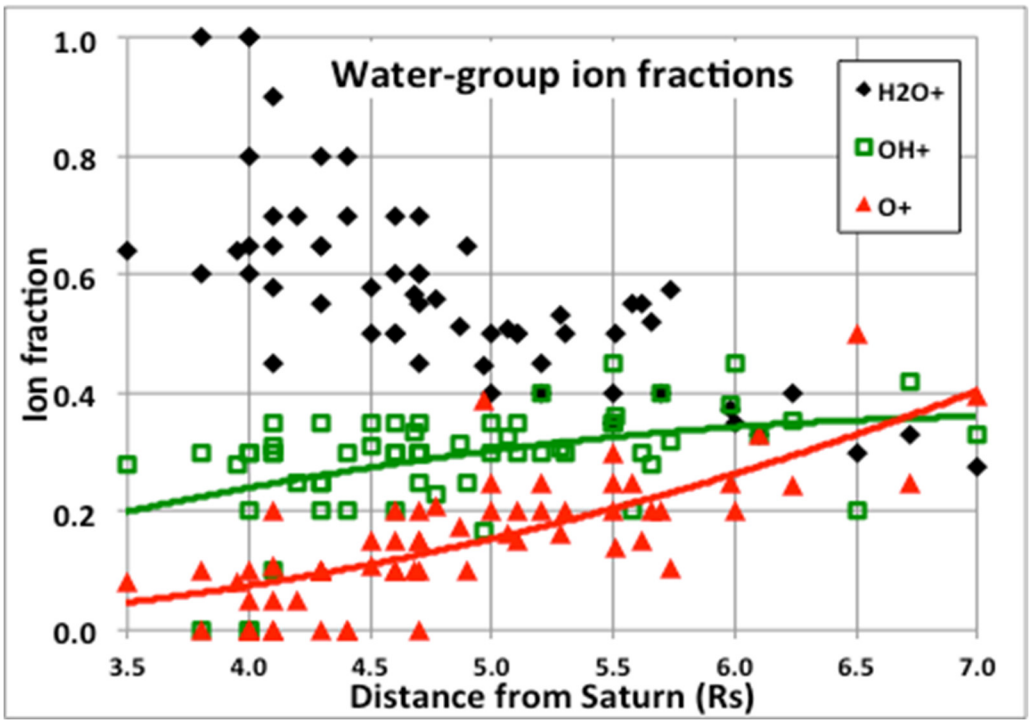

Figure INMS-38. The fraction of water-group ions plotted as a function of distance from Saturn. INMS finds that the highest fraction of H_3O^+ is near 4 R_S, as expected, as that is the orbit of Enceladus, the source of the neutral water that becomes the plasma.

Neutrals in Saturn's inner magnetosphere

In 2008, the Cassini INMS investigation made in situ measurements of neutral species near Saturn's equatorial plane within 0.5 Saturn radii (R_S) of the orbit of Enceladus. After removing the large background and modeling to interpret instrumental effects, the data provide constraints on the neutral distribution and composition. These data show an azimuthal asymmetry in the neutral densities (Figure INMS-39) and provide measurements used to compare simulations of neutral H_2O emitted from Enceladus (Figure INMS-40). Far from Enceladus, the neutral water densities, at a few times 10^3 molecules/cm^3, are near the detection limit of INMS. Near Enceladus, but outside of the plumes and north of the equatorial plane, the INMS detects particles within 5,000 km of Enceladus, with the density increasing to approximately 10^5 molecules/cm^3 at the equatorial plane.

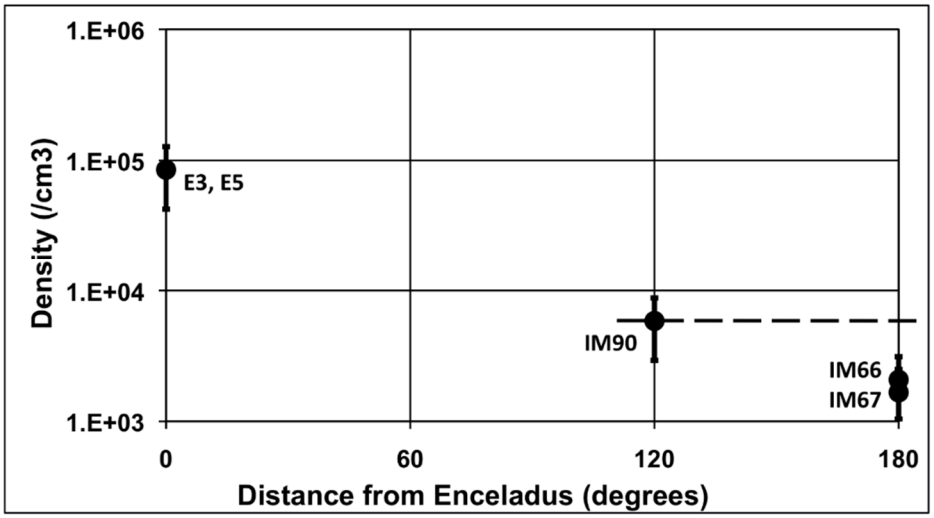

Figure INMS-39. Average densities near 4 R_S show the dependence on azimuth. The densities at 0 (near Enceladus) are north of Enceladus, outside the plumes. The difference between the measurements at 0° and 120° are much larger than the uncertainties. The measurements at 180° are at 4.5 R_S. The data at 180° are a factor of three below the data at 120°. The displayed *error bars* are ±50%.

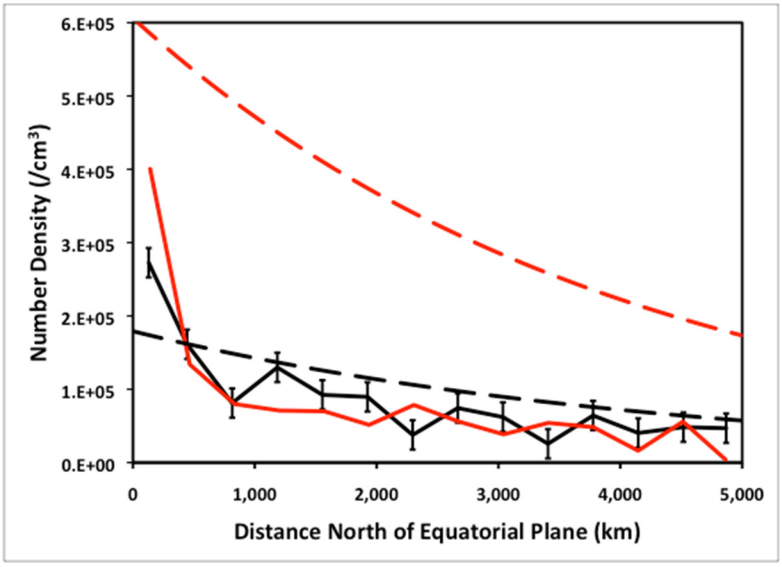

Figure INMS-40. Neutral cloud density north of Enceladus, before close approach and outside of proximal influence of the south-pole plumes. The solid lines are the INMS data. The *dashed lines* are simulations using the charge-exchange model of the neutral cloud [Smith et al. 2010]. The E5 simulation is based on the source rate derived from modeling the E5 plumes, and the E3 simulation is based on the source rate derived from modeling the E3 plumes. The E3 and E5 INMS densities are similar to each other and to the E3 simulation. E5 error bars (not shown to reduce clutter) are the same size as E3 error bars.

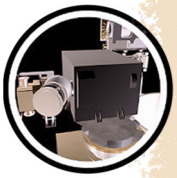

28 u neutrals in Saturn's inner magnetosphere

INMS observes inner-magnetosphere neutrals with a mass of 28 u that have unexpectedly high densities, no apparent source, and no clear molecular identification. With densities as high as 30% of the neutral-water density, the candidate molecules, N_2 and CO, should be abundant in the Enceladus emissions, but multiple observational approaches show that neither molecule comprises more than 3% of the H_2O density (Figure INMS-41).

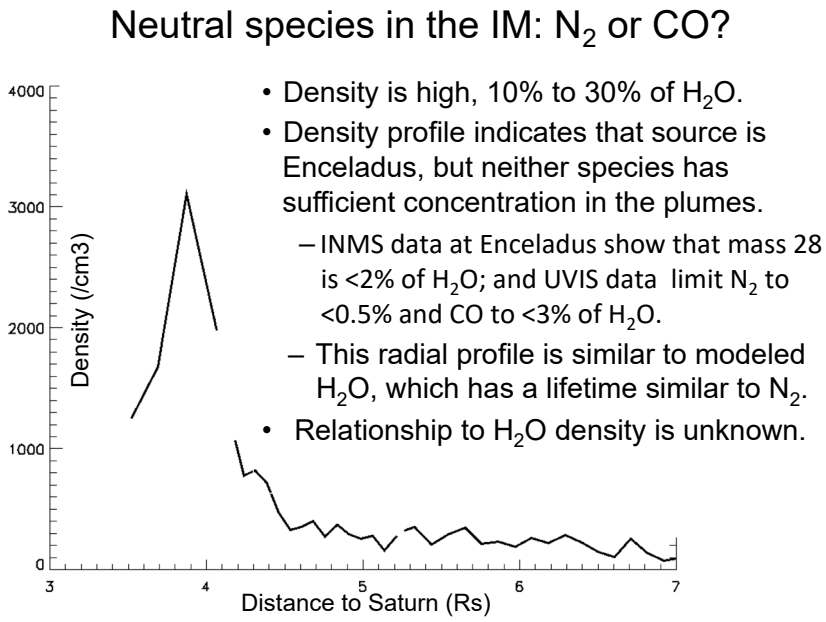

Figure INMS-41. Mass 28 u mystery compound in the inner magnetosphere.

SATURN INNER MAGNETOSPHERE OPEN QUESTIONS

1. What explains the mass 28 signal?

F-ring Science

F-ring observations: primary neutrals

INMS found two neutral species with remarkable consistency during the F-ring passes: H_2 and a species at 28 u (Figure INMS-42). The scale height, or the half-width-half-max of the INMS counts, for both of these species was approximately 3,000 km, or 0.05 Saturn radii (R_S). This parameter and the total counts were nearly identical in each pass.

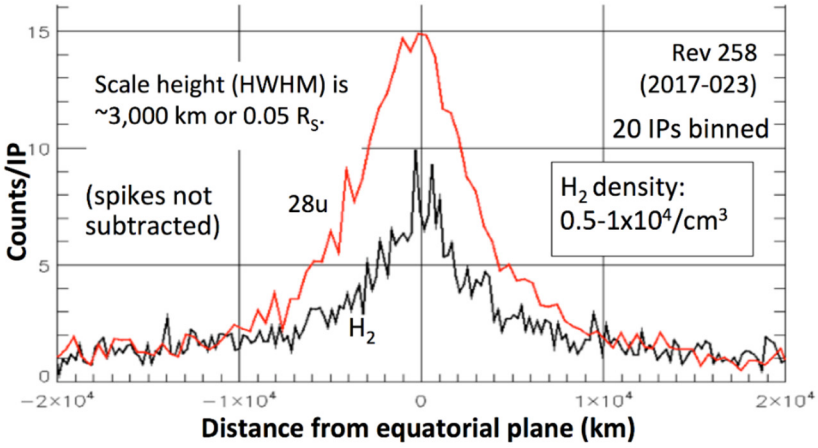

Figure INMS-42. The major neutrals measured by INMS in the F-ring. Twenty measurements (integration periods or IPs) were binned for this plot.

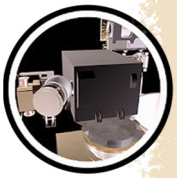
Although H_2 was expected in this area of the rings, models and Earth-based observations predicted a larger scale height for H_2 from Saturn's atmosphere, and the narrow distribution of the observed H_2 suggests that it is more liked to originate in the rings. The lack of variability indicates a stable ring atmosphere. Atomic hydrogen is not measured by INMS due to instrumental noise at 1 u.

A complication for INMS neutral observations is the high speed of Cassini relative to the ring particles. At 20 km/s, the molecules carry 2.1 eV per nucleon, which is sufficient energy to cause some dissociation in the INMS antechamber, particularly for larger molecules. If a molecule dissociates, only volatile products are measured. Without considering dissociation, the density of the H_2 is 0.5-1 × 10^4 cm^{-3}.

F-ring observations: other neutrals and 28 u

CH_4 (16 u) and CO_2 (44 u) are the only other measured species. They both have a count rate that is approximately 20% of the H_2 rate. CH_4 is confirmed by the presence of 15 u counts at the correct electron impact dissociative ionization ratio, the amount produced from CH_4 in the INMS ionization chamber. CO_2 is not a common dissociation product and may be a native species, it exists on the surface of several icy moons. Count rates for both CH_4 and CO_2 are depressed due to dissociation and they may be more abundant than indicated by the measurements. There are small amounts of 26 u and 27 u, which are expected products from ionization of C_2H_4, one possibility for the 28 u measurements. However, the count rates for these two cracking products are lower than expected if the entire 28 u signal was produced by C_2H_4. This deficiency implies that another species such as CO may contribute to the 28 u signal.

Several expected neutral species are missing, most notably H_2O and O_2. Since water is temporarily adsorbed onto the walls of the INMS inlet, H_2O counts are suppressed and delayed. Combined with the radiation background, which increases after passing through the equatorial plane, INMS would not detect low densities of H_2O particularly after some loss due to high-velocity



dissociation. Models show that O_2 could be abundant, but that densities decrease a factor of 1,000 approaching the location of Cassini's trajectory, moreover, much of the O_2 would be lost due to dissociation.

F-ring observations: ions

INMS observed only water-group ions in the F-ring. Unlike the neutrals, the ion densities were not symmetrical with respect to the equatorial plane, varying in both total density and the relative fractions within the water group (Figure INMS-43). The predominance of O^+ versus the other water-group ions indicates that there may be a source of O^+ other than as a byproduct of water. One possibility is that CH_4^+ contributes a fraction of the 16 u ions.

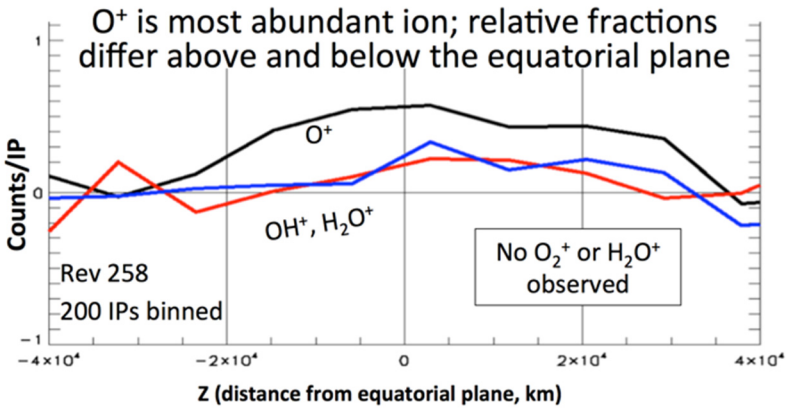


Figure INMS-43. Distribution of water-group ions south and north of the equatorial plane. O+ comprises a higher fraction of the ions in the south.

The velocity distribution of the ions (Figure INMS-44) shows that the ions are cold, with a mean velocity below the pickup velocity of 8 km/s, corresponding to a temperature of approximately 3 eV. These results are consistent with analyses and modeling of data from the CAPS.

The lack of O_2^+ in the F-ring, which INMS previously observed during Cassini's insertion into orbit about Saturn, is likely due to the INMS energy limit at the F-ring speeds—O_2^+ exceeds the INMS energy limit for ions. The lack of H_2^+ is surprising and not yet explained. As with neutrals, noise prevents INMS measurement of H^+ at 1 u.

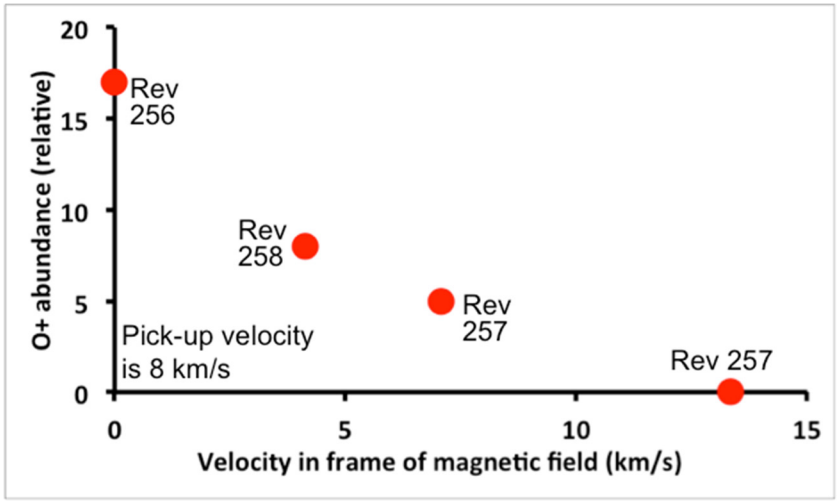

Figure INMS-44. The distribution of ions in the rest frame of the magnetic field. Ions are concentrated near the core, as expected for cold ions.

Saturn Ionosphere, Atmosphere, and Atmosphere-Ring Interaction Science

Saturn Upper Atmosphere Major Findings (Neutral Thermosphere):

- INMS made the first in situ measurements of Saturn's atmosphere, and made surprising discoveries of several species of high mass neutrals, e.g., CH_4, CO, CO_2.
- The INMS made the first in situ characterization of the thermal structure in the upper atmosphere of Saturn, indirectly through its measurements of the H_2 densities.
- Helium has been measured for the first time in Saturn's upper atmosphere, providing constraints on possible deep-atmosphere mixing ratios of Helium and whether or not Saturn has a solar-like composition or something else.

During the Cassini Grand Finale, the INMS made an unprecedented series of measurements of Saturn's upper atmosphere during the Proximal Orbit Phase, sampling from ~3500–1370 km altitude above the one bar pressure level. Prior to these orbits, it was anticipated that Saturn's upper atmosphere consisted primarily of H, H_2, with trace amounts of H_2O and He. However, the INMS measurements revealed an atmosphere with an unexpectedly rich composition, containing significant amounts of organics spanning the entire mass range sampled by INMS, shown in Figure INMS-45. These results were completely unanticipated and they have effectively turned our understanding of the high altitude thermosphere-ionosphere chemistry on its head [Waite et al. 2018; Perry et al. 2018; Yelle et al. 2018].

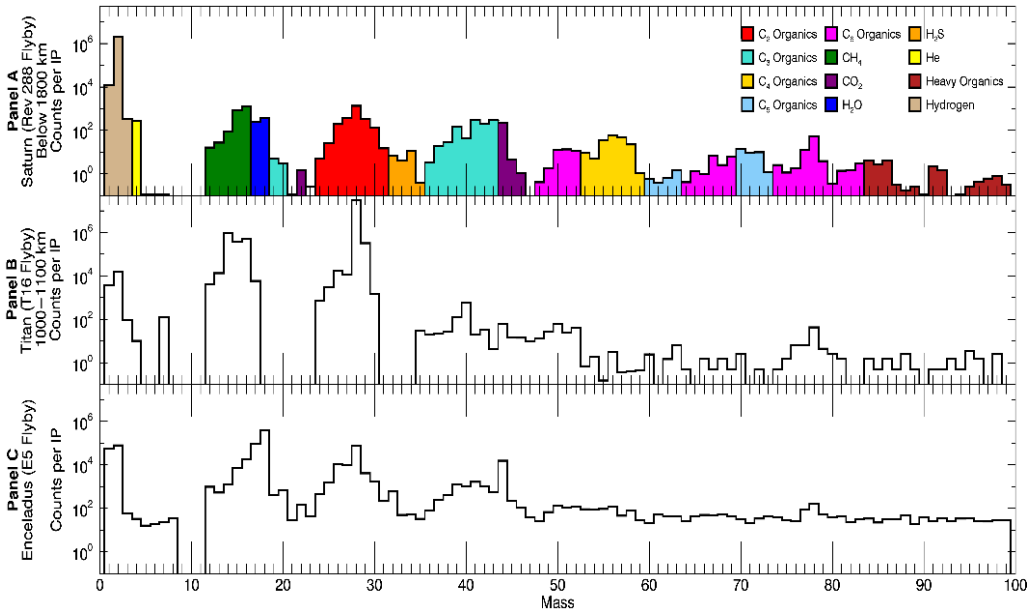

Figure INMS-45. INMS mass spectra from the Grand Finale orbits at Saturn (*Panel A*), compared with those of Titan (*Panel B*), and Enceladus (*Panel C*). Horizontal axis is in units of mass per charge. See Waite et al. [2018] for details.

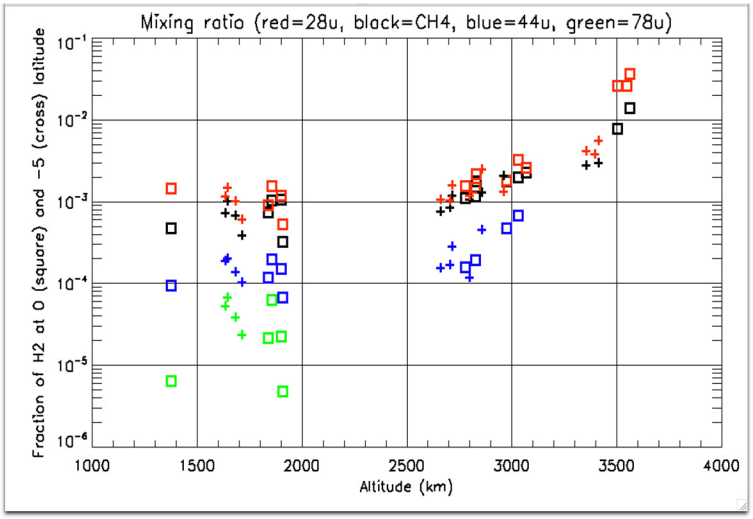

Figure INMS-46. Volume mixing ratios (*vertical axis*) of the heavy species identified by INMS in the Saturnian upper atmosphere as a function of altitude above the 1-bar pressure level (*horizontal axis*).

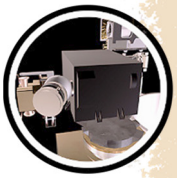
In particular, INMS has identified methane (CH_4) as a significant component of the upper atmosphere of Saturn above 1370 km. As shown in Figure INMS-46, INMS has found significant amounts of methane that reach up to ~10% of the composition near 3500 km altitude above the 1-bar pressure level. Additional heavy species (masses 28 u, 44 u, and 78 u) have also been

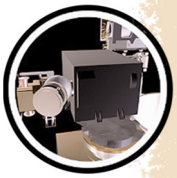


identified. All of these species can potentially play major photochemical roles in the atmosphere of Saturn [cf. Moses and Bass 2000; Kim et al. 2014].

Using a combination of National Institute of Standards and Technology (NIST) data and calibration data collected using the refurbished engineering unit, preliminary fits to spectra at altitudes between 1700 and 1800 km for three representative orbits were made to identify contributing species in the measured mass spectra (for example, Figure INMS-45). In general, the spectrum below ~70 u can be fit by a combination of species that is dominated by hydrocarbons. Ammonia (NH_3) is detected at 17 u. Other N-bearing species are neither excluded nor required by the spectra. The same is true for O-bearing organics. Inclusion of S species, especially H_2S, improves the fit of the spectrum. However, of the non-H_2, non-He material, less than 1 mol percent is contributed by S-bearing species. We estimate that between 30 and 50 mol percent of the non-H_2, non-He material measured by INMS is comprised of organics other than methane, which may constitute an additional 20 to 35 mol percent. C_4 species, including butane (C_4H_{10}) at 58 u, are particularly abundant compared to other hydrocarbons. Above 70 u, the spectra are consistent with contributions from heavier aromatic species, including species such as naphthalene ($C_{10}H_8$, 128 amu) with primary peaks that are beyond the range of INMS.

Other Cassini instruments, including the Charge-Energy-Mass Spectrometer (CHEMS) from the MIMI, reported detections of heavy (8,000 to 40,000 amu) particles during the Grand Finale orbits [Mitchell et al. 2018]. To understand the relationship of these particles to INMS data, we compared the total amount of material detected by INMS to the particle sizes observed by MIMI [Perry et al. 2018]. The results suggest that INMS may have mainly sampled smaller particles that were dominated by volatile and organic material with very little contribution from refractory mineral phases. The altitude-density profiles of these particles indicate very low densities, likely on the order of 0.1 g/cm^3 or less. These densities may be consistent with the densities of interplanetary dust particles from small bodies [Rietmeijer 1993]. Some masses, including 15 u (mainly from CH_4), 28 u (possibly N_2 or CO) and 17 u (mainly NH_3), have altitude-density profiles that are consistent with molecular radii. Other masses, including 58 u (possibly butane, C_4H_{10}) and 78 u (possibly benzene, C_6H_6), have profiles that suggest larger radii, on the order of nanometers or tens of nanometers.

In addition to the heavy species in the upper atmosphere of Saturn, INMS has also made the first in situ measurements of H_2, He, and H-D in the atmosphere of Saturn (shown in Figure INMS-47). Molecular hydrogen (H_2) is the dominant species in the thermosphere, and its density scale height reveals the expected background temperature of Saturn's upper atmosphere. Thus, measurements of H_2 reveal information about the thermal state of Saturn's upper atmosphere. Prior to the INMS measurements, only remote sensing observations were possible [cf. Koskinen et al. 2015; Vervack and Moses 2015], which provide temperatures through inversion techniques. The measurements in **SIA3**, however, provide the first-ever direct sampling of the Saturn atmosphere [Waite et al., 2018; Yelle et al. 2018], allowing us to infer thermal structure from these measurements using models of the atmosphere, such as Müller-Wodarg et al. [2006b, 2012].



Finally, there has been considerable uncertainty about the amount of Helium in the Saturnian atmosphere [Ben-Jaffel and Abbes 2015]. He abundances are key to determining the most likely formation scenarios for Saturn's atmosphere. Currently, it has been suggested that Saturn would be depleted in Helium relative to Jupiter (~13.5% volume mixing ratio) or the protosolar value (~15.6%) due to Helium raining out in the lower atmosphere. The measurements provided by INMS, combined with diffusive modeling, can lead to constraints on the Helium content in the lower atmosphere providing a missing component in our understanding of planetary evolution.

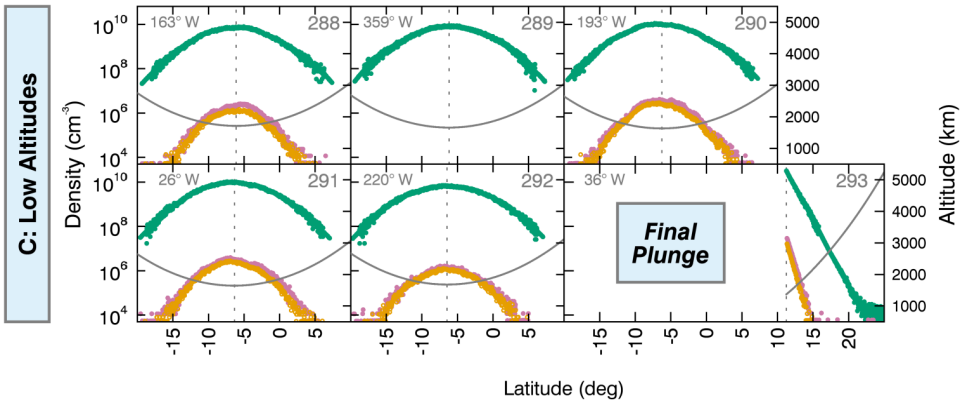


Figure INMS-47. INMS measurements of H_2 (green), He (red), and Mass 3 u (orange) as a function of altitude (*right-hand axis*) and latitude (*horizontal axis*).

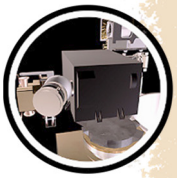
Saturn Upper Atmosphere Major Findings (Charged Gases, i.e, the Ionosphere):

- The INMS made the first in situ measurements of the ion composition of the ionosphere of a gas giant planet (i.e., Saturn), allowing the first determination of ion mixing ratios and number densities as well as their temporal variabilities.
- INMS measurements of the minor ion (H_2^+) represent a strong constraint on local ion production rates providing a check on outer planet projections of solar irradiances, including evidence for ring shadowing of the ionosphere.
- Combined with RPWS and MIMI measurements, INMS in situ data paint a clear picture of Saturn's equatorial ionosphere being dominated by heavy molecular ions that result from ring-derived material.

Prior to the Cassini Grand Finale, observations of Saturn's ionosphere were limited to altitude profiles of electron density (the presumed sum of the ion densities) at dawn or dusk, periods of rapid change in an ionosphere. Trace emissions from an expected major ion (H_3^+) were also detected, but column-integrated densities could only be derived at auroral latitudes. Therefore, ion densities throughout the majority of Saturn's ionosphere were based solely on model comparisons with radio occultation measurements, for example, Moses and Bass [2000]; Moore et al. [2006, 2010]. In situ measurements by INMS provided key constraints on the expected major ion species, H^+ and H_3^+ [Waite et al. 2018; Cravens et al. 2018; Moore et al. 2018], finally providing closure on a decades-long debate regarding the dominant chemical losses of H^+, for example, Connerney and Waite [1984].



In addition, INMS was able to measure the expected minor ion species H_2^+ and He^+. The chemistry of these ions is relatively straightforward, and the extremely short chemical lifetime of H_2^+ makes it an ideal tracer of the in situ ion production rate. Therefore, H_2^+ densities from INMS measurements can be used to gauge the accuracy of commonly used projections of solar irradiances at Saturn. These projections rely on Earth-based data, and the assumption of a relatively stable solar irradiance over a period of days. Comparisons between measured H_2^+ with modeled H_2^+ based on projected solar irradiances find a ~50% discrepancy, implying that future outer planet modeling will require better estimates of the solar irradiance. A drop-off in the H_2^+ density (i.e., ionization rate) observed by INMS near 15° S latitude is consistent with shadowing by the B-ring [Waite et al. 2018; Cravens et al. 2018].

Finally, Cassini's high speed near periapsis during the Grand Finale (~32 km s^{-1}), meant that INMS could only sample ions with masses up to 7 u. The sums of the light ion densities measured by INMS were found to be an excellent match with the electron densities from RPWS, for example, Persoon et al. [2019], at high altitudes (> ~2200 km), implying that Saturn's high-altitude ionosphere was charge-neutral and dominated by H^+ with minor contributions from H_3^+, as expected (Figure INMS-48). However, at low altitudes the total ion densities from INMS differed significantly from the electron densities. This massive discrepancy was interpreted as a signature of an ionosphere dominated by heavy (> 7 u) ions, which would be entirely consistent with the expected ion chemistry to follow from the ring-derived influx of complex neutrals measured by INMS (Figure INMS-46). Detailed model-data comparisons indicated that in the main ionosphere, a complex, and heavy, neutral species was needed to react with H^+ and H_3^+, and thus reduce the model densities of these light species to measured values [Cravens et al. 2018; Moore et al. 2018]. The neutral mixing ratios required were consistent with the values measured by the closed source and described earlier. The ion species produced by these reactions were suggested to be those needed to fill the ion-electron density gap evident in Figure INMS-48.

The ionosphere was demonstrated to be chemically controlled at lower altitudes where the heavy ions are dominant [Cravens et al. 2018; Moore et al. 2018], but at higher altitudes, where H^+ dominates the measured ion composition, transport processes should become important. During the relatively high altitude proximal orbit 287, the INMS open source was operated in a special energy scan mode and some limited information on proton flow speeds was obtained [Cravens et al. 2018]. Proton speeds of a couple km/s were detected in the Northern Hemisphere at latitudes connecting to the B-ring shadow in the Southern Hemisphere.

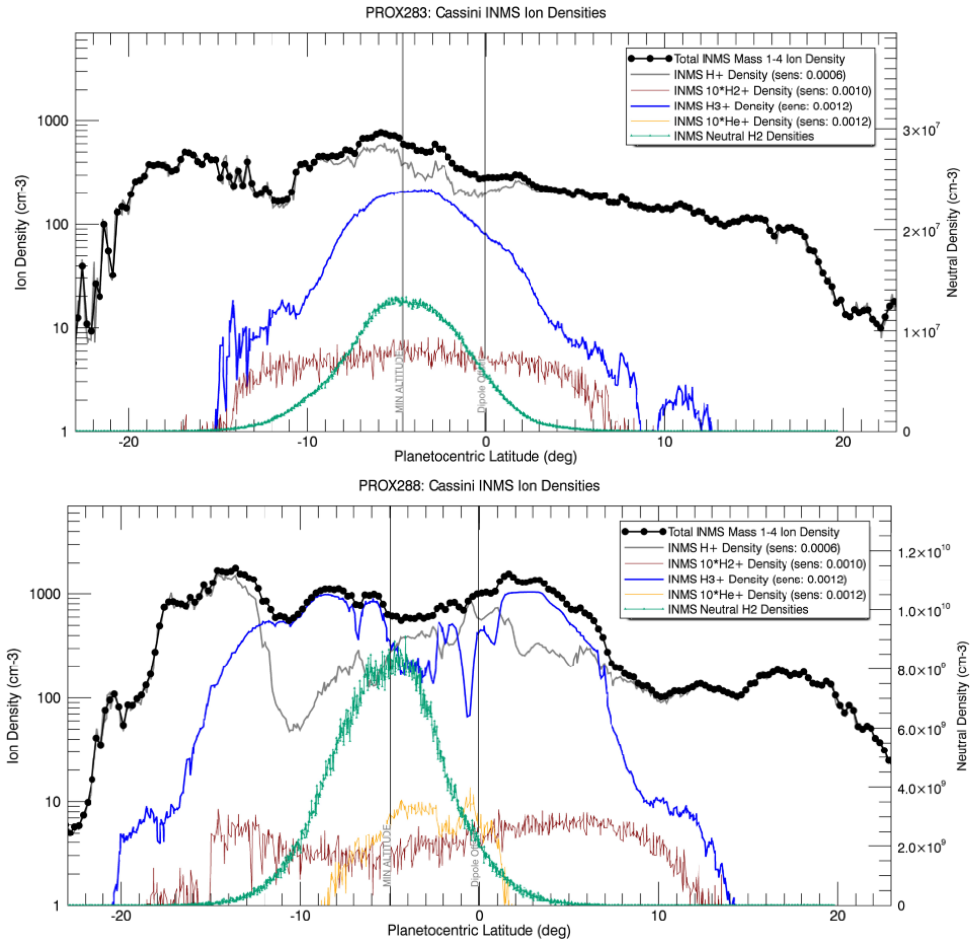


Figure INMS-48. INMS measurements of H_2 (*green*), H^+ (*gray*), H_2^+ (*red*, multiplied by 10), H_3^+ (*blue*), He^+ (*gold*, multiplied by 10), and total light ion density (1–4 u, *black*) as a function of planetocentric latitude (*horizontal axis*). Ion measurements were taken for four proximal orbits, 283, 287, 288, and 292, though only one representative high altitude (283, top) and low altitude (288, bottom) orbit is presented here.

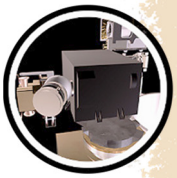
Saturn proximals open questions

1. INMS made the first in situ measurements of He and HD in Saturn's atmosphere. What are the implications of the upper atmosphere He measurements for the abundance of He in the bulk atmosphere? How is the measured HD affected by ring inflow?

2. INMS measured the temperature structure of Saturn's upper atmosphere with significantly higher precision and altitude resolution than is possible with remote sensing techniques. The energy balance in Saturn's upper atmosphere remains an open question.



3. INMS measurements revealed significant influx of material from the rings to the atmosphere.

    a. What causes this inflow, how it relates to ring erosion processes and magnetospheric processes, as well as the implications for atmospheric chemistry remain open questions.

    b. Is the ring influx uniformly distributed about Saturn?

    c. Is the ring influx constant or is there a time dependence?

    d. Does the ring influx respond to magnetospheric processes or solar wind drivers?

    e. How long has the ring influx been taking place? Is the time the same for all species (methane, nanograins, etc.)?

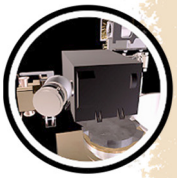
    f. What are the dynamics in equatorial region and how are they affected by the Joule heating measured by MAG??

    g. Presence of negative ions in the equatorial region (and auroral regions too)?

    h. What is the balance between chemistry and transport operating in the low-latitude Saturnian ionosphere?

Open Questions for Saturn System Science

The open questions are found under each subtopic. The big open question for the Saturn system—Is there life in the ocean of Enceladus?



ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AACS	Attitude and Articulation Control System
AO	Announcement of Opportunity
CAPS	Cassini Plasma Spectrometer
CDA	cosmic dust analyzer
CHEMS	Charge-Energy-Mass Spectrometer
CIRS	Composite Infrared Spectrometer
CS	closed source
CSM	Cassini Solstice Mission
CSN	Closed Source Neutral
Da	Daltons
ELS	Electron Spectrometer
ENA	energetic neutral atom
EUV	extreme ultraviolet
GCM	General Circulation Model
IBS	Ion Beam Spectrometer
IP	integration period
ISE	Ion Source Enclosure
ISS	Imaging Science Subsystem
LP	Langmuir probe
MAG	Magnetometer
MAPS	Magnetospheres and Plasma Science
MHD	magneto-hydrodynamic
MIMI	Magnetospheric Imaging Instrument
NAV	Navigation
NIST	National Institute of Standards and Technology
OS	open source
OSI	open source ion
OSNB	open source neutral beam
OSNT	open source neutral thermal
PA	proton affinities
PAH	polycyclic aromatic hydrocarbon
QMA	quadrupole mass analyzer
RPWS	Radio and Plasma Wave Science
TAMWG	Titan Atmospheric Working Group
UVIS	Ultraviolet Imaging Spectrograph
UVS	Ultraviolet Spectrometer
VIMS	Visual and Infrared Imaging Spectrometer

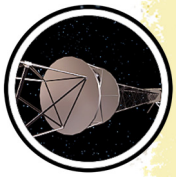
MAGNETOMETER

The Magnetometer (MAG) experiment/instrument onboard the Cassini spacecraft consisted of two magnetometers that measured the magnetic field in and near Saturn's magnetosphere. The **science objectives** of MAG were to determine Saturn's internal magnetic field, map the magnetospheric magnetic field, and characterize the magnetospheric interaction with Titan and the icy satellites. MAG was the first instrument to detect an unusual signature from Enceladus that foreshadowed the Enceladus plume.

MAG consisted of a three-axis Flux-Gate Magnetometer (FGM) and a Vector/Scalar Helium Magnetometer (V/SHM) designed to record the direction and strength of magnetic fields in the Saturn system. On the Cassini spacecraft, the FGM was located midway out on the 11-meter (36-foot) magnetometer boom, and the V/SHM was located at the end of the boom.



CONTENTS

Tables

Executive Summary

The key science results from the Cassini MAG team include, but are not restricted to:

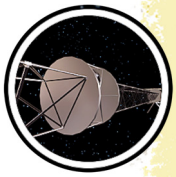
- Discovery of the atmosphere of Enceladus via its magnetospheric interaction.
- Confirmation of the extreme axisymmetry of Saturn's magnetic field (this work, as well as an attempt to pin down the internal rotation rate, continues with analysis of the Grand Finale data set).
- Discovery of low-latitude, intra-D-ring field-aligned current system at Saturn.
- Mission-long magnetic field measurements of Saturn's planetary period oscillations (PPOs) demonstrate strong, but not simple, seasonal control.
- Saturn's atmosphere-ionosphere-magnetosphere coupling current system consists of two interlinked components.
- Much better understanding of Saturn magnetospheric dynamics.
- MAG-led discovery of Titan's magnetic memory.
- MAG-led discovery of Saturn's two-state magnetosphere.
- MAG/ Magnetospheric Imaging Instrument (MIMI) discovery of the internal inflation for Saturn's magnetosphere.

The key outstanding questions from Cassini MAG data and science output include:

- What are the implications of the extremely axisymmetric planetary magnetic field for the internal structure and dynamics of Saturn?
- What is the dynamo process generating this unique planetary field?
- How are the PPOs driven in the atmosphere/ionosphere of Saturn?
- Understand the variety of currents observed during the periapse periods of the Grand Finale orbits and their implications for coupling between the atmosphere-ionosphere-magnetosphere-rings.

MAG Instrument Summary

The Cassini dual technique MAG consisted of a FGM and a V/SHM capable of operating in scalar mode. The instrument was intended to measure small changes in fields spanning four orders of magnitude with extremely high sensitivity. This was achieved in part by mounting the sensors on an 11-meter spacecraft boom, the V/SHM at the end of the boom, the FGM halfway along it. The FGM was based on three single-axis ring core fluxgate sensors mounted orthogonally on a machinable glass ceramic block. In each sensor, a drive coil was wound around a high permeability ring core, which was completely enclosed in a sense winding. The drive coil was driven by a square wave that was used to generate a magnetic field driving the core into saturation twice per cycle.



The presence of an ambient magnetic field component parallel to the axis of the sense coil caused the saturation of the core to become asymmetrical. This induced a second harmonic of the drive frequency in the sense coil, which was proportional to the magnitude of the magnetic field component along that axis. The V/SHM was based on field-dependent light absorption (the Zeeman Effect) and optical pumping to sense the magnetic field. Helium in an absorption cell was excited by a radio frequency discharge to maintain a population of metastable long-lived atoms. Infrared radiation at 1,083 nm from a helium lamp passed through a circular polarizer and the cell to an infrared detector. The absorption of the helium in the cell was dependent on the ambient magnetic field direction. The normal data rate for the instrument was 32 vectors/second with the ability to take data in a burst mode at 64 vectors/second. Magnetic field information was needed by other investigations on the spacecraft and to this end, magnetic field data were made available to Magnetospheres and Plasma Science (MAPS) [Blanc et al. 2002] onboard users every second.

Calibration plans had to be changed a year after arrival at Saturn when the V/SHM stopped operating with regular calibration rolls around two separate axes required for the rest of the mission lifetime to enable calibration of the single FGM and hence resolution of the science objectives of the MAG team. MAG is described in detail in Dougherty et al. [2004]; Kellock et al. [1996]; Smith et al. [2001].

KEY OBJECTIVES FOR MAG

The key science objectives for MAG, as described in the Dougherty et al. [2004] paper, are listed below and divided into two main areas, focusing on the planet and its magnetosphere and on Titan. The third area examining the icy satellites of Saturn gained much more importance of course after the initial observations during the first four years of the mission and the water vapor plume discovery [Dougherty et al. 2006] at Enceladus.

All of the MAG objectives have been achieved, with only the 3-D global field model remaining until all of the end-of-mission data has been completely analyzed and modelled.

Saturn

- Resolve the internal planetary magnetic field to at least fourth order.
- Establish relative contributions to electromagnetic and mechanical stress balance.
- Identify the energy sources for dynamical processes.
- Understand the coupling that occurs between the magnetosphere and ionosphere.
- Characterize the phenomena of the distant dayside/flank planetary environment.
- Survey satellite/dust/ring/torus electromagnetic interactions.
- Determine the tail structure and dynamic processes.

- Provide a three-dimensional (3-D) global model of the magnetospheric magnetic field.

Titan

- Determine the magnetic state of the body and conditions of the atmosphere.
- Characterize and model the Titan electromagnetic environment.
- Interpret and model all Titan-plasma flow interactions and the variation of the Titan-magnetosphere interaction with respect to the Titan orbital phase.
- Determine the nature of the low-frequency waves in the near-Titan plasma environment.

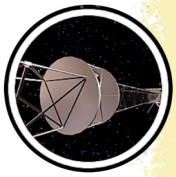
Saturnian satellites other than Titan

- Probe the magnetic state and plasma environment of the Saturnian satellites to the extent possible within the limitation of the chosen trajectory.

All of the above objectives have been achieved, with the exception of the 3-D global field model, which still requires work and will be achieved once all of the end-of-mission data has been completely analyzed and modelled.

Key Objectives for MAG from Announcement of Opportunity (AO) and Cassini Solstice Mission (CSM)

- R_AO5—Ring Magnetosphere-Ionosphere Interactions. Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.
- M_AO1—Determine the configuration of the nearly axially symmetric magnetic field and its relation to the modulation of Saturn kilometric radiation (SKR).
- M_AO2—Magnetosphere Charged Particles. Determine current systems, composition, sources, and sinks of magnetosphere charged particles.
- M_AO03—Investigate wave-particle interactions and dynamics of the dayside magnetosphere and the magnetotail of Saturn and their interactions with the solar wind, the satellites, and the rings.
- M_AO4—Magnetosphere and Solar Interactions with Titan. Study the effect of Titan’s interaction with the solar wind and magnetospheric plasma.
- M_AO5—Plasma Interactions with Titan’s Atmosphere and Ionosphere. Investigate interactions of Titan’s atmosphere and exosphere with the surrounding plasma.
- I_AO5—Icy Satellite Magnetosphere and Ring Interactions. Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.



- J_AO3—Explore the dusk side of the magnetosphere and intermediate regions of the magnetotail unvisited by previous spacecraft.
- C_AO2—Investigate the behavior of the solar wind during solar minimum, for comparison with earlier Galileo and Ulysses measurements.
- S_AO3—Saturn Interior Structure and Rotation. Infer the internal structure and rotation of the deep atmosphere.
- S_AO4—Saturn Ionosphere-Magnetosphere Interaction. Study the diurnal variations and magnetic control of the ionosphere of Saturn.
- T_AO4—Determine the physical state, topography, and composition of the surface; infer the internal structure of the satellite.
- IN1a—Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.
- IN1c—Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.
- IN2b—Determine whether Tethys contributes to the E-ring and the magnetospheric ion and neutral population.
- SC2a—Observe the magnetosphere, ionosphere, and aurora as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.
- SN1a—Determine Saturn's rotation rate and internal structure despite the planetary magnetic field's unexpected high degree of axisymmetry.
- MC1a—Determine the temporal variability of Enceladus' plumes.
- MC1b—Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.
- MC2a—Observe seasonal variation of Titan's ionosphere from one solstice to the next.
- MN1a—Determine the dynamics of Saturn's magnetotail.
- MN1b—Conduct in situ and remote sensing studies of Saturn's ionosphere and inner radiation belt.
- MN1c—Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the SKR periods are imposed from close to the planet (3–5 R_S) out to the deep tail.
- MN2a—Determine the coupling between Saturn's rings and ionosphere.

- TC2a—Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.
- TN1b—Determine internal and crustal structure: liquid mantle, crustal mass distribution, rotational state of the surface with time, intrinsic and/or internal induced magnetic field.

MAG Science Assessment

Table MAG-1. AO and TM objectives are paired with MAG science objectives.

Fully/Mostly Accomplished: **Partially Accomplished:** **Not Accomplished:**

MAG Science Objectives Characterize the following:	AO and TM Science Objectives	MAG Science Assessment	Comments, if yellow (partially fulfilled)
Planetary magnetic field	S_AO3, M_AO1, SN1a		
Magnetospheric structure and dynamics			
Magnetospheric periodicities	MN1c, SC2a		
Saturn magnetosphere-ionosphere coupling	R_AO5, S_AO4, MN1b, MN1c, MN2a		
Magnetospheric current systems	M_AO2		
Magnetosphere—dayside, middle magnetosphere, magnetotail, solar wind interaction	M_AO3, MN1a		
Seasonal and solar wind variation	SC2a, MC1b		
Ring-magnetosphere interactions	R_AO5, MN2a		
Titan			
Titan and magnetospheric interaction	M_AO4, M_AO5, T_AO4, MC2a, TC2a, TN1b		
Icy satellites			
Enceladus internal structure and activity	MC1a, IN1a

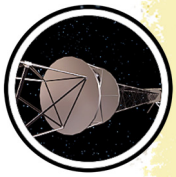
MAG Saturn System Science Results

Saturn's Bow Shock

The distant apoapsis orbits by the Cassini spacecraft around Saturn over many years enabled hundreds of bow shock crossings. This allowed for thorough analyses from modelling the (3-D) shape and predicting the location of the boundary to investigating the microphysics of high Mach



number shocks. The magnetometer instrument proved indispensable in advancing our understanding of Saturn's bow shock. Below are the highlights:

Detailed characterization of Saturn's bow shock

Masters et al. [2008a] and Went et al. [2011a] developed the most comprehensive semi-empirical model of Saturn's dayside bow shock. The average 3-D shape of the boundary was constructed and equations relating the response of the subsolar point to variations in solar wind dynamic pressure were derived. The identification of bow shock crossings was most reliably and straightforwardly achieved using MAG. The classic signature for an inbound crossing, i.e., from the solar wind to the magnetosheath, was an abrupt rise from a low and steady to a large (~4x) and turbulent magnetic field strength. The reverse was the case for an outbound crossing.

The magnetometer instrument proved indispensable in advancing our understanding of Saturn's bow shock.

Achilleos et al. [2006] presented magnetic field signatures of some of the earliest crossings in the mission. Their results showed clearly defined overshoot and foot signatures that are typical of quasi-perpendicular shocks. This is one of two configurations of shocks in magnetized plasmas (the other being quasi-parallel) where the local normal to the shock surface makes an angle of >45° to the interplanetary magnetic field. This is by virtue of the Parker spiral structure of the interplanetary magnetic field (IMF) at 10 AU, where the magnetic fields met the bow shock with very large azimuthal components. Sulaiman et al. [2016] characterized Saturn's bow shock using the largest sample of crossings to date. With the utility of the aforementioned models, they showed Saturn's dayside bow shock was in the quasi-perpendicular configuration for a large majority of the time. Further, they estimated the Alfvén Mach numbers (a measure of the shock's strength) for all crossings to show that Saturn's bow shock spans over a very wide range of parameter space. The bow shock was found to exhibit characteristics akin to both terrestrial and astrophysical regimes. This laid the foundation for further detailed studies specific to astrophysical shocks (e.g., surrounding young supernova remnants), providing an in situ insight into such regimes, which were otherwise studied using remote observations and/or simulations. Masters et al. [2008b, 2009a] presented a survey of hot flow anomalies at Saturn's bow shock, all of which were associated with energization of solar wind electrons. Having been a well-established phenomenon at the Earth's bow shock, these works underlined hot flow anomalies as a solar system-wide phenomenon.

Dissipation at high Mach number shocks

In the presence of an obstacle, shock waves in a neutral gas efficiently dissipate the supersonic flow to subsonic through the action of collisions. In space plasmas, however, shocks cannot rely on collisions to adequately dissipate the flow since the collisional mean free path is many orders of magnitude larger than the shock's width. Here, electromagnetic forces play important roles to compensate for the additional dissipation required. Their roles are well understood for modest Mach

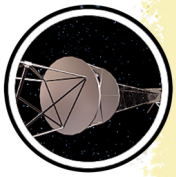
numbers (e.g., 2–10). However, the dissipation becomes more complicated at larger Mach numbers since additional kinetic processes, namely ion reflection and reformation, come into play to complete the process. Fortunately, such high Mach number phenomena were explored using the Cassini magnetometer dataset. Sulaiman et al. [2015] showed evidence for the timescales of ions reflection at a shock undergoing reformation to be 0.3 times the upstream gyroperiod. This was in excellent agreement with what had been theorized.

Masters et al. [2011a] investigated the Mach number dependence of electron heating across a bow shock. Their work presented a positive correlation between the electron temperature increase across the shock and kinetic energy of an incident proton, where electron heating accounts for ~3%–7% of the incident ram energy. Further, they confirmed that the trend of the decreasing percentage with increasing Alfvén Mach number continues into the poorly explored high Mach number regime, up to ~150. Masters et al. [2013a] compared observations of overshoots between Mercury's and Saturn's bow shocks, both of which represent drastically different Mach numbers in parameter space. They showed, on average, the overshoots at Saturn's bow shock were much higher than those observed at Mercury's. This supported the larger role of particle dynamics at higher Mach numbers. The low Mach number class of shocks were also explored. Sulaiman et al. [2017a] examined the dispersive properties of Saturn's bow shock through the identification of electromagnetic precursors consistent with whistler waves. These waves were believed to play a limited role in the dissipation process and were found to be right-handed circularly polarized with a frequency of 0.2–0.4 Hz in the spacecraft frame.

Electron acceleration at high Mach number shocks

Collisionless shock waves are also known to be efficient particle accelerators. It is widely believed that a large proportion of cosmic rays originate from energetic charged particles accelerated at collisionless shocks associated with supernova explosions in our galaxy. Masters et al. [2013b] confirmed, for the first time, electron acceleration up to relativistic energies at an unusually strong Saturn bow shock under a quasi-perpendicular configuration. This contradicted previous knowledge purporting a magnetic dependence on this phenomenon. Further works by Masters et al. [2016] and Masters et al. [2017] provided the full picture of suprathermal electrons at Saturn's bow shock. They showed results that are consistent with the theory in which the injection of thermal electrons into an acceleration process is possible for all magnetic field configurations at high Mach numbers.

Additionally, MAG provided important observations to study the properties of Saturn's foreshock, the portion of the upstream solar wind magnetically connected to Saturn's bow shock. An in-depth characterization of the waves originating from solar wind-charged particles backstreaming from the shock [Bertucci et al. 2007a] was followed by the identification of the spatial extent of the region where these waves are observed [Andres et al. 2013] with a technique that was also successfully applied to the Earth's foreshock [Andres et al. 2015].



Saturn's Magnetosheath

Long-term sampling of Saturn's magnetosheath by Cassini afforded the most complete coverage of this intermediary region between the unshocked solar wind and Saturn's magnetosphere. A relatively high Alfvén Mach number solar wind and a polar-flattened magnetosphere make Saturn's magnetosheath both physically and geometrically distinct from the Earth's. Fast rotating gas giants, such as Saturn, are bulged along the equator and flattened along the poles owing to their embedded plasma disks and for this reason, Sulaiman et al. [2014] showed that the magnetic structure of Saturn's magnetosheath significantly deviated from axisymmetry. Their results showed large northward/southward components in the magnetic field despite the prevailing Parker spiral configuration being largely in the equatorial plane.

Sulaiman et al. [2017b] addressed the impact of nonaxisymmetry with the aid of magneto-hydrodynamic (MHD) simulations. They showed that Saturn's polar-flattened magnetosphere channels ~20% more flow over the poles than around the flanks at the terminator. They further showed the pressure gradient force is the primary driver accelerating the magnetosheath plasma. This is by virtue of the high-β plasma and, in turn, the high Mach number bow shock. This translated into larger pressure gradients over shorter paths (over poles) compared to longer paths (around flanks), which explained the net torque on magnetic field lines to produce the large northward/southward components. These results are anticipated to provide a more accurate insight into the global conditions upstream of Saturn and the outer planets.

Saturn's Magnetopause

Data taken by MAG at the magnetopause boundary of Saturn's giant magnetosphere have allowed us to examine the ways in which energy can be transferred into and out of near-Saturn space. Understanding this is crucial for revealing the dynamics of the coupled planetary system of magnetosphere, moons, rings, and atmosphere.

A good understanding of the geometry of the magnetopause, and how its position changes with the pressure of the solar wind, is important for characterizing the distant dayside magnetosphere and in developing a 3-D global model of the magnetospheric magnetic field. Arridge et al. [2006] used early measurements of the magnetopause from Cassini/MAG, combined with measurements from Voyager 1 and 2, and Pioneer 11, to develop a new model of Saturn's magnetopause. This study employed a new mathematical formulation, borrowed from studies of the terrestrial magnetosphere, and a new modelling methodology. This revealed that Saturn's magnetosphere was more compressible than previously thought: more compressible than Earth's magnetosphere, but less than that of Jupiter. This was confirmed and enhanced in further studies using larger datasets from Cassini/MAG [Kanani et al. 2010; Pilkington et al. 2015a]. In a study by Achilleos et al. [2008], the MAG team analyzed some of the early orbits and the points along those orbits where the spacecraft crossed the magnetopause. By analyzing the distribution of the magnetopause crossings, we concluded that the size of the magnetosphere was certainly being controlled by the dynamic pressure of the solar wind upstream of the planet, but that there was also

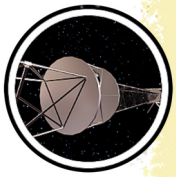
evidence for an additional influence, probably due to a process internal to the magnetosphere. The system preferentially spent most of the time in one of two states, characterized by subsolar magnetopause distances near ~22 and ~27 Saturn radii.

A study some years later [Pilkington et al. 2015b] built upon this work by constructing an up-to-date empirical model of Saturn's magnetopause, based on an extensive set of magnetopause crossings observed by the spacecraft. We found that we could not satisfactorily fit these crossings in their entirety by assuming a system whose size responded only to solar wind pressure. By separating the crossings into subsets based on additional plasma data from the MIMI instrument, we were able to demonstrate that Saturn's magnetosphere plausibly made transitions between states that were plasma-light and plasma-loaded, this form of internal control exerting additional influence on the magnetopause size. The work of Pilkington et al. [2015b] represented a natural progression from an earlier version of the Saturn magnetopause model developed by Arridge et al. [2006], based on a necessarily more limited dataset from several years earlier in the mission.

The structure of the magnetopause boundary itself provides information about the processes at work in this region of Saturn's space environment. MAG data have shown that the magnetopause current layer itself is typically in motion at speeds of order 100 km s^{-1} [Masters et al. 2011b]. This very high speed is considerably faster than that of the spacecraft during magnetopause encounters (a few km s^{-1}). The data also provide the first clear evidence for the existence of a boundary layer of mixed plasma immediately inside the magnetopause [Masters 2011a]. This low-latitude boundary layer is particularly important because it is the direct result of the mass and energy transport that we wish to understand. Magnetic field measurements have played a crucial role in determining that the typical thickness of the layer is approximately 1 Saturn radius (~60,000 km).

The observed variability in low-latitude boundary layer properties between spacecraft crossings of the near-magnetopause region led to a number of surprises. Firstly, the basic thermal electron structure of the layer is significantly variable—a phenomenon not reported in the context of Earth's magnetosphere, and yet to be explained [Masters et al. 2011c]. Secondly, the thickness of the layer itself shows no clear response to the direction of the Sun's interplanetary magnetic field in the vicinity of Saturn, in stark contrast with the behavior of the equivalent region of Earth's magnetosphere [Masters et al. 2011b]. The latter of these two unexpected results can help us to reveal the nature of a particular boundary process.

Magnetic reconnection is a fundamental process that can operate at a current sheet. It results in the release of energy stored in the local magnetic field, leading to acceleration of charged particles and allowing the direct transfer of mass and energy across an otherwise closed boundary. While evidence for the known operation of reconnection at Saturn's magnetopause has been sparse, MAG observations have formed the basis of important assessments that have broad implications. The first such assessment demonstrated that conditions at the magnetopause boundary of Saturn's magnetosphere are dramatically unlike those at Earth's magnetopause. As a result, reconnection at Saturn's magnetopause should be more restricted to regions where magnetic field lines adjacent to the boundary are locally anti-parallel to each other [Masters 2012a].



This Cassini result led to a shift in how we think about the solar wind-magnetosphere interaction at Saturn, with implications for other magnetized planets.

> Understanding the ways in which energy can be transferred into and out of near-Saturn space is crucial for revealing the dynamics of the coupled planetary system of magnetosphere, moons, rings, and atmosphere.

MAG data has also shown that when reconnection operates at Saturn's magnetopause it likely does so at a speed that is far slower than that associated with reconnection in environments closer to the Sun—for example, the solar corona, the solar wind, Earth's magnetopause, Earth's magnetotail [Masters et al. 2014a]. The reason for this is the way that solar wind properties change as the plasma moves away from the Sun. The Alfvén speed, which dictates the speed of reconnection, drops with heliocentric distance, producing a relatively slow reconnection process at Saturn's magnetopause and consistent with the lack of evidence for rapid boundary later response discussed above. This result directly contributed to further work that showed that driving of Saturn's magnetosphere by global magnetopause reconnection is rarely strong enough to compete with the internal driving of the system that results from the combination of fast planetary rotation and plasma production due to the plumes of Enceladus [Masters 2015].

A search for reconnection signatures at the Saturnian magnetopause from 10:00 to 14:00 Saturn local time (SLT) was carried out. We found brief intervals during which the normal component of the magnetic field across the magnetopause becomes significantly enhanced for typically 1 to 10 minutes. Through these magnetic bridges, the magnetosphere is connected to the magnetosheath. To determine if the magnetic reconnection leads to a measurable transfer of magnetic flux from the dayside, we checked the location of the magnetopause standoff distance for both northward and southward magnetosheath field. We found no obvious dependence of the distance on the direction of the magnetosheath field, indicating that dayside reconnection does not play a significant role in Saturnian magnetospheric dynamics [Lai et al. 2012].

The other important mechanism by which solar wind energy can enter a planetary magnetosphere is via a viscous-like interaction. This is underpinned by another fundamental process: Growth of the Kelvin-Helmholtz (K-H) instability. Where there are large plasma flow shears across a magnetopause this instability can lead to the evolution of small boundary perturbations in to gentle waves and eventually in to large, rolled-up vortices. The first evidence for magnetopause surface waves from Cassini came in the form of normals to the boundary determined from magnetic field observations that exhibited an oscillation in a preferred direction from one magnetopause crossing to the next [Masters et al. 2009b]. The direction of wave propagation (direction of boundary normal oscillation) was controlled by the local direction of the magnetic field inside the boundary, consistent with K-H-driven waves.

Extension of this initial study to consider hundreds of magnetopause crossings over a period of years subsequently revealed the bigger picture [Masters et al. 2012a]. Such waves are

ubiquitous, present at approximately half of all magnetopause encounters made by Cassini. Further evidence of the influence of adjacent magnetic fields on the wave propagation direction and a dawn-dusk difference in typical wave period demonstrated that growth of the K-H instability is one of the major drivers of these waves and, potentially, the dominant driver.

Perhaps the most compelling evidence for K-H instability at Saturn's magnetopause is the reported evidence that the spacecraft flew through a K-H–driven plasma vortex on the magnetopause in December 2004 [Masters et al. 2010]. Surprisingly, this vortex encounter coincided with detection of electrons with energies exceeding ~20 keV. This unexpected feature led Cassini scientists to speculate that there may be electrodynamic coupling between boundary vortices and Saturn's upper atmosphere, potentially producing some of the spot-like features regularly observed in the sources of planetary auroral emissions.

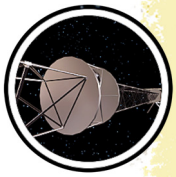
Similar to many topics, Cassini has revolutionized our understanding of how the solar wind influences Saturn's giant magnetosphere, where magnetic field observations are an essential element. Many questions have been answered, with a number of unexpected results. Cassini has made us redefine major open questions, to be addressed by future missions. An important open question relevant for this topic in the post-Cassini era is: Does the solar wind primarily interact with Saturn's magnetosphere through K-H instability?

Saturn's Magnetosphere

Saturn's cusp

At Earth, the solar wind is the primary energy source that can drive dynamical processes in the magnetosphere, and it is also a primary source of plasma. Before Cassini's arrival, it was not clear what role the solar wind played in driving the Saturnian magnetosphere, and so understanding the coupling between the solar wind and the magnetosphere, characterizing the phenomena of the distant dayside/flank planetary environment was an important goal. This included studying viscous and magnetic reconnection processes at the magnetopause. Flux transfer events are a signature of dayside magnetic reconnection at Earth, Mercury, and Jupiter, and consist of a rope of magnetic flux and plasma peeling away from the magnetopause. Jasinski et al. [2016] presented an example of a flux transfer event at Saturn (the only one) and showed that this single event made a fairly small contribution (<10%) to the magnetic flux transport budget, although it was not clear how typical this event was, and if they are more prevalent at locations on the magnetopause not sampled by Cassini.

At higher latitudes, a region known as the cusp maps to a very wide region of the magnetopause and so is ideal for remote monitoring of the magnetopause for reconnection signatures, revealing coupling between the solar wind and the magnetosphere. Cassini's inclined orbits during 2007/2008 and 2013/2014 were ideal to study this coupling process in plasma—Cassini Plasma Spectrometer (CAPS)—and the magnetic field—MAG. Some of the early inclined orbits in early 2007 showed evidence of solar wind plasma gaining entry into the magnetosphere



[Arridge et al. 2016a]. This work showed evidence for movement of the cusp region in phase with magnetospheric (so-called planetary-period) oscillations, indicating the presence of current systems in the magnetosphere. It was also found that magnetopause reconnection was possible under both compressed and expanded magnetospheric conditions [Jasinski et al. 2016; Arridge et al. 2016a], and that the reconnection process could proceed in an unsteady fashion and at various locations on the magnetopause [Jasinski et al. 2014, 2016; Arridge et al. 2016a]. Cavities, where the plasma reduced the local magnetic field strength, were also detected, similar to Earth and Mercury, but at Saturn, the plasma was less capable of reducing the magnetic field strength, and there were important morphological differences due to the presence of internal plasma in the magnetosphere [Jasinski et al. 2017]. Saturn's cusp is the most thoroughly surveyed amongst the giant planets, and sets important context for the Juno mission at Jupiter.

Disk-like magnetosphere

Saturn's magnetosphere is an example of a rapidly rotating system dominated over much of its extent by a large magnetodisk of rotating plasma, this material falling further behind corotation with the planet as we go to larger distances from the planet. Because the system is so large, centrifugal force becomes very effective at keeping the cold plasma confined as this near-equatorial disk. In order to develop a first-principles model of Saturn's magnetodisk region, Achilleos et al. [2010a] adapted a model of field and plasma developed for the Jovian system by Caudal [1986], using plasma data available at that time to constrain the model's boundary conditions. This model was successfully used to explain the observed response of the planet's magnetospheric field to changes in system size. We were also able to compare the model contributions to the total magnetodisk current associated with the various forces on the plasma—centrifugal force and pressure gradient force—for both the Kronian and Jovian magnetodisk systems. A follow-up study by Achilleos et al. [2010b] explored particularly the influence of global changes in the energetic particle population on Saturn's magnetodisk structure. This model was also used in a study by Sorba et al. [2017], who developed theoretical compressibility curves showing how the magnetodisk size responds to changes in solar wind pressure and internal plasma content (energetic particles). These theoretical results were in good agreement with the observational analysis of Pilkington et al. [2015b] and we were also able to use the model to explain why one would expect the compressibility of the system to vary with system size. We have also had some success in using this magnetodisc model, combined with the current sheet elevation model of Arridge et al. [2011a], in order to model global, near-planetary-period oscillations in the magnetic field and plasma properties [Achilleos et al. 2014].

It has been shown that periodic variations of the plasma density peak at different rotation phases depending on radial distance in the magnetosphere. We showed that this variation arises as a consequence of the interaction between simple rotation and the expansion and contraction of the magnetosphere associated with propagating compressional disturbances [Ramer et al. 2017]. Propagating compressional disturbances also cause the magnetopause to move in and out non-sinusoidally and somewhat asymmetrically [Kivelson and Jia 2014]. The simulation also explains

the dawn–dusk asymmetry of field configuration and plasma flows in Saturn's magnetosphere [Jia and Kivelson 2016].

Drivers of magnetospheric dynamics

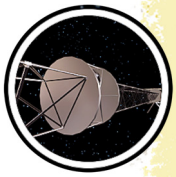
Saturn is often placed in between Earth (solar wind driven) and Jupiter (internally driven) in terms of its magnetospheric dynamics, but this is an oversimplified picture. Much work has been done to characterize the structure of the solar wind upstream of the planet. Jackman et al. [2004] analyzed several solar rotations worth of upstream IMF data while Cassini was approaching Saturn, and Jackman et al. [2005a] followed up with an analysis of the solar wind excursion on Cassini's long first capture orbit. Overall, it was found that during the declining phase of the solar cycle, the IMF is structured into a very clear pattern of two compressions per solar rotation separated by rarefactions. This structuring is very useful because it helps to predict the phasing of intermittent driving of the magnetosphere by the solar wind. Jackman et al. [2004] developed an empirical formula to calculate how much open flux is generated through dayside reconnection, dependent on the IMF direction, the solar wind velocity, and assuming a certain length of a predicted reconnection x-line at the dayside magnetopause. This formula has since been widely used by many other authors, in particular to compare to auroral images that seem to indicate addition and removal of flux—for example, Badman et al. [2005, 2012]. The solar wind conditions at Saturn (and Jupiter) spanning all stages of the solar cycle were summarized in Jackman and Arridge [2011a]. Reconnection voltages were predicted to be slightly lower at solar minimum than solar maximum, while increased photoionization of the Enceladus torus at solar maximum can lead to a more plasma dominated system at this stage of the solar cycle.

In a review article [Khurana et al. 2018], we showed that both azimuthal and radial currents in Saturn's magnetosphere exhibit local time asymmetries as has been reported in Jupiter's magnetosphere. Further, in these magnetospheres, the corotation enforcement currents (CEC), which flow in the radial direction in the current sheet, rival the strengths of their azimuthal ring currents. We also reviewed our knowledge of the field-aligned currents (FACs) in these magnetospheres.

> Before Cassini's arrival, it was not clear what the role the solar wind played in driving the magnetosphere, and so understanding the coupling between the solar wind and the magnetosphere … was an important goal.

Magnetic flux and plasma circulation

In Lai et al. [2016], we investigated the returning flux tubes in the inner Saturnian magnetosphere. By studying the location distribution of the flux tubes, we confirmed that their magnetic signatures are different depending on the background plasma environments. Inside the plasma disk, the returning magnetic field is enhanced in strength, while outside the plasma disk, the magnetic field is depressed in strength. We also suggested that the flux tubes break into smaller ones as they convect in. By statistically comparing the entrance and exit normal vectors of the flux tubes, we



determined the shape of their cross-section. We found that it is closer to circular than fingerlike as produced in the simulations based on the interchange mechanism. In addition, no sudden changes in any flux tube properties can be found at the boundary, which has been claimed to separate the reconnection and interchange-dominant regions. By matching the magnetic flux transporting rate with the tail reconnection rate, a reasonable cold plasma loss rate (~150 kg/s) is derived. Meanwhile, the estimated outflow velocity agrees with earlier observations [Wilson et al. 2008].

Magnetotail structure

Cassini MAG measurements (often in concert with plasma measurements) have been used to characterize the tail in terms of distinguishing the lobe and plasma sheet regions and exploring how they change with distance from the planet. The current sheet is found to be warped out of the equatorial plane [Arridge et al. 2008a], with a characteristic hinging distance of ~25 R_S. This warping made a significant impact in Saturn's southern hemisphere summer in 2006 when Cassini executed its deepest tail orbits, first in the equatorial plane (below the hinged current sheet) and later at higher latitudes (close to the hinged current sheet). The current sheet has also been found to flap, or oscillate vertically with a period close to the ~10 hours linked to the mysterious planetary periodicities. Jackman and Arridge [2011b] performed a statistical study of Saturn's lobes and plasma sheet during 2006, developing numerical definitions for these regions, and deriving the falloff of the field strength in the lobes with radial distance. They found that the near magnetotail of Saturn is similar to that of Jupiter and Earth (when scaled to a common distance). Unlike at Earth, we do not have spacecraft coverage of the asymptotic tail region, but rather have likely only covered the part of the tail where the magnetopause boundary is still flaring outward and where the lobe field strength is falling off before reaching a steady asymptotic level. We do not know the exact length of Saturn's tail, but can consider arguments first made by Dungey [1965] for the Earth where length was estimated by time for open field lines to be dragged over the poles before ultimately sinking in toward the center of the tail before reconnection (giving ~1,000 R_E). Milan et al. [2005] examined the case at Saturn where the polar cap refresh time (i.e., the time for magnetic flux to be cycled through dayside to nightside reconnection) is expected to be many days—for example, Jackman et al. [2004] compared to a much shorter (~10–11 hours) planetary rotation period. This may be expected to twist the lobes of the tail and Milan argued each turn of a twisted lobe could be ~900 R_S long. They theorized that Saturn is a last-in–first-out system in which recently opened field lines are the first to be closed by reconnection in the tail, due to this twist. This implies that Saturn's tail lobes contain a core of old open field lines that can be stretched to incredible lengths (>15,000 R_S).

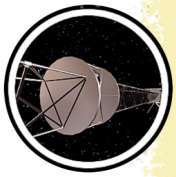
It has been described how periodic compressional waves can account for periodic variation in the thickness of Saturn's nightside plasma sheet and proposed resonances as an explanation for the appearance of banded structure in ion dynamic spectra [Thomsen et al. 2017].

In situ observations of reconnection

Saturn's magnetosphere is observed to undergo dramatic, explosive energy release events. The first indication of such behavior was on the outbound pass of Saturn Orbit Insertion (SOI) where Bunce et al. [2005] reported an episode of solar wind compression-induced tail reconnection, with dipolarizing field and injection of hot plasma. The products of reconnection tailward of the x-line (plasmoids and travelling compression regions [TCRs]), were first observed with the Cassini magnetometer by Jackman et al. [2007]. They are identified primarily by a bipolar deflection in the north-south component of the field, with northward turnings implying reconnection products tailward of the x-line and southward turnings implying dipolarizations planetward of the x-line. Multi-instrument views of reconnection events reveal changes in the flow pattern from azimuthal to tailward and local heating of the plasma—for example, Jackman et al. [2008a]. It is sometimes observed that northward turnings are not purely bipolar but instead have an extended interval where the field remains northward. This has been interpreted as the Kronian equivalent of the post-plasmoid plasma sheet [Jackman et al. 2011], which represents an interval where previously open flux is being closed by reconnection.

Over the years, catalogs of reconnection events were built up from by-eye surveys and basic automation involving simple background thresholding of the magnetic field and searching for significant deflections above or below these thresholds. Surveys covering the deepest tail orbits of 2006 revealed a significant imbalance between the rate of mass loss inferred from plasmoid release and the rate of mass loading from the moon Enceladus, which has been termed the mass budget problem [Jackman et al. 2014]. More sophisticated automated event searches have returned surveys of >2,000 events from tail orbits during 2006, 2009, and 2010, and Smith et al. [2016] revealed that the rate of observed reconnection events peaked post-midnight, with a highly variable radial location of the reconnection x-line, with an average ranging from 20–30 R_S from the planet. To date only one study has identified the x-line region itself [Arridge et al. 2016b], while more recently Smith et al. [2018a] presented a series of very short duration reconnection-related inward and outward flows in quick succession on the dusk flank. Their interpretation was that over a 7-hour interval investigated, reconnection sites had formed both tailward and planetward of the spacecraft, showing that reconnection can operate on small spatial/temporal scales. A second case study showed an event during which the reconnection site was inferred to retreat tailward, resulting in progressively hotter, dipolarizing material reaching Cassini.

The properties of dipolarizations planetward of the x-line give us another view of the impact of reconnection on the magnetosphere. Jackman et al. [2013] published a case study that showed rapid acceleration of newly-reconnected field lines back toward the planet. The transition from a radially stretched to dipolar field configuration can cause a current which usually flows across the tail to divert into the ionosphere, potentially leading to bright, distinct spots of auroral emission. Jackman et al. [2015] further showed that dipolarization of the field can be accompanied by ion flows at speeds of up to 1,500 km/s toward the planet following tail reconnection, representing a significant departure from the slower, subcorotational flow typically seen in the tail. A reconnection event that starts at a small x-line can have a big impact on the magnetosphere as a whole.



Dipolarizations themselves have also been shown to have a dramatic effect on the local plasma: Smith et al. [2018b] investigated dipolarizations as identified from southward deflections of the magnetic field and found they were clustered preferentially post-midnight. The analysis of the accompanying CAPS data showed that the dipolarizing material was systematically hotter and less dense than the ambient plasma sheet. This density depletion and heating was found to be much more variable post-midnight, suggesting a more variable reconnection site.

Remote observations of global impact of reconnection

It is also important to consider how reconnection fits into the bigger picture of global magnetospheric dynamics. Jackman et al. [2016] reported that, like so many other phenomena, tail reconnection at Saturn is organized by northern and southern magnetic phase. Events are specifically linked to current sheet thinning and outward displacement of field and plasma. Little evidence was found for visibility effects associated with the north-south motion of the plasma sheet.

The question of whether reconnection is linked to internal or external drivers is an important one, and one approach to exploring this is to examine the radio data that accompany the magnetometer observations. Jackman et al. [2005b] explored concurrent IMF and SKR data from Cassini during Saturn Orbit Insertion. They showed that the SKR intensified and extended to lower frequencies coincident with the arrival of a solar wind compression, while many other studies have also explored this strong link between the radio power (and frequency) and the nature of the solar wind.

Jackman et al. [2009a] explored the SKR in more detail, focusing on several case studies where reconnection had been observed in Saturn's magnetotail. In general, they found a good correlation between the timing of reconnection events and enhancements in the SKR emissions. A physical mechanism was put forward whereby reconnection increases the precipitation of energetic particles into the auroral zones, leads to the formation of a potential drop, and thus stimulates the motion of the SKR source region to higher altitudes along the field line (and, hence, lower frequencies of radio emission). These low frequency extensions (LFEs) of the SKR were seen as strong proxies for dynamic solar wind compression and/or tail reconnection events.

Reed et al. [2018] attempted to automate the search for these LFEs in the SKR data and correlated 282 LFEs found during 2006 with a larger catalogue of reconnection events. LFEs were grouped into two categories, with short events of duration <20 hours separated by a median waiting time of ~10 hours, and strongly correlated with the northern and southern SKR phases. 60% of short LFEs have a reconnection event within the preceding 6 hours. The second category, long events, had duration >20 hours, often lasting multiple planetary rotations and associated with increases in solar wind dynamic pressure.

Saturn's magnetodisk current

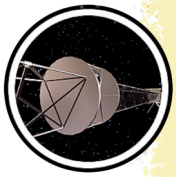
Amongst the central goals of the Cassini magnetic field investigation is the characterization of the large-scale current systems that flow in Saturn's magnetosphere, their typical properties together

with their variability and dynamical behavior. The largest of these is Saturn's ring/magnetodisk current. This current flows in the equatorial magnetosphere eastward around the planet, extending the field lines radially outward and carried by the differential drift of ions and electrons in the plasma trapped on Saturn's magnetic field lines, which grades into the cross-tail plasma sheet current separating the lobes of the magnetic tail on the nightside. Although the existence of the ring current was first established from magnetic data acquired during the Pioneer-11 and Voyager flybys, little was known of the variability of the current, and its physical nature remained a matter of controversy, whether due to centrifugal action of the plasma mass or to the effect of plasma pressure. Data from the initial sequence of near-equatorial Cassini orbits was first used to determine the strength and radial extent of the current, showing that these vary strongly with the size of the magnetosphere dependent on the dynamic pressure of the impinging solar wind [Bunce et al. 2007]. While the inner edge of the current lies nearly unvaryingly at an equatorial radial distance of ~7 R_S, the radius of the outer edge varies between ~15 R_S when the magnetosphere is strongly compressed to ~22 R_S when it is significantly expanded, these distances typically lying only few R_S inside the dayside magnetopause. Correspondingly, the total eastward current varies from ~9 to ~15 MA, with a magnetic dipole moment that varies between ~0.2 and ~0.6 that of the internal field of the planet. A consequence is that while the dayside and comparably near nightside field is quasi-dipolar in form when the system is compressed, the field lines extend into an equatorial magnetodisk when it is expanded [Bunce et al. 2008a]. Later, when data from the first highly inclined Cassini orbits became available, the first direct measurements of the north-south thickness of the current sheet were also made, with values being typically ~3 R_S on the dayside, while varying between ~1 and ~5 R_S on the nightside [Kellett et al. 2009].

Cassini/MAG data revealed the magnetodisc [Arridge et al. 2008b; Bunce et al. 2008a] was particularly sensitive to the solar wind pressure, essentially disappearing on the dayside when the magnetosphere was compressed by the solar wind and explaining why it was not detected by Pioneer 11 or Voyager 1 and Voyager 2 [Arridge et al. 2008b].

The current sheet was also found to be warped out of the equatorial plane, as expected by analogy with Earth and Jupiter, but it was also found to be deformed at noon. Effectively the current sheet had the geometry of a shallow bowl, or upturned umbrella [Arridge et al. 2008a]. Subsequently, a detailed study of data from Earth's magnetosphere, inspired by Cassini/MAG measurements at Saturn, has revealed a similar effect at Earth [Tsyganenko and Andreeva 2014]. Superimposed upon this global warping was a flapping motion that occurred in phased with other periodicities in Saturn's magnetosphere [Arridge et al. 2008c, 2011b] and which had a lag or delay that propagated into the outer magnetosphere. However, latitudinal effects were also shown to play an important role, connected with differing periods in the northern and southern hemispheres [Provan et al. 2012].

Small ripples were also found superimposed on this bowl-shape [Arridge et al. 2007] that are largely propagating away from Saturn, indicating a source closer to the planet, possibly produced by plasma transport in the inner/middle magnetosphere [Martin and Arridge 2017].



The presence of the current sheet, and its deformation into a bowl shape, has important consequences for Titan's magnetic and plasma environment, and so the structure of its induced magnetosphere [Backes et al. 2005; Arridge et al. 2011b; Simon et al. 2013], as not only is the magnetic field (oriented in a different location to that found by Voyager 1) but also the bowl-shaped current sheet means that the Titan is not continuously immersed in Saturn's magnetospheric plasma.

Detailed collaborative work with the CAPS, MIMI, and Radio and Plasma Wave Science (RPWS) teams also examined the physical nature of the current [Kellett et al. 2010, 2011; Sergis et al. 2018]. It was shown that inside ~10–12 R_S the current is carried principally by the relatively unvarying population of warm (~100 eV) water plasma picked up from the Enceladus torus, comprising principally of inertia and pressure anisotropy currents. Beyond these distances it is carried mainly by the more variable hot tenuous plasma (~10 keV and above) periodically injected from the tail, forming a pressure gradient current (see section entitled Saturn Storms). While, by analogy with Earth, the term ring current particles is often taken to be synonymous with hot injected plasma, this usage has thus proven to be inappropriate at Saturn, since the outwardly-transported warm water plasma is at least as significant in carrying the current.

In a publication dealing with periodic current sheet tilt [Khurana et al. 2009], we provided evidence that Saturn's inner/middle magnetosphere contains semi-permanent azimuthal anomalies in the magnetodisk current region in the fluxes of energetic charged particles, plasma density, magnetic field, and electrical current with a longitudinal wave number m = 1. We demonstrated that in the presence of these anomalies and a finite solar elevation angle, the solar wind lifts Saturn's magnetosphere asymmetrically in longitude, generating a tilt in the current sheet of Saturn.

Current sheet dynamics

Current sheets are also locations where dynamical behavior can be detected and studied. Magnetic reconnection is one important dynamical process that has been studied in detail with Cassini/MAG. Most studies only remotely or indirectly inferred that reconnection was happening—they were detecting the smoke from a distant fire. The location of the fire, the ion diffusion region, remained undetected until MAG played a critical role in the detection and analysis of an ion diffusion region in Saturn's magnetotail [Arridge et al. 2016a]—the only diffusion region to be detected and studied at a giant planet. This revealed the presence of fast magnetic reconnection and highlighted the possible effects of a multicomponent plasma, as studied in the terrestrial magnetosphere. The observations were used to examine the poorly understood mass and magnetic flux transport process, previously referred to as the mass crisis, where the observations of mass loss and magnetic flux transport were insufficient to balance transport and sources in other parts of the system. The observations showed that mass and flux could be conserved, and that undersampling may play a role in generating an apparent crisis. Using MAG, we were able to show that the geometry of the current sheet was important in the correct detection and interpretation of reconnection signatures [Jackman et al. 2009a]. Study of the current sheet has also revealed dynamical behavior connected with the ionosphere. Felici et al. [2016] presented evidence for

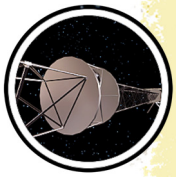
plasma flowing out of the ionosphere into the magnetotail where magnetic reconnection was also occurring. This revealed evidence for strong magnetosphere-ionosphere coupling associated with magnetic reconnection that drove outflow from the ionosphere into the magnetosphere.

Planetary period oscillations

Although the singular phenomenon of Saturn's PPOs was first observed by the Voyagers in modulated SKR emissions observed remotely from the planet, and later noted in both Voyager and Pioneer-11 magnetospheric magnetic data, Cassini observations have demonstrated the near ubiquity of oscillations near the planetary rotation period in essentially all magnetospheric plasma, field, and wave data despite the close axisymmetry of the internal planetary magnetic field. Initial work on the magnetic PPOs established their basic properties, first confirming the rotational nature of the oscillations via the Doppler effect of the azimuthal spacecraft motion [Cowley et al. 2006], and second showing that while the perturbation fields in the equatorial region are quasi-uniform in nature [Andrews et al. 2010a], rotating in the equatorial plane as indicated by the earlier flyby studies, the fields at high latitudes are instead quasi-dipolar in form [Provan et al. 2009a], associated with a rotating transverse dipole. The dipole moment is not internally generated by the planet, however, but by an external current system coupling the ionosphere and magnetosphere (see section entitled Field-Aligned Currents). The PPOs are thus associated with a second large-scale current system, and, due to their ubiquitous nature, have proved to be a major aspect of the Cassini Magnetic Field Investigation throughout the mission. In addition, their imprint is seen more widely in the entire Cassini magnetosphere data set. It was shown that the radial distance of the dayside magnetopause and bow shock are also significantly modulated by this phenomenon [Clarke et al. 2006, 2010a, 2010b].

With the further realization, initially from SKR data, that two such oscillations are generally present at the same time with slightly different periods, one associated with the northern polar region and the other with the southern, it was shown that the phase jitter in the equatorial magnetic oscillations previously observed is due to the vector superposition of the two systems [Provan et al. 2011], while the polar oscillations were found to be pure northern and southern on the central polar field lines in the two hemispheres [Andrews et al. 2012]. Cassini data from the deeper tail passes in 2006 correspondingly showed that while the two tail lobes are modulated at their separate polar periods, mixed signals are again present within the plasma sheet that are associated with both north-south oscillations of the current layer together with significant modulations in its thickness [Provan et al. 2012; Szego et al. 2013; Nemeth et al. 2015, 2016]. A model of these PPO-related variations has been derived, which provides a simple explanation of the sawtooth plasma sheet field variations observed during equinoctial conditions of near-equal northern and southern PPO amplitudes [Cowley et al. 2017; Thomsen et al. 2017]. The model has further been

> The final proximal orbits have provided access to previously unexplored field lines crossing and inside Saturn's ring system.



successfully applied to the more northern-dominated conditions prevailing during northern spring [Cowley and Provan 2017].

With the additional realization that the two PPO periods slowly change with Saturn's seasons by ~±1% about ~10.7 h (i.e., ~±6 min), a long-term program of precise (~±10 s) measurement of the magnetic oscillation rotation period and phase has been carried out over the whole Cassini mission [Andrews et al. 2008, 2010b, 2012; Provan et al. 2013, 2014, 2016, 2018]. The results have subsequently been employed by many Cassini and Hubble Space Telescope (HST) teams as a framework to organize their data. The two PPO periods were found to be well-separated in late southern summer conditions at the beginning of the Cassini mission, ~10.6 h for the northern system and ~10.8 h for the dominant southern system, but then slowly converged with near-equal amplitudes to a near-common value ~10.7 h over a ~2 (Earth) year interval centered near vernal equinox (August 2009) [Andrews et al. 2012]. There followed a ~3-year interval in early northern spring when the relative amplitudes changed abruptly at ~100–200-day intervals between southern and northern dominance and near-equal amplitudes [Provan et al. 2013], the southern period ~10.69 h remaining slightly longer than the northern ~10.65 h, before the periods of the two systems coalesced at ~10.70 h in antiphase during the first half of 2014 [Provan et al. 2016]. In mid-2014, the period of the then-dominant northern system began to increase towards ~10.8 h, similar to the southern system in southern summer, while the southern period remained near-fixed at ~10.7 h, thus leading to the first enduring reversal in PPO periods, northern longer than southern, during the Cassini era. The periods remained close to these values across northern summer solstice in May 2017 to the end of mission [Provan et al. 2018]. Possible physical origins of the post-equinox interval of abrupt changes have been discussed in terms of both atmospheric effects [Cowley and Provan 2013] and solar wind influences during the rising phase of the solar cycle [Provan et al. 2015], though clear causality remains to be demonstrated. An additional important theme of these studies has been the comparison of the magnetic field phases and periods with those derived independently by others from analysis of SKR modulations. Although some areas of contention have been debated [Yates et al. 2015a, 2015b; Cowley and Provan 2015, 2016], the overall picture is one of good agreement [Andrews et al. 2008, 2010b, 2011, 2012; Provan et al. 2014, 2016].

The final proximal orbits have provided access to previously unexplored field lines crossing and inside Saturn's ring system. The behavior of the PPO oscillations on these field lines is presently under intense investigation.

Theoretical work [Southwood and Kivelson 2007] describes how a system of rotating field-aligned currents (cam currents) located on a magnetic shell in the range L = 12–15 would account for the periodicity observed in the magnetic field perturbations near the equator. Later, it was shown that the interaction of the rotating cam currents would interact with the global magnetic structure of the magnetosphere to produce periodic variations of current intensity and account for the modulation of the power of SKR [Southwood and Kivelson 2009].

A series of papers elucidated how appropriately placed vortical flows in a rotating ionosphere drive field-aligned currents consistent with the cam current previously proposed. These rotating

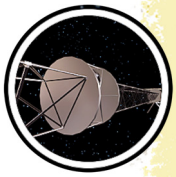
currents were shown to provide a quantitatively consistent description of all of the periodic dynamics reported in the system [Jia, X. et al. 2012a; Jia and Kivelson 2016; Kivelson and Jia 2014]. Theoretical work continues to best understand the origin of the two rotations rates [Southwood 2011, 2014, 2015; Southwood and Cowley 2014; Southwood and Chane 2016].

Field-aligned currents

A further major area of study for the Cassini Magnetic Field Investigation relates to large-scale field-aligned current systems, which couple the magnetosphere to the planet's upper atmosphere, ultimately producing the auroral displays seen in images, for example, at ultraviolet (UV) wavelengths. As in other magnetized environments, field-aligned currents in Saturn's magnetosphere play a fundamental role in the transfer of momentum along field lines between the ionosphere, the magnetosphere, and (potentially) the solar wind. At their ends, such currents close cross-field in association with $j \times B$ forces on the corresponding plasmas. Field-aligned currents further relate to the generation of bright discrete auroral forms at ionospheric heights, if current densities directed away from the planet exceed that which can be carried by the ambient precipitating magnetospheric electrons, at which point the latter are accelerated downward into the ionosphere by field-aligned voltages where they deposit their charge and energy. Initial theoretical expectations for Saturn related to meridional magnetosphere-ionosphere currents associated with the transfer of angular momentum from the planet's ionosphere to the net radially-outward transported equatorial plasma principally of Enceladus origin, i.e., the subcorotation currents [Cowley et al. 2004], together with dawn-dusk asymmetries associated with the solar wind interaction [Jackman and Cowley 2006].

Observationally, field-aligned currents are detected and quantified via variations in the azimuthal magnetic field on high-latitude and relatively low-altitude passes across the planet's polar regions. The first such data were acquired by Cassini/MAG in 2006/2007, with simultaneous HST UV imagery on one pass confirming that Saturn's auroral oval indeed maps into a region of upward current requiring downward acceleration of the observed magnetospheric electrons [Bunce et al. 2008b; Cowley et al. 2008]. An overall survey of these data showed that while their basic properties are consistent with theoretical expectations for subcorotation currents, with ~6 MA flowing down into the central polar ionosphere and the same return current flowing upward at lower latitudes in the auroral region, the currents are also modulated by the PPOs [Talboys et al. 2009a]. A much larger data set was then acquired in 2008 that allowed statistical studies to be undertaken [Talboys et al. 2009b, 2011]. It further allowed detailed exploration of the PPO dependence by comparing currents observed under conditions of differing PPO phase [Hunt et al. 2014, 2015, 2018a].

The principal PPO currents are found to be directed upward in a given hemisphere and downward on the opposite hemisphere of the planet's polar ionosphere, and rotate around the pole at the PPO period of the corresponding hemisphere. They are also approximately colocated with the upward current region of the subcorotation system, and of comparable strength, such that where the PPO current flows down, the total field-aligned current is reduced near to zero, while where it flows up the current is doubled, thus suggesting a dynamical connection. It is also found



that the auroral region oscillates in latitude with amplitude ~1° in concert with these rotating modulations [Nichols et al. 2008; Provan et al. 2009b; Hunt et al. 2014; Bunce et al. 2014]. A complementary multi-instrument study also established the typical locations of the boundary of open field lines in the two hemispheres at ~13° colatitude in the north and ~16° in the south [Jinks et al. 2014], showing that the main PPO field-aligned currents flow just equatorward of this boundary on closed field lines. Correspondingly, interhemispheric coupling along closed magnetospheric field lines also occurs between the two PPO systems [Hunt et al. 2015; Provan et al. 2018]. Overall, the form of the PPO currents is consistent with driving by rotating twin-vortex flows in the two polar thermospheres/ionospheres [Hunt et al. 2014; Southwood and Cowley 2014].

Comparison between the 2008 data, obtained in the midnight sector, with the dawn-dayside data from 2006/2007 showed little difference, confounding expectations of observing long-term current asymmetries associated with the solar wind interaction [Hunt et al. 2016]. Highly unusual current distributions are observed in a small subset of passes, however, some of which have been associated with Saturn auroral storm solar wind compression events (see section entitled Saturn Storms) [Bunce et al. 2010]. Significant solar wind-related currents thus do flow in Saturn's magnetosphere at least intermittently. Indirect evidence of less dramatic solar wind effects have been obtained from HST studies of the dayside auroras (though not directly in field data), using Cassini as an upstream monitor of the IMF. Morphological auroral differences are found depending on the sense of the north-south component of the IMF, suggestive of dayside reconnection and related driving of flows and currents when the IMF points north [Meredith et al. 2014]. More generally, collaboration with colleagues at Moscow State University has resulted in the development of Saturn magnetospheric field models validated with Cassini data, which incorporate ring/tail and magnetopause currents, and are also parameterized by the strength and direction of the IMF [Alexeev et al. 2006; Belenkaya et al. 2006, 2007, 2010, 2011, 2014, 2016]. These models have been used during intervals when Cassini was located in the solar wind measuring the impinging IMF to map auroral features observed by the HST along field lines into their magnetospheric source regions, namely the middle and outer ring current region typically at dawn, and to the vicinity of the open-closed field boundary for high-latitude emissions near noon.

While the 2006/2007 and 2008 high-latitude data sets both correspond to Saturn's late southern summer, a third interval of high-latitude data was obtained in 2012/2013 during northern spring [Bradley et al. 2018]. The PPO currents were found to be of similar form but somewhat weaker than in 2008, while the subcorotation currents exhibited strong opposite seasonal asymmetries in the north and south polar regions, indicative of weak polar ionospheric conductivity in the winter polar cap. Investigation of the current signatures observed on the F-ring and proximal orbits spanning northern summer solstice at the end of the Cassini mission are currently ongoing [Hunt et al. 2018b].

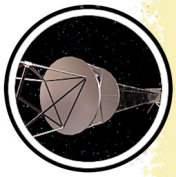
Saturn auroral storms

Although Voyager radio data had previously demonstrated that SKR emissions are strongly positively correlated with solar wind dynamic pressure, the nature of the related magnetospheric

dynamics remained unknown. This was partially revealed in early 2004 during the Cassini approach to Saturn when an intensive HST campaign imaging Saturn's UV auroras was undertaken, with Cassini acting as upstream solar wind/IMF monitor. As expected during the declining phase of the solar cycle, the recurrent solar wind structure consisted of two corotating interaction regions (CIRs) per ~25-day solar rotation, exhibiting two few-day compression events of enhanced dynamic pressure, one major and one minor [Jackman et al. 2004]. The HST caught the impingement of the major compression region on Saturn's magnetosphere towards the end of the campaign, and observed a major increase in UV and SKR emissions with bright auroral forms extending throughout the dawn sector up to the planetary pole itself [Clarke et al. 2005; Bunce et al. 2006]. It was suggested that such auroral storms are caused by major bursts of compression-induced reconnection in Saturn's nightside tail, that inject hot plasma towards Saturn, which subsequently flows around the planet via dawn under the action of magnetosphere-ionosphere coupling [Cowley et al. 2005]. Estimates of the reconnection rate yielded associated voltages of at least several hundred kV [Badman et al. 2005]. Monitoring of the interplanetary field prior to SOI showed that the same compression region would likely impinge on the system during the SOI fly-through of the magnetosphere [Jackman et al. 2005a, 2005b], and indeed did, with a corresponding magnetic dipolarization event, plasma energization, and enhanced SKR emissions being observed in the nightside magnetosphere on the outbound pass [Bunce et al. 2005]. Analysis of a larger number of compression events observed by Cassini acting as upstream IMF monitor during the approach phase, as well as outbound after SOI in late 2004, also showed characteristic enhancements in SKR, but with the regular pulsing at the PPO period generally being undisturbed in phase [Badman et al. 2008].

Studies led elsewhere subsequently detected numerous reconnection-related events during the main Cassini tail exploration interval in 2006, namely planetward-travelling dipolarizations and tailward-travelling plasmoid structures, which were found to be related in timing to both the pulsing of the SKR emissions and the magnetic PPO phase [Jackman et al. 2009a, 2016]. Specifically, the events were found to be preferentially initiated during intervals when the PPO perturbations stretch the field lines radially outward from the planet and thin the plasma sheet leading to instability (see section entitled Planetary Period Oscillations), especially when the two PPO systems act in this manner in concert, i.e., when they are near antiphase. Ongoing work is presently investigating dipolarization events and auroral storms during the sequence of proximal orbits observed just prior to end of mission.

A further important related topic concerns the mass loss associated with plasmoid release down-tail as part of the Vasyliunas cycle, compared with the ~100 kg s^{-1} Enceladus water plasma source rate. Although simple estimates based on the duration of observed plasmoid field perturbations yield mass loss values at least an order of magnitude smaller than this, given the typically several-hour interval between plasmoid releases, it has been suggested that the overall plasma structure released by such events may be at least an order of magnitude longer than the few tens of R_S lengths inferred from the magnetic data directly [Cowley et al. 2015].



Wave analysis

Preparatory studies concentrated on ultra-low frequency (ULF) waves in the Kronian magnetosphere and the resonant mode coupling process—for example, Cramm et al. [1998]. Later studies on plasma waves were conducted using observations made during the Cassini Earth flyby and after orbit insertion—for example, Bogdanov et al. [2003]; Kleindienst et al. [2009]. A more recent study of ULF waves has been carried out [Yates et al. 2016].

Saturn's Internal Magnetic Field and Implications for Interior Structure

Numerous planetary magnetic field models have been developed over the time of the Cassini orbital mission at Saturn beginning with Saturn Orbit Insertion [Dougherty et al. 2005]. Burton [2009] derived a model of Saturn's internal planetary magnetic field based on data obtained from the first three years of the mission, from July 1, 2004–July 1, 2007. Due to the uncertainty in the rotation rate, the model was constrained to be axisymmetric. In that analysis, one-minute averages of the vector magnetic field data obtained by the fluxgate magnetometer from all orbits within 10 R_S (1 R_S = 60268 km). Data from 45 orbits were used in that study. The contribution of the eastward flowing ring current is known to be significant close to the planet. Its contribution was modeled using the analytical expression derived by Giampieri and Dougherty [2004a] based on the simple axisymmetric equatorial current sheet centered on the planet's equator, first described by Connerney et al. [1981]. The ring current magnetic field was modeled separately for the inbound and outbound legs of each orbit because the current sheet structure and characteristics are known to vary with local time [Arridge et al. 2008b] and temporal variations in the solar wind and magnetosphere are likely to occur over time scales corresponding to that of a periapsis pass (several days). The ring current field was modeled and removed from the data and standard generalized inversion techniques were used to model the magnetic field presumed to originate in Saturn's interior.

The internal field model derived in that study was found to be quite consistent with previous models. An axisymmetric octupolar (degree 3) model was found to fit the data adequately based on an examination of the root-mean-square misfit or residual for each orbit. The spherical harmonic coefficients derived were g_{10} = 21,162, g_{20} = 1514, g_{30} = 2283. Units are nanoteslas (nT) and are based on a planetary radius of 60,268 km. Saturn's magnetic was found to be offset northward by 0.036 Saturn radii, consistent with earlier Pioneer-11 and Voyager models. Reanalysis and comparison with data obtained by Pioneer 11 and Voyager 1 and 2 showed little evidence for secular variation in the field in the almost 30 years since those data were obtained.

A subsequent study [Burton 2010] used data from the entire Cassini Prime Mission (through July 2008) and a methodology that differed in significant ways from the earlier modeling approach [Burton 2009]. Only data obtained at radial distances closer than the L-shell of Enceladus (dipole L-value of 3.8) were used to derive the model. Measurements obtained by all Cassini fields and particles instruments had demonstrated that the structure and dynamics of Saturn's inner magnetosphere are governed by plasma created at Enceladus [Kivelson 2006]. The observed field

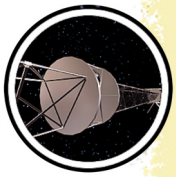
at radial distances outside the orbit of Enceladus is modified by processes in the inner magnetosphere and does not necessarily reflect the magnetic field generated in Saturn's interior.

The approach to modeling the external ring current field also differed from the earlier modeling approach. As time went on, our understanding of Saturn's magnetodisc had evolved and a simple symmetric ring current centered on the equator was no longer thought to be an accurate representation. Instead, the current sheet was found to be displaced from Saturn's rotational equator and to assume the shape of a bowl or basin, referred to as a magnetodisc [Arridge et al. 2008b]. Instead of modeling the external field as an oversimplified axisymmetric ring current as in Burton [2009], the internal plus external field was modeled using the standard spherical harmonic formulation and a single set of spherical harmonic coefficients was obtained that describes the internal and external field in a least squares sense. Accordingly, the axisymmetric model coefficients differ somewhat from the previous model.

In Burton [2010], an attempt was made to determine the planetary rotation rate by deriving a number of non-axisymmetric magnetic field models for a plausible range of planetary rotation periods and assessing the power in the non-axisymmetric components of the field and the root-mean-square misfit between the model and the data. The methodology is as follows. A presumed planetary rotation period was varied in one-second increments from 10 hours 28 minutes to 10 hours 40 minutes and a pseudo-longitude calculated for each measured data point. A degree 3, non-axisymmetric magnetic field model was derived and the power in the non-axial magnetic field and the misfit were calculated. The underlying premise is that the planetary rotation period could be determined based on a peak in the non-axial power and minimum in the misfit. Although no such peak was identified unambiguously, the analysis did provide an upper limit on the extent of the dipole tilt. Based on the distribution of the non-axial spherical harmonic model coefficients for the range of rotation rates, a mean value for the dipole tilt was determined to be 0.03 degree. The upper limit of all tilt angles was found to be 0.1 degree.

We have further developed the state-of-the-art internal magnetic field model for Saturn using Cassini magnetometer measurements prior to the Grand Finale, which placed the most stringent constraint to date on the tilt and secular variation of Saturn's intrinsic magnetic field [Cao et al. 2011]. The tilt of Saturn's dipole must be smaller than 0.06 degree from the spin-axis of Saturn, and the time variation of Saturn's intrinsic magnetic field must be an order of magnitude slower than that of the Earth's [Cao et al. 2011]. These results are very challenging for dynamo theory, as Cowling's theorem excludes the possibility of a purely axisymmetric magnetic field being maintained by dynamo action.

We have also derived degree 4 and degree 5 internal magnetic moments for Saturn, albeit with relatively large uncertainties, from reanalyzing the Cassini SOI MAG measurements [Cao et al. 2012]. Based on these observational findings, we worked out the implications on helium rain inside Saturn [Cao et al. 2011, 2012]. These also provided the framework for our current analysis of the magnetometer measurements from the Cassini Grand Finale.



The latest Cassini Grand Finale gravity measurements indicate that the ~100 m/s zonal flows observed at the cloud deck of Saturn extend almost 10,000 kilometers into the planetary interior. Given that the electrical conductivity at such depth are high enough for significant MHD effects, zonal flow magnetic field interaction in the semi-conducting region of Saturn is now a central issue in understanding the interior dynamics. On the theoretical side, we have developed a mean-field model for zonal flow magnetic field interaction in the semi-conducting region of Saturn [Cao and Stevenson 2017]. In this work, we proposed that the interaction between zonal flow and a magnetic field in the semi-conduction region of Saturn would generate small-scale axisymmetric magnetic fields that are spatially correlated with zonal flows [Cao and Stevenson 2017]. The amplitude of the wind-induced magnetic perturbations would depend on the amplitude of the deep differential rotation as well as the amplitude of the small-scale deep convective flow. Thus, measuring/constraining wind-induced magnetic perturbations along the Cassini Grand Finale orbits would place important constraints on the properties (profile and amplitude) of deep differential rotation and convective flow in the semi-conducting region of Saturn.

With magnetic field measurements at unprecedented proximity to Saturn by the Cassini Grand Finale [Dougherty et al. 2018], we are working on deriving: 1) non-axisymmetric internal magnetic moments of Saturn from the Cassini Grand Finale magnetometer measurements, which can tell us about the deep interior rotation rate of Saturn and/or helium rainout and stable stratification inside Saturn; 2) small-scale axisymmetric magnetic features—for example, high-degree axisymmetric internal magnetic moments—which can be used to constrain deep differential rotation inside Saturn; and 3) time variations in the internal magnetic fields, which would reveal characteristic time scale in Saturn's internal magnetic field and deep interior dynamics. These expected results would constitute the observational facts about the internal magnetic fields of Saturn for many years to come, which would further serve as tests for theories about giant planet interiors and have profound implications about giant planets outside the solar system.

Titan Science

The MAG team has significantly contributed to the understanding of the interaction between Saturn's major moon, Titan, and its plasma environment. The virtual absence of an intrinsic field at Titan makes this interaction mainly atmospheric as fields and charged particles from Saturn or the Sun impinge on the moon's chemically complex atmosphere, exosphere, and ionosphere. Atmospheric interactions are common elsewhere in the solar system with Mars and Venus as their most typical examples. In these cases, as well as in Titan's, charged particles from its atmosphere (originating from photoionization, charge exchange, and electron impact) become electro-magnetically coupled to those carried by the plasma winds that flow past it [Bertucci et al. 2011].

The exchange of momentum and energy between the atmospheric charged particles and those being part of the external wind lead to a steady perturbation in the ambient external magnetic field known as induced magnetosphere and characterized by the draping of the external magnetic field lines around the unmagnetized, atmospheric body. Cassini MAG observations were crucial in

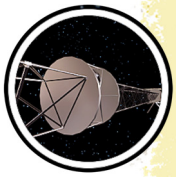
providing constraints to the structure of Titan's magnetotail [Bertucci et al. 2007b] and characterizing Saturn's magnetic field at Titan's location [Bertucci et al. 2009].

However, one of the most remarkable features revealed by MAG was that Titan's induced magnetosphere is formed by layers of different polarity of the external magnetic field that allows for reconstruction of the history of the moon's magnetic environment. Indeed, in the same way as older sediments lay beneath more recent deposits in geology, the magnetic fields fossilized in the deep layers of Titan's induced magnetosphere provide information about the orientation of the external field Titan was exposed up to three hours before the encounter with Cassini [Bertucci et al. 2008]. This magnetic memory of Titan is significantly longer than those at Venus and Mars and is a result of the capacity of Titan plasma to remove momentum from the external plasma. Cassini MAG data were also essential to characterize Titan's unique example of interaction with the supersonic solar wind [Bertucci et al. 2015] as structures found at Mars and Venus (an induced magnetospheric boundary and a collisional bow shock) were successfully captured by the instrument.

The Cassini Titan mission consisted of the encounters TA, TB, TC, T3, T4 … T126 in project nomenclature, all with useful magnetic field data. The magnetic field conditions upstream of these flybys were strongly variable and different from the single encounter during the Voyager 1 mission—for example, Neubauer et al. [1984]. For example, the simple model derived from Voyager 1 with the flow along the direction of orbital motion and the magnetic field perpendicular to Titan's orbital plane was at most approximately fulfilled in rare cases.

Titan's orbit is typically located inside Saturn's magnetosphere, but could occasionally move outside it into the magnetosheath or even into the solar wind.

The first part of the exploration strategy was to analyze individual encounters with particularly noteworthy characteristics. The first encounter TA on October 26, 2004, was carefully investigated and compared with the results of a newly developed numerical model. The comparison showed best agreement with a MHD-model, which separately described ionospheric (cold) electrons and magnetospheric (hot) electrons [Backes et al. 2005]. In joint studies of the TA flyby a comparison between MAG and RPWS-data was done by Wahlund et al. [2005] and a comparison between Cassini and Voyager data using both plasma spectrometer (PLS) and magnetic field data by Hartle et al. [2006]. The next more detailed study was using magnetic field and PLS electron data and included TA, TB, and T3 [Neubauer et al. 2006]. The data showed a draping boundary as the outer boundary of strong magnetic field draping. Further, the induced magnetospheric tail near Titan was investigated. The shape of the tail was found to be similar to a delta wing in aerodynamics. It was shown that the long travel time of frozen-in magnetic field lines into the lower ionosphere of Titan led to the observation of old or fossil field lines compared with their times of arrival in front of Titan. This concept was later called memory effect by Bertucci et al. [2008] in a paper discussing Titan encounter T32 which occurred for the first time in the Saturnian magnetosheath, but also contained old Saturnian magnetospheric field as a memory effect—see also Ma et al. [2009].



The first opportunity to study the induced tail at medium distances occurred at T9, which led to a data analysis paper by Bertucci et al. [2007b]. It also led to a number of modelling papers that helped to disentangle the detailed plasma and magnetic field characteristics [Kallio et al. 2007; Wei et al. 2007; Ma et al. 2007] of the complex magnetotail.

These early Cassini/MAG data at Titan also led to the conclusion that an internal magnetic field of Titan was at most very small. Using the magnetic field observations on flyby orbits very close to Titan. Wei et al. [2010a] found an upper limit on the dipole moment of 0.78 nT × R_T^3 improving the Voyager 1 upper limit by a factor of five.

Considering further the ionosphere of Titan with its embedded magnetic field, a study of Titan's nightside ionosphere was published by Cravens et al. [2009]. Data collected along T96, the first encounter presumably occurring in the supersonic solar wind, was also compared to modeling results from a hybrid kinetic code [Feyerabend et al. 2016].

An important kinetic process in the interaction between a streaming magnetized plasma and Titan's atmosphere is the pick-up process, which has been observed to lead to the generation of often strong ion cyclotron waves in the cases of atmospheric interactions (Venus, Mars, Galilean satellites of Jupiter, Saturnian satellites, comets). In the case of Titan, only two flybys T63 and T98 were associated with ion cyclotron waves of relatively high amplitude, as a study of the MAG team shows [Russell et al. 2016].

In parallel to the studies of single flybys, we have also undertaken a systematic study of all Titan flybys by looking at the characteristics of the magnetic field variations upstream and also downstream of the interaction region proper close to Titan with duration ±1 h. Most of the regions of ±8 h around the interaction region can be characterized as a sequence of intervals with magnetic fields of the northern/southern magnetospheric lobe type and the magnetospheric current sheet [Arridge et al. 2008c], which can be found near the magnetic equator. Mixtures of these regions do also occur. In rare cases, encounters occurred in the magnetosheath of Saturn (T32, T42, and T85) and in the solar wind (T96).

The individual results have been collected in Simon et al. [2010a, b] for TA–T62, Simon et al. [2013] for TA–T85 and Kabanovic et al. [2017] for the remainder. The latter paper also indicates appreciable variations of the occurrence of the types of magnetic field regions as a function of Saturnian season. Results are given for 2004–2008, 2009–2010, 2011–2017 for about half a Saturn year.

A special study of the magnetotails of Titan has investigated the tails by wake flybys with closest approach (CA) distances >2.5 R_T in the whole set of flybys TA–T84 [Simon et al. 2014a]. The resulting eight flybys confirmed the delta wing structure found in Neubauer et al. [2006] leading to a thickness of the wing of ±3 R_T. Magnetotail studies in the set T85–T126 have not been done yet.

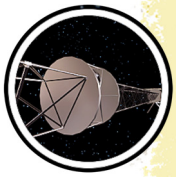
Titan's orbit is typically located inside Saturn's magnetosphere, but could occasionally move outside it into the magnetosheath or even into the solar wind. To better understand the magnetic and plasma environment of Titan, the plasma environment at Titan's orbit is compared with Titan present and absent from 06/2004 to 12/2008. Cassini observations reveal that the presence of Titan appears to affect the magnetopause location. Near noon, the Saturn magnetopause is more frequently inside of Titan's orbit with the moon absent than with it present. Titan's presence near noon appears to locally enhance the total pressure and reduce the magnetosphere compressibility, possibly by mass-loading. Near local midnight, the stretching and sweepback angles for cases with Titan present and absent suggest that the moon enhances the tail reconnection rate, in agreement with previous studies of the moon's influence on the Saturnian magnetosphere [Wei et al. 2009].

Due to Titan's thick atmosphere, ion cyclotron waves are expected to be created when the atmospheric particles are ionized and picked up by Saturn's magnetospheric plasma. However, ion cyclotron waves are rarely observed near Titan, due to the long growth times of waves associated with the major ion species from Titan's ionosphere, such as CH_4^+ and N_2^+ [Cowee et al. 2010]. In the more than 100 Titan flybys obtained by Cassini, there are only two wave events, for just a few minutes during T63 flyby and for tens of minutes during T98 flyby. These waves occur near the gyrofrequencies of proton and singly ionized molecular hydrogen. From hybrid simulations for T63, we find the pickup protons with densities ranging from 0.01/cc to 0.02/cc and singly ionized molecular hydrogens with densities ranging from 0.015/cc to 0.25/cc can drive ion cyclotron waves with amplitudes of ~0.02 nT and of ~0.04 nT within appropriate growth times at Titan, respectively [Russell et al. 2016].

During the interaction between Titan's ionosphere and its ambient plasma, Cassini observations find that the lower ionosphere of Titan is often magnetized, with large-scale magnetic fields and some structures resemble magnetic flux ropes. These flux ropes are either starting to form or maturely formed, with their axial orientations in agreement with the theoretical formation mechanism [Wei et al. 2010b]. A special example of ionospheric flux rope is observed during Titan flyby T42. The observed magnetic field attained a maximum value of 37 nT between an altitude of 1,200 and 1,600 km, much larger than other similar passes. Cassini observations from the plasma and magnetic instruments indicate that Titan's ionosphere was strongly magnetized during an enhanced solar wind dynamic pressure interval right before this flyby, and it caused this large fossil field that later got further twisted while sinking into lower ionosphere [Wei et al. 2011].

The interaction between Titan and the corotating Saturnian plasma forms an induced magnetosphere with an elongated Alfven-wing-style magnetotail. During the first mid-tail flyby T9, Cassini plasma and magnetic field instruments detected in one tail lobe a magnetic flux tube connected with ionosphere and filled with cold ionospheric plasma. This magnetic structure indicates that Titan's ionosphere appears to be escaping along field lines down the tail, leading to particle loss from the atmosphere [Wei et al. 2007].

To understand the internal magnetic moments of Titan, the radial component of Cassini magnetometer observations near Titan surface (from 950 km to 1,100 km) was used to calculate the permanent dipole moment. The upper limit to Titan's permanent dipole moment is



0.78 nT × R_{Ti}^3, using the observations during the southern summer season of Saturn (April 2005 to March 2009). This weak internal field indicates the interior of Titan may not contain a liquid core sufficiently electrically conductive for a magnetic dynamo to be generated inside Titan or even for the simple amplification of the external magnetic field [Wei et al. 2010a]. For the signs of the calculated internal field components, the g11 and h11 component, corresponding with the Titan-to-Saturn direction and the corotation direction, respectively, are in agreement with the signs of the averaged ambient field around Titan during the observation period. This indicates that these estimated internal moments may be due to the penetration of the ambient field into the interior of Titan, generating induced fields. After Saturn's equinox, August 2009, the ambient field of Titan changes sign in the Titan-to-Saturn direction and the corotation direction, as Titan moved from below Saturn's current sheet to above it. Thus, we compared the calculated internal moments using the observations before and after Saturn's equinox, and found that the g11 and h11 moment changed sign in agreement with the sign of Titan's ambient field.

A multispecies MHD model has been employed to study plasma interaction with Titan, model results have been compared with several Cassini Titan flybys to better understand the plasma environment of Titan.

1. Ta and Tb flyby [Ma et al. 2006]: The Cassini spacecraft passed by Titan on October 26, 2004 (Ta flyby), and December 13, 2004 (Tb flyby). In both cases, the Cassini spacecraft entered Titan's ionosphere and flew through Titan's dynamic wake region. We simulated both flybys using our three-dimensional multispecies MHD model. The calculations used the best available upstream plasma and magnetic field parameters obtained by Cassini. Model results were compared with relevant plasma measurements and showed close agreement between the two, demonstrating that the general interaction features can be pretty well reproduced by the MHD model.

2. T9 flyby [Ma et al. 2007]: The wake region of Titan is an important component of Titan's interaction with its surrounding plasma. The Cassini spacecraft passed through the distant downstream region of Titan on December 26, 2005 (T9 flyby). In this study, we compared the observational data with numerical results using a three-species Hall MHD Titan model. There is a good agreement between the observed and modeled parameters, given the uncertainties in plasma measurements and the approximations inherent in the Hall MHD model. Our simulation results also show that Hall MHD model results fit the observations better than the non-Hall MHD model for the flyby, consistent with the importance of kinetic effects in the Titan interaction. Based on the model results, we also identified the controlling physical processes in different plasma regions based on ion gyroradius.

3. T32 flyby [Ma et al. 2009]: When the Cassini spacecraft flew by Titan on June 13, 2007, at 13.6 hr Saturn local time, Titan was directly observed to be outside Saturn's magnetopause. Cassini observations showed dramatic changes of magnetic field orientation as well as other plasma flow parameters during the inbound and outbound segments. We studied Titan's ionospheric responses to such a sudden change in the

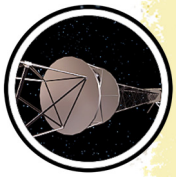
upstream plasma conditions using our multispecies global MHD model. Simulation results are compared against Cassini MAG, Langmuir Probe, and CAPS observations. The main interaction features, as observed by the Cassini spacecraft, are well reproduced by the time-dependent simulation cases. The simulation results provide clear evidence for the existence of a fossil field that was induced in the ionosphere due to a different convection time around Titan. These simulations also reveal how the fossil field was trapped during the interaction and shows the coexistence of two pileup regions with opposite magnetic orientation, as well as the formation of a pair of new Alfvén wings and tail disconnection during the magnetopause crossing process.

4. T34 flyby [Ma et al. 2011]: We improved the previously used multispecies MHD model by solving both the electron and ion pressure equations instead of a single plasma pressure equation. This improvement enabled a more accurate evaluation of ion and electron temperatures inside Titan's ionosphere. The model is first applied to an idealized case, and the results are compared in detail with those of the single-pressure MHD model to illustrate the effects of the model improvement. These simulation results show that the dayside ionosphere thermal pressure is larger than the upstream pressure during normal conditions, when Titan is located in the dusk region; thus Saturn's magnetic field is shielded by the highly conducting ionosphere, similar to the interaction of Venus during solar maximum conditions. This model is also applied to a special flyby of Titan, the T34 flyby, which occurred near the dusk region. It is shown that better agreement with the MAG data can be achieved using the improved MHD model with the inclusion of the effects of super thermal electron heating. This clearly demonstrates the importance of super thermal-electron heating in Titan's ionosphere.

Enceladus Science

The most significant highlight of the MAG investigation during the Cassini mission was the discovery of an atmospheric plume at Enceladus by the MAG team [Dougherty et al. 2006] on February 17, 2005, and confirmed and strengthened by subsequent measurements on later flybys and other instruments. The discovery of a thin neutral atmosphere by the magnetic signature of an electrodynamic interaction proved to point to one of the unique capabilities of the MAG experiment. In another MAG publication on Enceladus [Khurana et al. 2007], we showed that the effective diameter of the obstacle (the plume) is at least 6 R_E, and the obstacle is displaced by >2 R_E south of Enceladus and downstream by at least 1 R_E. The total current produced in the interaction is $<10^5$ Amps (40–60% of the Neubauer limit). We estimated that the mass picked up by the plasma within 5 R_E of Enceladus is <3 kg/s.

This dynamic atmospheric plume was later shown by the Imaging team to be due to geyser activity on the southern hemisphere of Enceladus. The electrodynamic interaction involves southern and northern Alfvén wings such that the atmospheric influence not only shows up in the



southern but also the northern wing—hemispheric coupling [Saur et al. 2007]. Using these concepts and magnetic field observations of flybys E0, E1, E2 and neutral density measurements at E2 the time variability of the plumes was investigated [Saur et al. 2008]. Subsequent modelling based on analytical theory clearly showed that the MAG results required the presence of negatively charged dust particles [Simon et al. 2011a]. The paper also proves the presence of the hemispheric coupling currents required by Saur et al. [2007]. The interaction was later modelled numerically in detail using a hybrid (fluid electron) kinetic code including charged dust particles [Kriegel et al. 2011]. As a unique feature at Enceladus, dust–plasma interactions play an important role to explain the observations.

Since Saturn has a rotation dominant magnetosphere powered by the plasma sources in its inner magnetosphere, quantifying the gas and plasma torus is crucial to understand the magnetospheric dynamics of Saturn. The primary source of the Saturnian torus is ejections from Enceladus. This newly released gas, dust, and plasma interacts with Saturn's magnetosphere, and strong disburbations in the magnetic field are generated. We studied the magnetic signals observed by Cassini/MAG at Enceladus, to determine the gas and dust production rate at Enceladus and how do they vary with time.

The neutrals sent to space from Enceladus are partly ionized via photoionization, electron or proton impact ionization, and charge exchange processes. These new ions are loaded into the magnetosphere, which is, in turn, slowed down into an 80% subcorotation.

We employed a 3-D MHD model to simulate the plasma interaction at Enceladus. The model is applied to the Block Adaptive Tree Solar-wind Roe Upwind Scheme (BATS-R-US) code in an 80 x 80 x 160 Enceladus radii computational domain. The neutrals are treated as a background condition, with a density described by analytical functions: the torus component and a moon component that falls off by a factor of r^{-2} with distance. The upstream boundary is an inflow boundary, with density, velocity, temperature and field conditions obtained from the Cassini flyby data. The inner boundary at the Enceladus surface is absorbing the moon condition, which absorbs the inflow plasma, and fixes the outflow density as a floor value. The field has no gradient at the inner boundary. This code has been applied to a spherical obstacle in a plasma flow to show the effect of the moon and local pickup separately [Jia, Y. -D. et al. 2010a]. With this model, we have refined the plume geometry with E2 data [Jia, Y. -D. et al. 2010b] and constrained the outgassing rate of the Enceladus plume with data from the nine early flybys [Jia, Y. -D. et al. 2010c, 2010d].

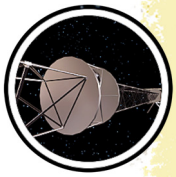
Plume brightness is found to be varying by a factor of a few around the apocenter of Enceladus orbit, using visual images. In contrast, outgassing rate deduced from our data-modeling comparison suggested 50% variation in gas production rate during the first nine passes E0-E8 [Jia, Y. -D. et al. 2010c, 2010d]. The magnetometer could not confirm this postulation with local interaction data. Then, the field perturbation perpendicular to both the direction of magnetospheric flow, and to the magnetic field has been studied with our multi-fluid code, to illustrate the effect of charged dust in creating such a field perturbation [Jia, Y. et al. 2011].

Other Icy Satellite Science

In addition to the large number of flybys at Titan and Enceladus, there was also a small number of targeted flybys of some of the other icy satellites. The magnetic signatures observed were used to investigate in detail the magneto-plasma interaction with these satellites with the help of 3-D hybrid kinetic models introduced before. On September 24, 2005, the only Tethys encounter took place close enough to the satellite to be diagnostically useful. No evidence for an atmosphere/ionosphere system was found. Instead, the magnetic field signatures were explained by the plasma absorption by the satellite [Simon et al. 2009a]. The Dione encounters on October 11, 2005 and April 7, 2010, led to the observation of Alfvén wing signatures. The analysis yielded an atmospheric column density of 10^{17} m^{-2} [Simon et al. 2011b]. The two flybys at Rhea on March 2, 2010, and January 11, 2011, were not associated with magnetic signatures due to the atmosphere, which was identified by other means. The magnetic signature was also dominated by plasma absorption features [Simon et al. 2012].

We characterized the submagnetosonic plasma interaction of Rhea in Khurana et al. [2008]. Main conclusions were: 1) Rhea is also an inert moon and devoid of any internal magnetic field; 2) no induction field was observed from any subsurface conductor; 3) no appreciable mass-loading occurs near Rhea; and 4) the region of plasma depletion is greatly elongated along the field direction. The submagnetosonic interaction of Rhea with the Saturnian plasma was further explored in Khurana et al. [2017] where we showed that the wake refilling process generates Alfvén wings in the wake region from a plasma density gradient force directed in the direction of corotating plasma. The plasma pressure gradient force slows down the plasma streaming into the wake along field lines. As on the same field lines, outside of the wake, the plasma continues to move close to its full speed; this differential motion of plasma bends the magnetic flux tubes, generating Alfvén wings in the wake. The current system excited by the Alfvén wings transfers momentum from plasma outside the wake to the wake plasma. Our work demonstrates that Alfvén wings can be excited even when a moon does not possess a conducting exosphere. In another work on Rhea's interaction with the Saturnian plasma [Teolis et al. 2014], we showed that sharp magnetic perturbations are present at the edge of the Rhea flux tube, which are consistent with field-aligned flux tube currents. We showed that the current system results from the difference of ion and electron gyroradii and the requirement to balance currents on the sharp Rhea surface.

On September 26, 2005, Cassini conducted its only close targeted flyby of Saturn's small, irregularly shaped moon Hyperion. Approximately 6 minutes before the closest approach, the electron spectrometer (ELS), part of the CAPS instrument detected a field-aligned electron population originating from the direction of the moon's surface. We showed that this constituted a remote detection of a strongly negative (~200 V) surface potential on Hyperion, consistent with the predicted surface potential in regions near the solar terminator [Nordheim et al. 2014].



MAG Non-Saturn Science Results

Early science used the measurements along the flyby of Earth and Jupiter. The Earth flyby produced fairly original observations at high resolution of what appeared to be interchange motions on the nightside outbound pass. Inbound, high-resolution measurements of the whistler waves in the electron foreshock were reported. In addition, the down-tail passage allowed observation of two geomagnetic sequential substorm cycles [Southwood et al. 2001; Smith et al. 2001; Khan et al. 2001; Tsurutani et al. 2001]. Passage by Jupiter allowed coordination with Galileo during its 28th and 29th orbits. The most important conclusion was good evidence of changed magnetospheric shape in response to local solar wind magnetic field changes in the north-south component. There is increased flaring when the field is northward, opposite of what happens at Earth. As the Jovian dipole is oppositely oriented, this is consistent with reconnection being important to magnetospheric configuration at Jupiter despite the rapid planetary rotation [Kivelson and Southwood 2003, 2005].

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AO	Announcement of Opportunity
AU	astronomical unit
BATS-R-US	Block Adaptive Tree Solar-wind Roe Upwind Scheme
CA	closest approach
CAPS	Cassini Plasma Spectrometer
CEC	corotation enforcement currents
CIR	corotating interaction region
CSM	Cassini Solstice Mission
ELS	electron spectrometer
FAC	field-aligned current
FGM	Flux Gate Magnetometer
HST	Hubble Space Telescope
IMF	interplanetary magnetic field
LFE	low frequency extension
MAG	Magnetometer
MAPS	Magnetospheres and Plasma Science
MHD	magneto-hydrodynamic
MIMI	Magnetospheric Imaging Instrument
PLS	plasma spectrometer
PPO	planetary period oscillation
RPWS	Radio and Plasma Wave Science
SKR	Saturn kilometric radiation
SLT	Saturn local time
SOI	Saturn orbit insertion
TCR	travelling compression region
ULF	ultra-low frequency
UV	ultraviolet
V/SHM	Vector/Scalar Helium Magnetometer

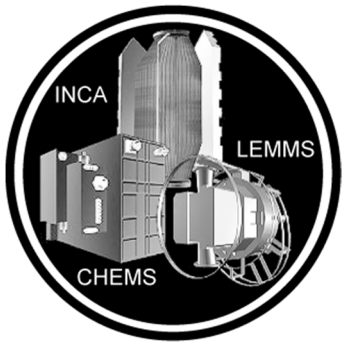
Magnetosphere Imaging Instrument



The Magnetosphere Imaging Instrument (MIMI) was comprised of three sensors designed to measure energetic electrons, ions, and neutrals in the Saturn system: the Low Energy Magnetospheric Measurement System (LEMMS), the Charge-Energy-Mass Spectrometer (CHEMS), and the Ion and Neutral Camera (INCA). Each sensor made in situ particle measurements and INCA had the additional capability of creating images out of energetic neutral atoms (ENAs) that can reach the spacecraft from large distances. The **science objectives** of MIMI were to map the charged particle populations of Saturn's magnetosphere, study the global configuration and dynamics of Saturn's magnetosphere and its interaction with the solar wind, Saturn's atmosphere, Titan, and the icy satellites. In concert, MIMI's three sensors extensively characterized the planetary radiation belts of Saturn, discovered a transient radiation belt, and characterized magnetospheric dynamics with global ENA images of Saturn's magnetosphere.

Executive Summary

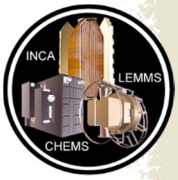
MIMI measured energetic electrons, ions, and neutrals using three separate sensors: 1) LEMMS, 2) CHEMS, and 3) INCA. Each of these sensors detected particles in the local environment of the spacecraft and INCA had the additional capability of creating images out of ENAs that can reach the spacecraft from large distances. The sensors were able to carry out some separation by species and CHEMS could also separate ions by charge state. MIMI made measurements in cruise and around the planetary flybys and, at Saturn, was operated essentially continuously from orbit insertion in 2004 to the end of mission in 2017. MIMI data characterized Saturn's ion and electron radiation belts; the space environments of the rings, inner satellites, and Titan; and the magnetosphere, high latitude regions, and boundaries, and made advances in our understanding of the dynamics of Saturn's magnetosphere. Through ENA imaging, MIMI also expanded our understanding of the heliosphere.

MIMI extensively characterized the planetary radiation belts of Saturn, including the segmentation of the belts due to the rings and moons and discovered a transient belt.

Highlights from MIMI science. MIMI extensively characterized the planetary radiation belts of Saturn, including the segmentation of the belts due to the rings and moons and discovered a transient belt. INCA obtained global ENA images of Saturn's magnetosphere showing detailed dynamics such as injections, planetary rotational periodicities in ring current intensity, images of the heliosphere and its structure, images of ion acceleration in the auroral region, global ENA emissions of Jupiter, and images of Titan's interaction with the magnetosphere. Satellite and ring absorption signatures predicted a global electric field with no known source. CHEMS and LEMMS data were used to infer regions dominated by the neutral gas torus. MIMI LEMMS measured the inner radiation belts between the middle of the D-ring and the planetary atmosphere. MIMI INCA and CHEMS data led to the discovery of ring dust precipitating into the equatorial atmosphere. MIMI data found periodic features in the magnetosphere.

Key open questions. Some of the open questions relevant to this science are (this follows and expands on the ones in the individual sections below):

- What is the relationship between small and large-scale injections at Saturn and what is the role of injections in the flow of mass and energy through the system?
- What are the mechanisms that create the injections, both in the outer magnetosphere (Titan's orbit and beyond) and between ~18 R_S and Enceladus?
- How do periodicities in charged particle fluxes come about?
- How is the radiation belt inward of the C-ring formed and sustained?



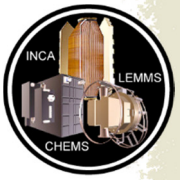
- How can we explain the fluxes of the MeV particles, both inward and outward of the rings and how does the radiation belt co-existing with the F-ring form? What is the source rate of cosmic ray albedo neutron decay (CRAND) neutrons?
- To what extent are the accessible satellite surfaces and atmospheres (including Titan) modified by charged particles?
- What influence does the solar wind have on the magnetosphere?
- Is the mass loss rate from the rings to the atmosphere episodic, or continuous?
- What would Saturn's magnetosphere look like without Enceladus?

Instrument Summary

MIMI comprised three separate sensors and is described in complete detail in Krimigis et al. [2004]. MIMI/LEMMS was a two-ended telescope with oppositely directed fields of view (low and high energy). Detected electrons and ions that entered the apertures were collimated and then reached a solid-state detector (SSD) stack. The stack used a series of coincidence and anti-coincidence requirements related to the energy deposited in the detectors within a timing window to separate species and energies. Electrons entering the low-energy end were magnetically deflected onto detectors for which direct ion pathways are much less probable. Up until about March 2005, a stepping motor changed the telescope fields of view so that good local pitch-angle sampling could be achieved. MIMI/INCA was like a pin-hole camera used to detect ions and ENAs. Collimator blades in front of the detection system could be used to significantly reduce the local charged environment that enters the aperture so that ENAs can be detected more cleanly. When the collimator blade voltages were off, INCA detected the local environment of energetic ions, which typically dominates the neutral intensities. Both ions and neutrals were then measured in a time-of-flight (TOF) system. Secondary electrons triggered start and stop pulses whose positions also identify the particle trajectory. The system was capable of a crude light/heavy ion separation. MIMI/CHEMS measured ions in three directions using an electrostatic analyzer (ESA) followed by a TOF and SSD system. CHEMS stepped through E/q ESA values from about 3 keV/q to 220 keV/q, and selected ions then passed through the TOF system and into one of three SSDs. This allowed for good species and charge state separation (the only sensor on MIMI that can measure charge state). Because of the duty cycle inherent in stepping through 32 E/q steps, CHEMS required more time integration to get good signal statistics.

Key Objectives for MIMI (Announcement of Opportunity (AO) first, then Cassini Solstice Mission (CSM))

- R_AO5 – Ring Magnetosphere-Ionosphere Interactions. Study interactions between the rings and Saturn's magnetosphere, ionosphere, and atmosphere.
- M_AO2 – Magnetosphere Charged Particles. Determine current systems, composition, sources, and sinks of magnetosphere charged particles.



- M_AO4 – Magnetosphere and Solar Interactions with Titan. Study the effect of Titan's interaction with the solar wind and magnetospheric plasma.
- M_AO5 – Plasma Interactions with Titan's Atmosphere and Ionosphere. Investigate interactions of Titan's atmosphere and exosphere with the surrounding plasma.
- I_AO2 – Icy Satellite Surface and Crustal Modifications. Define the mechanisms of crustal and surface modifications, both external and internal.
- I_AO5 – Icy Satellite Magnetosphere and Ring Interactions. Investigate interactions with the magnetosphere and ring systems and possible gas injections into the magnetosphere.
- J_AO3 – Explore the dusk side of the magnetosphere and intermediate regions of the magnetotail unvisited by previous spacecraft.
- C_AO2 – Investigate the behavior of the solar wind during solar minimum, for comparison with earlier Galileo and Ulysses measurements.
- SC2a – Observe the magnetosphere, ionosphere, and aurora as they change on all time scales—minutes to years—and are affected by seasonal and solar cycle forcing.
- MC1a – Determine the temporal variability of Enceladus' plumes.
- MC1b – Observe Saturn's magnetosphere over a solar cycle, from one solar minimum to the next.
- MC2a – Observe seasonal variation of Titan's ionosphere, from one solstice to the next.
- MN1a – Determine the dynamics of Saturn's magnetotail.
- MN1b – Conduct in situ and remote sensing studies of Saturn's ionosphere and inner radiation belt.
- MN1c – Investigate magnetospheric periodicities, their coupling to the ionosphere, and how the Saturn kilometric radiation (SKR) periods are imposed from close to the planet (3–5 R_S) out to the deep tail.
- MN2a – Determine the coupling between Saturn's rings and ionosphere.
- TC2a – Observe Titan's plasma interaction as it goes from south to north of Saturn's solar-wind-warped magnetodisk from one solstice to the next.

MIMI Science Assessment

Table MIMI-1 shows the MIMI science objectives and assessment.

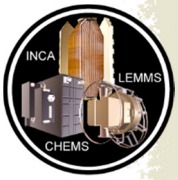


Table MIMI-1. MIMI Science Assessment. AO and Traceability Matrix (TM) objectives are paired with MIMI science objectives.

Fully/mostly accomplished: **Partially accomplished:** **Not accomplished:**

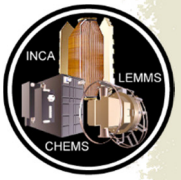
MIMI Science Objectives Characterize the following:	AO and TM Science Objectives	MIMI Science Assessment	Comments if yellow (partially fulfilled)
Magnetospheric structure			
Radiation belts and time variations	MN1b		
Composition, sources, and sinks	M_AO2		
Infer neutral properties	MC1a		
Proximal orbits, D-ring gap	M_AO2		
Middle magnetosphere and tail	MN1a		
High latitude magnetosphere, aurorae	SC2a		
Magnetospheric dynamics			
Dynamic phenomena	SC2a		
Periodicities, solar cycle, seasonal effects			
Periodic phenomena	SC2a, MN1c		
Response to season and solar wind	SC2a, MC1b		
Ring and moon interactions			
Moon-magnetosphere interactions	I_AO2, I_AO5		
Ring-magnetosphere interactions	R_AO5, MN2a		
Titan			
Titan-magnetosphere interactions	M_AO4, M_AO5, MC2a, TC2a		
Non-Saturn results			
Properties of the heliosphere			
Jovian magnetosphere	J_AO3		
Properties of the solar wind	C_AO2		

MIMI Saturn Results

Magnetospheric Structure (Roussos)

The structure of Saturn's magnetosphere is complex, due to its colocation with numerous moons, dense and dusty rings, and active plasma sources. Despite that, it is useful to identify several major regions based on which we can organize the MIMI findings. The regions can be naively divided on the basis of the L-shell (which is the field line distance along the magnetic equator in a dipole representation of the magnetic field):

- Inner magnetosphere, containing the radiation belts (L < 9)
- Middle magnetosphere and plasma/sheet (9 < L < 15)
- Outer magnetosphere and magnetotail (L > 15 out to the magnetopause)
- Upstream of the magnetopause



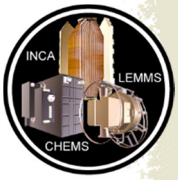
All locations have been extensively sampled by MIMI with different cadence at different mission periods. Below we summarize some of the key results for each region.

Inner magnetosphere and radiation belts: MIMI measurements achieved the most comprehensive description of the radiation belts of a planet besides Earth. More than 200 orbits crossed into the radiation belts, allowing us to understand and quantify their average structure, but also to monitor time variations, despite the single point measurements. The most detailed description of the radiation belts is given by Kollmann et al. [2011] where the L-shell, local time, and pitch angle (latitudinal) structure of the belts is given for electrons and protons of different energies. Heavier ions and their charge states are studied by DiFabio et al. [2011], Dialynas et al. [2009], Carbary et al. [2010a], and Christon et al. [2013, 2014, 2015]. The latter three studies provide the most detailed characterization of trace energetic ions and their charge states at an outer planet, showing how their origin may be connected to the planet's rings, the activity of Enceladus, and seasonal or solar cycle effects.

Allen et al. [2018] conducted a mission-long overview of internal to external sources of energetic plasma at Saturn. They found that solar wind-originating He^{++} ions are able to penetrate into the inner magnetosphere, although the fractional abundance in the inner magnetosphere is only about 0.001%.

Detailed investigations of the proton radiation belts in the MeV range have been published by Roussos et al. [2011, 2016a, 2018a], Kollmann et al. [2013, 2015, 2017], Armstrong et al. [2009], Paranicas et al. [2008, 2010a], and Buratti et al. [2019]. All studies establish how the proton belts are segmented by the icy moons of Saturn (Pandora, Prometheus, Janus, Epimetheus, Mimas, Enceladus, and Tethys) and the planet's main rings. They highlight interaction features with minor rings or ring arcs, such as those from Methone, Pallene, the G-ring, and the ringlets of the D-ring, most of which were unknown prior to Cassini. All studies established that the proton radiation belts inward of Tethys are disconnected from the short-term and large-scale changes that occur in the rest of the magnetosphere, and develop only over long time scales due to the combined influence from variable particle transport effects and the solar cycle, with the former being much more important. The origin of those belts is attributed to CRAND, rather than to extreme solar wind transients, a possibility that was considered before Cassini. Transient extensions of these belts, outside Tethys, have been linked with certainty to the occurrence of interplanetary coronal mass ejections (CMEs) in the vicinity of Saturn [Roussos et al. 2008a, 2018b], one of the first direct demonstrations of space weather at an outer planet with in situ data.

The electron radiation belts in the MeV range have been studied in a series of papers by Roussos et al. [2006, 2014, 2016b, 2019a], Paranicas et al. [2010b, 2012, 2014], Mauk et al. [2010], and Buratti [2019]. They are much more variable and longitudinally asymmetric than the corresponding proton belts, but on average they tend to increase monotonically in intensity inward towards the main rings at which point electrons get instantly absorbed. They evolve in time scales of weeks (as opposed to years for the protons) and are controlled by numerous factors, including the solar wind and internal magnetospheric dynamics. Interaction features of MeV electrons with material—for example, scattering and energy loss in collisions with material—and moons have

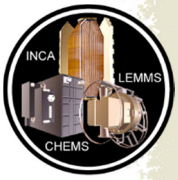


helped to constrain radial transport rates in the magnetosphere and discover previously unknown ring arcs. The source population of the MeV electron belts is now believed to reside in the ring current (middle magnetosphere).

Between energies of tens of keV and few hundred keV, both electrons and ions are on average diminished significantly inward of the orbit of Tethys, due to interactions of these particles with the neutral cloud of Enceladus, the dust of the E-ring or due to absorption by the moons [Paranicas et al. 2007; Kollmann et al. 2011; Carbary et al. 2009a]. The region between 5 and 9 R_S has been found to be dominated by a transient population of interchange injection events, which have been analyzed in single case studies as well as statistically [Paranicas et al. 2007, 2008, 2010b; Mueller et al. 2010; Mauk et al. 2005; and Rymer et al. 2007, 2008, 2009a]. The results have been used to constrain the plasma corotation speed in the inner magnetosphere and the inward radial transport velocities of plasma, and assess the importance of interchange for energetic particle transport and acceleration with respect to other processes like diffusion. The inner magnetosphere is also dominated by energetic electron microsignatures (gaps in the electron fluxes caused by electron absorption by Saturn's moons), which have been used to define the convective flows in the inner magnetosphere (a noon-to-midnight electric field) and radial diffusion rates [Paranicas et al. 2005a; Roussos et al. 2007, 2008a, 2013, 2019a; Andriopoulou et al. 2012, 2014; and Thomsen et al. 2012]. Statistically significant results on the angular distributions and energy spectra of electrons have been described for the first time in Carbary et al. [2011a, 2011b] and Clark et al. [2014].

Middle magnetosphere/ring current: The middle magnetosphere is the region where the so-called ring current of Saturn resides. This current likely has important components below the energy range of MIMI. But it has been found to contain energetic ions and electrons below 1 MeV, with relatively high fluxes. It is populated by large-scale injections in the nightside magnetosphere of Saturn, which sustain the ring current with a series of rotating, energetic ion and electron bundles, sometimes called blobs due to their appearance as such in remote sensing images by MIMI/INCA. The energy density of the energetic ion population is high enough to increase the plasma beta (the ratio of total particle pressure divided by magnetic pressure) above one, therefore causing a significant stretching of the magnetic field lines. Depending on the abundance of oxygen in the energetic ion distributions, the dynamics of the current sheet may be dominated by the presence of energetic particles. All these results are summarized in a series of studies by Sergis et al. [2007, 2009, 2010, 2011, 2013, 2017], Krimigis et al. [2007], Dialynas et al. [2009, 2013a], Carbary et al. [2008a, 2010b, 2012a, 2014a], and Kollmann et al. [2011]. All these measurements provided a most comprehensive, average description of Saturn's ring current, which can inform numerous empirical and physical models of Saturn's magnetosphere—for example, Achilleos et al. [2010]. The time variations in the ring current have been linked to changes in the radiation belts [Roussos et al. 2014, 2018a; Kollmann et al. 2017] and injections [Mitchell et al. 2009a, 2015, 2016], revealing the coupling of the system with different

All these measurements provided a most comprehensive, average description of Saturn's ring current, which can inform numerous empirical and physical models of Saturn's magnetosphere …

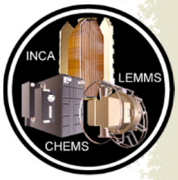


regions of the magnetosphere and the interplanetary space and the aurora—for example, Mitchell et al. [2009b]. The average properties of the ring current, as monitored by ENAs, have been inverted in order to probe the characteristics of Saturn's neutral gas cloud [Dialynas et al. 2013b]. Meanwhile, the average distribution of the middle magnetosphere energetic particles has been studied using observations from CHEMS [Allen et al. 2018].

Many of the studies focusing of the inner magnetosphere extended into the region of the ring current, meaning that energy spectra, angular and L-shell distributions, composition, as well as asymmetries are equally well quantified for $9 < L < 15$.

Outer magnetosphere: Since the outer magnetosphere is very dynamic, it is very challenging to describe its average properties. Still, the continuous in situ measurements by CHEMS and LEMMS and the remote monitoring by INCA have provided unique insights into that region. The most detailed study of the outer magnetosphere's average structure is given by Krimigis et al. [2007] and Sergis et al. [2009], which highlight the distinct day-night asymmetry in the vertical extent of the ring current (or plasma sheet). INCA images have been used to determine the most active sites for dipolarization (or large-scale injection events) in the outer magnetosphere being in the post-midnight sector of the magnetosphere [Mitchell et al. 2005a, 2009b; Carbary et al. 2008b]. They have revealed the wavy structure of the magnetodisk [Carbary 2013; Carbary et al. 2008a, 2015, 2016] and links to auroral emissions. LEMMS measurements have been used to identify an unexpected source of high energy electrons, seen as quasi-periodic pulsations with a period of about 65 minutes. These events are seen globally, they can accelerate electrons to the MeV range instantly and have been linked to reconnection, auroral transients, and similar periodic observations in magnetic field and plasma wave data [Roussos et al. 2016b; Palmaerts et al. 2016a, 2016b; Carbary et al. 2016]. The magnetospheric topology (e.g., open vs. closed field lines or the cusp) has been discussed in the context of MIMI observations—for example, Gurnett et al. [2010] and Arridge et al. [2016a]—while MIMI data have been central in the study and interpretation of reconnection/dipolarization events, in combination with other datasets—for example, Badman et al. [2013, 2016], Jackman et al. [2008, 2015], and Masters et al. [2010]. CHEMS observations also revealed outer magnetosphere asymmetries in the fractional abundance of solar wind-originating ions penetrating into the magnetosphere of Saturn [Allen et al. 2018]. These asymmetries indicate that solar wind He^{++} particles may be entering the magnetosphere due to a combination of Dungey-type reconnection as well as Kelvin-Helmholtz instabilities [Allen et al. 2018].

Upstream of the magnetopause: MIMI measurements have been used to characterize the environment also upstream of the magnetopause. In particular, Sergis et al. [2013] described the conditions of the planet's magnetosheath (the region of shocked solar wind outside the magnetopause), showing how it is strongly modified in the absence or presence of escaping, heavy energetic ions. Kanani et al. [2010] has factored in MIMI measurements to improve empirical models of the shape of Saturn's magnetopause. Measurements of Cassini in the solar wind extend the findings of Sergis et al. [2013], showing the escape of magnetospheric species into interplanetary space [Krimigis et al. 2009a]. Masters et al. [2013] have used MIMI measurements of energetic electrons to demonstrate how the bow shock at very high Mach numbers can be an efficient accelerator of electrons into relativistic energies.



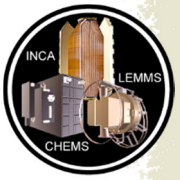
Open questions: What processes form and sustain the newly discovered radiation belt inward of the C-ring? How are energetic particles accelerated at Saturn and how are two-component spectra formed?

Magnetospheric Dynamics (Paranicas)

In addition to the magnetospheric structure presented above, a key aspect of Saturn's magnetosphere is its dynamics. This includes changes on long time scales (months to years) such as the formation and subsequent decay of transient radiation belts [Roussos et al. 2008a] or the gradual evolution of the main radiation belts [Kollmann et al. 2017]. On much shorter time scales, there are both global and more spatially limited injections of hotter plasma or energetic charged particles into the magnetosphere; see Thomsen et al. [2013] for a complete review of the subject. Other dynamics, like pulsations [Palmaerts et al. 2016b] and [Mitchell et al. 2016], are considered in the section entitled Periodicities, Solar Cycle, and Seasonal Effects.

Injections at Saturn have been coarsely characterized as small and large scale. The latter would likely be accompanied by reconfigurations of the planetary magnetic field. Small-scale injections are probably narrow in planetary longitude and physically can be flux tube bundles, flow channels, or more elaborate structures. This group of injections also perturbs the magnetic field locally—for example, Andre et al. [2005, 2007]—but probably at the level of a few percent of the planetary field. Andre et al. [2007] and Rymer et al. [2009a] present multi-instrument displays of interchange events in the magnetosphere of Saturn. This group of injections have been characterized as particle distributions with phase space densities that are very different from the surrounding medium in which they are observed [Mauk et al. 1999; Paranicas et al. 2016]. Mitchell et al. [2015] summarized the observational differences between small-scale and large-scale injections at Saturn. They found that small-scale injections tended to be found inward of about 12–15 R_S, although they also found large-scale injections that could be inward of that distance. It is probably the case that small-scale injections (which are found very frequently in the data) extend in energy up to the tens of keV or so. Rymer et al. [2007] used phase space density profiles derived from Cassini Plasma Spectrometer (CAPS) data to approximate a starting radial distance of interchange injections that are observed by Cassini. Paranicas et al. [2016] approximated the inward flow speed of injections and found values comparable to the theoretical computations of Hill et al. [2016] for $5 < L < 10$. It is believed that the radial speed of injections decreases as they approach Saturn.

Large-scale injections at Saturn have received much less attention in the literature than small-scale ones. Thomsen et al. [2013] have provided a good summary of the situation. Large-scale injections have been characterized by the MIMI data set. Mitchell et al. [2009b] linked some of these injections to ultraviolet (UV) data from Hubble Space Telescope (HST) and Cassini. Paranicas et al. [2007, 2010b] looked at the radial range of injection remnants. Because these extend into the hundreds of keV, it is likely Paranicas was studying large-scale injections. The effects of tail collapse, plasmoid production, and related processes have been documented with the help of magnetometer data—for example, Jackman [2011, 2015].



Because of their ubiquity, injections at Saturn have been used to characterize other features of the magnetosphere. Mauk et al. [2005] and Mueller et al. [2010] created azimuthal plasma flow speeds as a function of Saturn distance using MIMI injection data. Plasma flow speeds were later found using the plasma data—for example, Thomsen et al. [2010].

Open questions: What is the connection between large-scale and small-scale injections at Saturn? How much material do injections transport relative to radial diffusion? What creates the injections? How is radial diffusion driven?

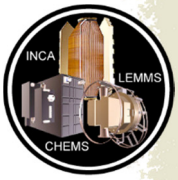
Saturn's magnetosphere displays a wealth of periodicities at a wide range of frequency scales.

Periodicities, Solar Cycle, and Seasonal Effects (Carbary)

Saturn's magnetosphere displays a wealth of periodicities at a wide range of frequency scales. The best known of these periodicities is the putative planetary period at ~10.7 hours. This periodicity was discovered in charged particles by the Voyager Low Energy Charged Particle (LECP) instrument in the early 1980s [Carbary and Krimigis 1982]. LEMMS and CHEMS instruments monitored this planetary periodicity throughout the 13-year Cassini mission, and, along with the Radio and Plasma Wave Science (RPWS) and Magnetometer (MAG) instruments, discovered that this periodicity slowly varied by ~1% over several years and that it split into dual periods, one associated with the northern hemisphere and the other with the southern [Carbary et al. 2009b, 2011a]. This dual periodicity is not always detected, however, which may be a consequence of the observer location and/or its actual disappearance [Carbary et al. 2014a, 2016]. Single and dual periodicities were also observed in ENA fluxes detected by INCA [Carbary et al. 2008b, 2014a; Carbary and Mitchell 2017]. INCA's global view of these periodicities revealed a local time dependence, namely, that one period might be detected at one local time but absent at another [Carbary et al. 2014a]. Finally, the energetic electrons apparently have the same period (~10.8 h) during the summer season when either the North or the South Pole tilts with respect to the direction to the Sun [Carbary et al. 2017a]. This discovery, made possible by Cassini's solstice-to-solstice extension, has strong implications for the solar driving of these planetary periodicities. A complete review of Saturn's magnetospheric periodicities, as of 2013, appeared in Reviews of Geophysics [Carbary and Mitchell 2013], and should be consulted for the overall context within which particle periodicities can be placed.

MIMI also discovered that energetic particles display oscillations at the much longer solar wind period (~26 d). This solar wind periodicity was discerned during solar minimum (i.e., 2008–2010) when the solar wind structure was not disrupted by solar activity. The solar wind periodicity was first recognized in the energetic electrons [Carbary et al. 2009c], but was perhaps even stronger in the energetic ions [Carbary et al. 2013a]. Because solar activity varied with the ~22-year solar cycle, the appearance of this 26-day periodicity itself should vary with the solar cycle.

The solar cycle is also evident in LEMMS measurements of Saturn's radiation belts. The very energetic protons (E > 1 MeV) that form Saturn's ionic radiation belts were found to be modulated



with the solar cycle, which provided clues that they might derive from CRAND from Saturn's atmosphere [Roussos et al. 2011]. As at Earth, the cosmic rays causing CRAND at Saturn are themselves modulated by the solar cycle, and LEMMS detected this for the first time using observations over many years. The ring current boundary, deduced from LEMMS observations, also appears to fluctuate in response to solar energetic particle (SEP) events, which are themselves conditioned according to the solar cycle [Roussos et al. 2014].

The LEMMS instrument also discovered another, completely unexpected periodicity at the relatively short time scale of ~1 hour [Roussos et al. 2016b]. These quasi-periodic (QP) oscillations have periods near ~60 minutes, tend to occur on the dusk side, and suggest acceleration at high latitude [Palmaerts et al. 2016a]. Similar QP-60 oscillations were detected in the polar cusp regions and are probably related to similar periodicities observed in the magnetic field and radio emissions [Palmaerts et al. 2016b]. The ~60-minute periodicities may be related to pulsed dayside reconnection, which generates Alfvén waves having these periods.

Open questions: What is the underlying cause of Saturn's periodicities? How are the observed periodicities related to the actual rotation of Saturn, and does it matter?

Particle Interactions with Moons and Ring Arcs (Krupp)

MIMI studied the environment during 23 Enceladus flybys, 5 Dione flybys, 4(5) Rhea flybys, 1 Tethys flyby, a distant Hyperion flyby, and a distant Mimas flyby.

Simon et al. [2015] summarized the moon magnetosphere interaction and compared Cassini data with hybrid code simulations.

Mimas: Hendrix et al. [2012] analyzed the Mimas UV albedo where the space weather effects caused by the energetic particles in the LEMMS energy range play a major role.

Enceladus: Krupp et al. [2012], Krupp et al. [2018a], and Jones et al. [2006a] studied the particle distributions and absorptions features near Enceladus with ramp-like, spike-like, and dust-related features.

Tethys: Roussos et al. [2005] reported low energy electron microsignature observations by LEMMS in the vicinity of Tethys' L-shell, during the first seven orbits of the Cassini mission. Double microsignatures seen for the first time suggest low radial diffusion coefficients and point to dynamic events in the magnetosphere.

Dione: Kotova et al. [2015] studied the particle distributions using particle tracing in hybrid code simulations and Krupp et al. [2013] summarized the LEMMS measurements near Dione.

Rhea: Jones et al. [2008] reported about particle observations possibly due to orbiting dust near Rhea. In Roussos et al. [2008b], three-dimensional hybrid simulations were performed in the vicinity of Rhea, and Roussos et al. [2012] reviewed the energetic electron environment of Rhea's

magnetospheric interaction. Khurana et al. [2017] identified the distant Alfven wing signature of Rhea several hundred moon radii away.

Hyperion: Nordheim et al. [2014] detected a dropout in energetic electrons observed by LEMMS, indicating that the moon and the spacecraft were magnetically connected when the field-aligned electron population was observed. It was shown that this constitutes a remote detection of a strongly negative (about -200 V) surface potential on Hyperion, consistent with the predicted surface potential in regions near the solar terminator.

Roussos et al. [2005] used LEMMS-displaced microsignature measurements near Tethys to study magnetospheric parameters, including a convective electric field.

Paranicas et al. [2005a] showed some of the earliest evidence of two microsignatures from Enceladus and Tethys in the LEMMS data.

Microsignature analysis from Roussos et al. [2007] revealed a high n dependence in D_{LL} ~L^n and an increase of its value toward equatorial pitch angles. This supports the idea that electron micro-diffusion refills microsignatures and partly accounts for transporting electrons at low L. It is driven by magnetic field pulsations.

Roussos et al. [2008c] looked at several energetic charged particle microsignatures of two Lagrange moons, Telesto and Helene, measured by the LEMMS instrument and inferred the possibility that the 3 km satellite Methone is responsible for two electron microsignatures detected by Cassini close to this moon's orbit; a previously undetected arc of material exists at Methone's orbit (R/2006 S5) (Figure MIMI-1).

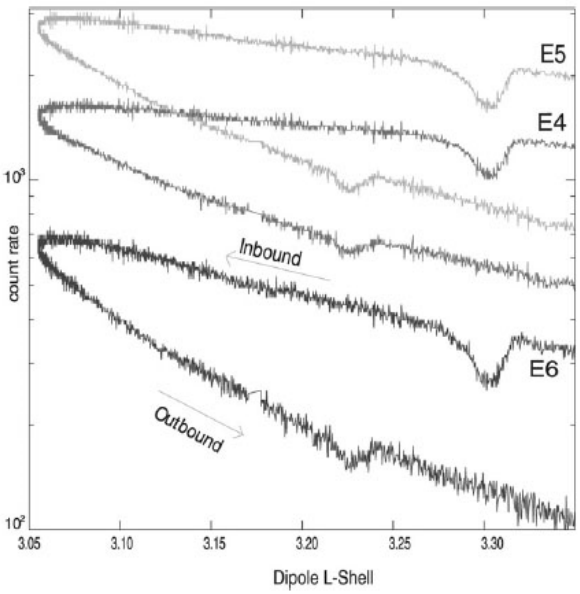


Figure MIMI-1. Flux depletions around Methone's orbit in the LEMMS E4–E6 channels as a function of dipole L shell. [Roussos et al. 2008c]

Roussos et al. [2010a] analyzed energetic electron microsignatures as tracers of radial flows and dynamics in Saturn's innermost magnetosphere including numerical simulation of energetic electron microsignature drifts [Roussos et al. 2013].

Andriopoulou et al. [2012, 2014] discovered a formerly unknown global noon-midnight electric field in Saturn's inner magnetosphere inferred from moon microsignature displacements, by carrying out an analysis of a large amount of LEMMS data (Figure MIMI-2 and Figure MIMI-3).

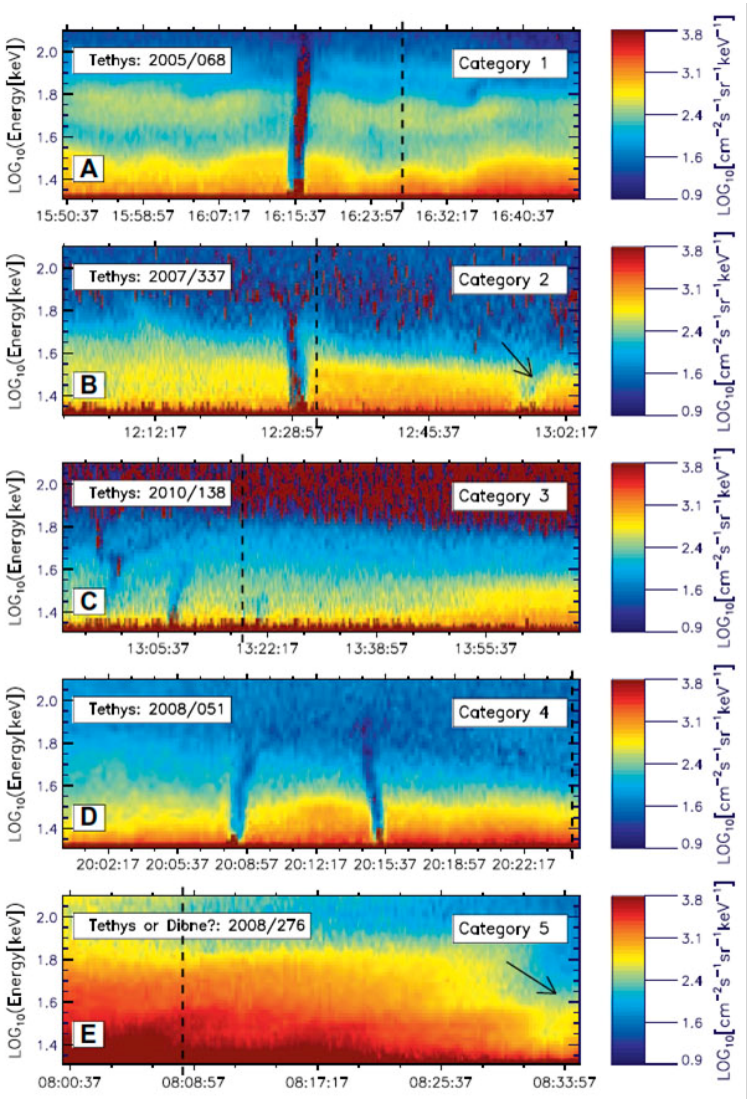

Figure MIMI-2. Microsignatures in the LEMMS data. [Andriopoulou et al. 2012]

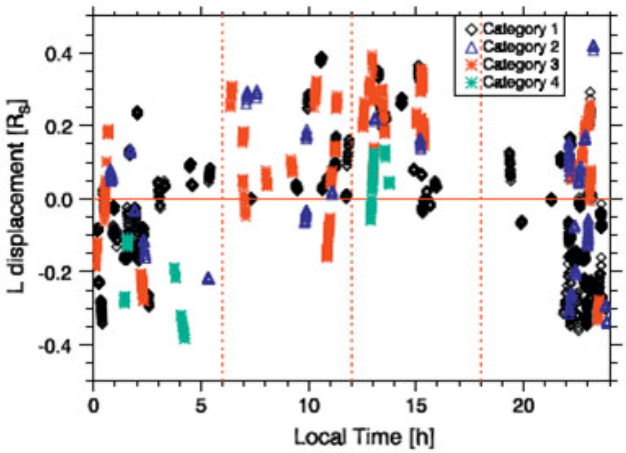

Figure MIMI-3. Microsignature displacements that led to the discovery of a global noon-to-midnight electric field at Saturn. [Andriopoulou et al. 2012]

Some other highlights included a study by Hedman et al. [2007] on the source of Saturn's G-ring and a study by Jones et al. [2006] that found evidence of lightning-induced electron beams in the formation of ring spokes at Saturn.

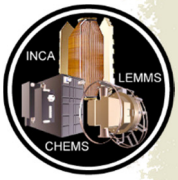
Open question: What would Saturn's magnetosphere look like without Enceladus?

Space Weathering, Surface Interactions, and Charging (Krupp and Paranicas)

Several optical studies related bombardment patterns by MIMI-range electrons to surface features. Schenk et al. [2011], using a color ratio from Cassini data, found a dark lens shape on the leading hemispheres of Mimas and Tethys that they related to energetic electron bombardment patterns. Howett et al. [2011], using Cassini data from the thermal infrared (IR), predicted that the bombardment of the same energetic electrons could cause regions of thermally anomalous surface ice, meaning the ice would not change temperature in sunlight in a predictable manner. Schiable et al. [2017] expanded on the possible nature of energetic electron bombardment of ice, its effects on spacing in the regolith grains and thermal conductivity.

Paranicas et al. [2014] presented the magnetospheric underpinnings of the lens feature that is observed by Schenk and Howett, following their earlier bombardment model [Paranicas et al. 2001]. Nordheim et al. [2017] expanded on Paranicas's model to include predictions for the bombardment of the leading and trailing hemispheres of Mimas and considered other species in their work.

Paranicas et al. [2018] discussed the energetic proton fluxes at the orbits of the inner moons and argued that the relatively low proton fluxes at the Saturnian moons (compared with the Jovian ones) might be the reason there is little to no amorphous ice in the Saturnian system [Clark et al. 2012]. Buratti et al. [2017] also discussed weathering issues.



Roussos et al. [2010b] considered the question of the surface charging of Saturn's inner moons.

Open question: Is all the ice in the Saturnian system in the crystalline state and if so why does radiation play no role in causing a transformation to the amorphous state?

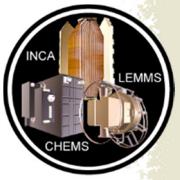
Titan (Regoli)

The spacecraft performed 127 flybys of Titan over the course of the whole Cassini mission. The flybys, varying in trajectory and closest approach altitude, served as gravity assists to change Cassini's trajectory, but also to bring our understanding of the moon's environment to an unprecedented level. MIMI's three separate sensors provided a large dataset of the environment surrounding Titan that has already produced important scientific results and that will certainly continue to be analyzed in the decades to come.

The INCA instrument had the capability of remotely measuring the exosphere of Titan, an ambient neutral population too tenuous to be measured by in situ mass spectrometers.

The INCA instrument had the capability of remotely measuring the exosphere of Titan, an ambient neutral population too tenuous to be measured by in situ mass spectrometers. Prior to the arrival of Cassini at Saturn, modeling of the production of ENAs began as a preparation for the first observations. Amsif et al. [1997] developed a model including the inner and outer exosphere, including the five major species contained in Titan's atmosphere, namely, H, H_2, N, N_2, and CH_4. The ENA production was modeled using a proton spectrum from the Voyager flyby. Taking into account the production from both the inner and outer exosphere (estimated using a Chamberlain model), they predicted that Cassini would be able to image the exosphere out to at least 5 Titan radii. Dandouras and Amsif [1999] analyzed the production of synthetic ENA images considering the same exospheric model from Amsif et al. [1997] but including the geometry of the interaction region and the expected ENA trajectories. They concluded that the INCA instrument would be able to provide information regarding the ion fluxes and spectra, as well as the magnetic field environment in the vicinity of Titan, based on a shadowing effect produced by the presence of the moon itself.

Using data from the INCA instrument collected during the first two close flybys of Titan by Cassini, namely TA and TB, Mitchell et al. [2005a] reported a variable halo of ENA emissions that is asymmetric around the moon, confirming the predictions made by the Dandouras and Amsif [1999] model. The overall shape of the ENA images showed a complex interaction region dominated by the variable magnetospheric environment present at the outer magnetosphere and the large gyroradii of the energetic parent ions.



Analyzing the images returned by INCA during the TA flyby, Garnier et al. [2007] found a discrepancy between the maximum flux altitude estimated by the models and the one derived by the data. In order to account for this, they proposed an updated exospheric model, adapted to fit the data provided by the Ion Neutral and Mass Spectrometer (INMS). Using the updated model and energetic ion data obtained by LEMMS, they obtained improved ENA flux profiles that were more consistent with the INCA data.

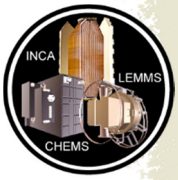
In a follow-up paper, Garnier et al. [2008] improved the shadowing by the moon by including the corotation velocity of the parent ions. They also found that, to properly interpret INCA data, multiple ionization and neutralization processes for a single parent ion need to be considered. Apart from changing the trajectories, this leads to a thermalization of the energetic ion population.

Combining data from the INCA and the INMS instruments, Dandouras et al. [2009] calculated profiles of the main exospheric species that revealed the non-thermal nature of their distributions. They also found that the ENA emissions from the interaction region get absorbed below an altitude of about 1000 km, where energetic ions deposit their energy. In terms of the extension of the atmosphere, they were able to measure it up to an altitude of 40,000 km.

Using data from Saturn Orbit Insertion (SOI) to 2007, Brandt et al. [2012] studied the exospheric composition of Titan. For this, 36 min accumulation time hydrogen data from the INCA detector when observing Titan without the magnetosphere behind it were analyzed. Combining these observations with a model for the production of ENAs, they found that the molecular hydrogen exosphere of Titan extends to a distance of about 50,000 km—almost 20 Titan radii, confirming the lower-limit of 5 Titan radii obtained by Amsif et al. [1997]. Taking into account the profiles obtained and the fact that ENAs have direct access to Titan's atmosphere, they estimated a precipitating energy flux from ENAs of 5×10^6 keV/(cm^2s), a number comparable to previous estimates of precipitating energetic ions [Sittler et al. 2009] and solar extreme ultraviolet (EUV) [Tobiska 2004].

Apart from remote-sensing studies of the exospheric structure and the interaction region using INCA, CHEMS, and LEMMS also provided in situ data to understand the upstream conditions at Titan's orbit as well as the energy deposition by energetic ions in the atmosphere. Cravens et al. [2008] studied the energy deposition by energetic H^+ and O^+ ions using two different LEMMS spectra: one for the T5 flyby that presented especially high fluxes, and one for a more typical condition. Using a combination of INMS measurements and an engineering model by Yelle et al. [1997] of Titan's atmosphere, they calculated the ionization rates for the precipitating ions concluding that these are important for the formation of the ionospheric layers below the main ionospheric peak as well as for the creation of negative ions observed by the CAPS instrument [Coates et al. 2007].

Smith et al. [2009] focused on the T18 flyby to study the energetic proton penetration in the atmosphere. They used LEMMS to obtain the incoming flux of energetic particles and INCA to analyze the proton penetration at lower altitudes than the Cassini closest approach distance. With these data, they derived an updated atmospheric model that they successfully used to reproduce the INCA observations.



Using a combination of a test particle code and hybrid simulations, Regoli et al. [2016a] analyzed the effect that the magnetic field configuration has on the access and subsequent energy deposition of energetic ions from the Saturnian magnetosphere. Using upstream fluxes detected by CHEMS during the T9 flyby, they found that the ionization rates can vary by up to 80% from one location to another, due to finite gyroradius effects.

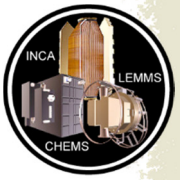
From the beginning of the Cassini mission, it became clear that the conditions assumed using the data collected by Voyager in the vicinity of Titan were not representative of the highly variable magnetospheric environment surrounding the moon. The fact that the moon is located at the outskirts of the magnetosphere and that the Saturnian current sheet is constantly moving up and down [Arridge et al. 2008] means that Titan can be located at completely different environments in rapid succession.

Rymer et al. [2009b] used a combination of the electron measurements taken by the Electron Spectrometer (ELS; part of CAPS) and LEMMS instruments to classify the plasma environment at Titan in four different categories, namely plasma sheet, lobe-like, magnetosheath, and bimodal, each with a distinct electron spectrum. They found that the bimodal distribution seems to arise from enhanced local pickup, introducing a cold electron population not present in the other environments. They also found that current sheet encounters were the more common ones, with magnetosheath ones being fairly rare, even though over half of the analyzed encounters occurred within two hours of noon, in terms of Saturn local time.

Using the same technique and instrumentation, Smith and Rymer [2014] extended the study up to the final data sampled by CAPS, before the instrument was switched off in 2012. For that study, they included the remaining dedicated flybys as well as all the orbit crossings when Titan was not there. With this extended dataset (77 encounters and 111 orbit crossings), they derived an empirical model for the electron distribution and also for the rate of occurrence of each environment with respect to Saturn local time.

A similar statistical analysis, but only looking at the energetic ions was made by Garnier et al. [2010] using LEMMS data for ions with energies from 27 to 255 keV and H ENA images corresponding to energies between 24 and 55 keV. They found that the ion population seems to be quasi-isotropic and a dawn-dusk asymmetry in the flux of energetic ions, with higher fluxes in the dawn sector of the magnetosphere. They also concluded that the variability observed in the ENA images from INCA are due to the variability in the magnetospheric fluxes, with the exosphere being roughly stable.

Bebesi et al. [2012] analyzed the locations of the mass-loading boundary (defined as the region where corotating plasma starts to slow down) and the electron drop-out region (where energetic electrons strongly interact with the moon’s atmosphere). They found that the location of these regions presents a scattering that they attributed to the highly variable magnetospheric environment.



Roussos et al. [2018c] took advantage of the ability of SEPs to penetrate the magnetospheric boundaries to use LEMMS as an upstream monitor to detect solar events even when Cassini is located inside the Saturnian magnetosphere. By performing a statistical study, they identified times with enhanced energetic protons, some of them occurring during dedicated Titan flybys, opening up the possibility of studying the effect that these events have on the energy deposition of energetic particles in the moon's atmosphere.

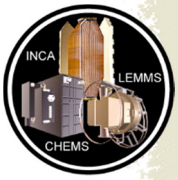
Using LEMMS and CHEMS data, Regoli et al. [2018] analyzed the energetic environment at the orbit of Titan from a statistical perspective, also finding a highly variable environment, but with a relatively clear distinction for the times when Titan is located inside and outside the Saturnian current sheet. In addition, using Kappa distribution functions, they derived an empirical model of the energetic protons that the moon encounters while orbiting Saturn.

Open questions: How do changes in the energetic environment affect the ionization of Titan's atmosphere? How does the induced magnetosphere of Titan react to changes in the solar wind when Titan is located beyond the Saturnian bow shock?

The Final Year (Kollmann)

The last year of the Cassini mission facilitated a variety of unique measurement opportunities that were not possible throughout the entire previous mission. This began in November 2016 with the so-called F-ring or ring-grazing orbits. Cassini not only came close to the edge of the main rings, it also kept revisiting this region every week. This allowed studying the time dependence of energetic charged particles in this region. Roussos et al. [2018d] reported on a strong enhancement of >1 MeV electrons inward of 6 R_S, possibly due to acceleration in the magnetotail. The fast sequence of orbits allowed observing the time evolution of the enhancement. It is consistent with radial diffusion driven by fluctuations of the noon-to-midnight electric field. Electrons that are quasi stationary in local time (because magnetic and corotation drifts cancel out) are affected the most. Their transport and subsequent loss is much faster than for the stably trapped protons in the same region.

In April 2017, the proximal orbits began, also called the mission Grand Finale. This enabled a comprehensive study of the proton radiation belt trapped approximately between the F-ring and A-ring. MIMI also found a previously unknown partial, electron belt within the F-ring (called "microbelt")—partial because it is only observed outbound at local noon. This microbelt is variable in intensity, although permanently present and stable in local time and L-shell. These results are compiled in Buratti et al. [2019] and Roussos et al. [2019a]. As part of the latter study, it was also shown that a small flux of particles observed on field lines above Saturn's main rings, are actually secondary MeV electrons that were produced by galactic cosmic ray (GCR) impacts on ring material, less than 1 sec before their observation. A clear radial profile of the rings, including the signature of the Cassini division, was visible on the MeV electron rates from LEMMS. This signal has been observed in the past by Pioneer 11 measurements, but it was unclear if those secondary electrons were from GCR impacts on the atmosphere or the rings.



The LEMMS instrument discovered a previously unknown radiation belt collocated with the D-ring and extending up to the dense atmosphere of Saturn. This belt was predicted earlier [Kollmann et al. 2015] but its properties were unknown. It was found that the belt is dominated by protons up to the GeV range, which is the first time that such high energies were directly observed at any of the giant planets. The suggested source is CRAND because protons are unable to diffuse past Saturn's dense A–C rings. There is no evidence for the presence of energetic electrons or ions heavier than protons. These results are compiled in Roussos et al. [2018d]. A follow-up study by Kollmann et al. [2018a] studied the pitch angle distribution and explained its steepness with a strong interaction with Saturn's atmosphere and D-ring. Particle fluxes inward of the main rings can therefore be diagnostic of properties of the D-ring and high-altitude exosphere that are difficult to constrain by other Cassini instruments or remote observations. During SOI, Cassini remotely detected protons at tens of kiloelectron volt (keV) from low (atmospheric) altitudes [Krimigis et al. 2005]. The proximal orbits revealed that this was a huge coincidence since similar observations were only found once during the proximal orbits [Krupp et al. 2018b], suggesting this ion population is transient. Since the ions derive from ENAs produced in the magnetosphere, their intensity likely depends on the conditions in the magnetosphere. Because these ions were not observed in situ, they must be located at altitudes below 3,800 km.

The most surprising measurement during the proximal orbits was likely that the MIMI/INCA and CHEMS instruments, which were designed to measure energetic particles, were detecting signatures of D-ring dust falling into Saturn's equatorial atmosphere. These particles are of 1–3 nm size, much smaller than what is detected by the Cosmic Dust Analyzer (CDA) instrument designed to measure dust. The dust is reaching the atmosphere within 4 h and provides a continuous influx of about 5 kg/s from the rings into the atmosphere. These results are compiled in Mitchell et al. [2018].

Open questions: How can we explain the fluxes of the MeV particles, both inward and outward of the rings and how does the radiation belt co-existing with the F-ring form? What is the source rate of CRAND neutrons?

Grand Finale Orbits (Paranicas, Kollmann)

Other research articles that significantly included MIMI data from the Grand Finale orbits are described next. Mitchell et al. [2018] participated in a series of articles about D-ring dust falling into the planet. They looked at signatures of this process in two of the MIMI sensors and found evidence for grain sizes that cannot be measured by the dedicated dust instrument CDA on Cassini. The spiraling dust may be an explanation for Saturn's hydrogen plume [Shemansky et al. 2009]. Roussos et al. [2018b] described heliospheric conditions inferred from MIMI data obtained at Saturn. Buratti et al. [2019] showed the relationship between trapped charged particles and the locations of small bodies close to the planet.

MIMI Non-Saturn Results

Cruise Observations (Carbary)

Ion conics were observed in proximity to a shock structure in the solar wind between the orbits of Jupiter and Saturn. These conics appear in energetic protons (~30–350 keV) detected by INCA during its approach to Saturn on October 8, 2003 (d 281) and again on October 20, 2003 (d 293).

Both conics have a distinct ring structure centered approximately on the magnetic field, but the first one was peaked along the field at ~35° pitch angles while the second peaked near ~145° anti-parallel to the field. Figure MIMI-4 shows these rings at several energies. The conics lasted for about an hour and display a time and energy dependence. Such events are seen rarely during the Cassini transit between Jupiter and Saturn, even when the spacecraft pointing was favorable near a shock. The conic structures can be explained as a consequence of back-scattering from a nearby shock in the solar wind [Decker et al. 1988]. These results were described by Hill et al. [2006].

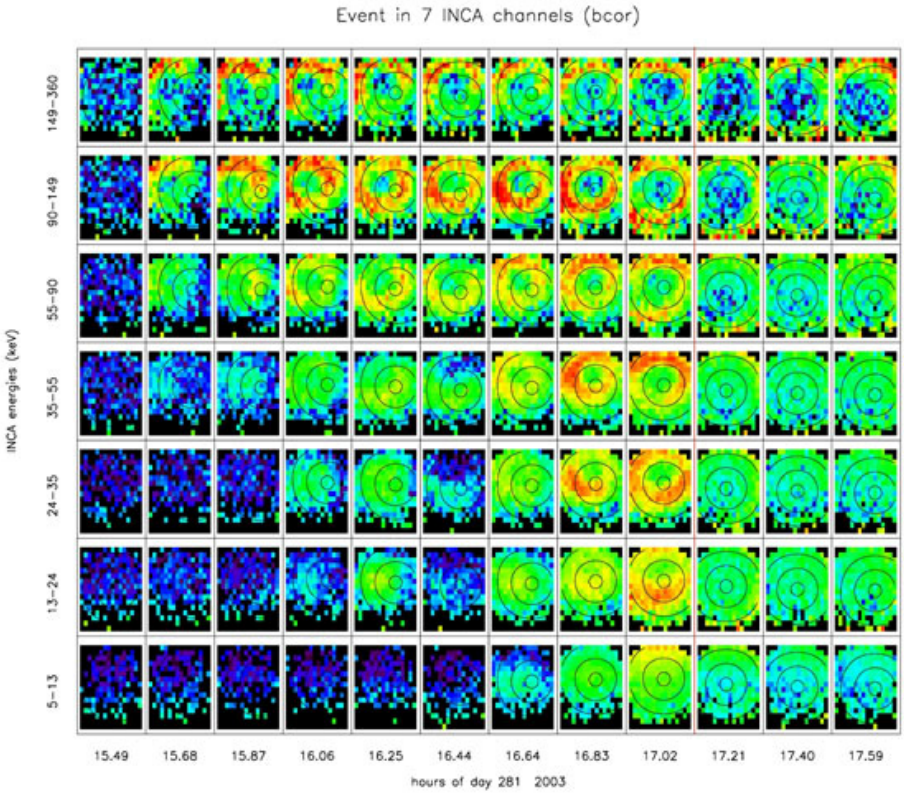


Figure MIMI-4. Sequence of INCA ion images at the highest time resolution available for the ion conic event. With pitch angles contours shown at increments of 10°, 30°, 50°, the images are arranged with time on the horizontal axis and INCA energy on the vertical. Images have been corrected for background and the solar wind flow. The vertical red line between 17.02 h and 17.21 h marks the time of the forward shock. The intensity scales in all cases are logarithmic, although they have different low- and high-energy limits.

Planetary Flybys (Carbary)

The Cassini spacecraft obtained gravity-assists at Earth (August 1999) and Jupiter (December 2000–January 2001). During the Earth flyby, MIMI operated for the first time in a planetary magnetosphere. INCA observed Earth's ring current from long range, CHEMS detected H^+ and O^+ from the outer ring current, and LEMMS reported complete energy spectra of ions and electrons during the pass, including bow shock and magnetopause crossings [Krimigis et al. 2004; Lagg et al. 2001; Ogasawara et al. 2011]. During the Jupiter flyby, INCA observed large fluxes of energetic neutral atoms, primarily H and O, from the planet [Mitchell et al. 2004]. INCA discovered an ENA torus associated with and located just outside the orbit of Europa [Mauk et al. 2003]. The neutral densities in this torus were comparable to those found in the Io-associated cloud, and suggested that Europa is a strong source of neutrals. Figure MIMI-5 shows the discovery ENA image of the Europa torus.

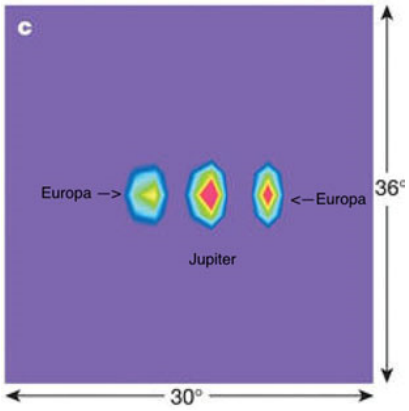

Figure MIMI-5. ENA image of the Europa torus. Seen from the side during the Cassini flyby of Jupiter in early 2001, the Europa torus appears on either side of Jupiter. The image was deconvolved for point sources and corrected for background. The intensity scale is linear.

Jupiter Cassini-Galileo Comparisons (Krupp)

During the Jupiter flyby of Cassini at the end of 2000/beginning of 2001, the Galileo spacecraft was still orbiting the gas giant. The LEMMS sensor was flown on both missions with nearly the same capabilities and identical energy channel configurations. This offered the opportunity to study the duskside Jovian magnetosphere from two different locations simultaneously. The comparison of both energetic particle measurements is summarized in Krupp et al. [2002, 2004].

Figure MIMI-6 shows the differential fluxes and the pitch angle distributions of ions and electrons measured with LEMMS onboard Galileo and Cassini in the vicinity of the Jovian magnetopause. The main results are:

- Passage of closed to open planetary field lines with distributions from bidirectional to monodirectional, with respect to the magnetic field near the magnetopause;
- Periodic variations of electron fluxes on both spacecraft with 40 min periods near Cassini and about 60 min at Galileo's location;

- Leakage of magnetospheric particles into the interplanetary space; and
- Sporadic electron beams outside the magnetosphere (Cassini at 300–900 R_J and Galileo at 130 R_J).

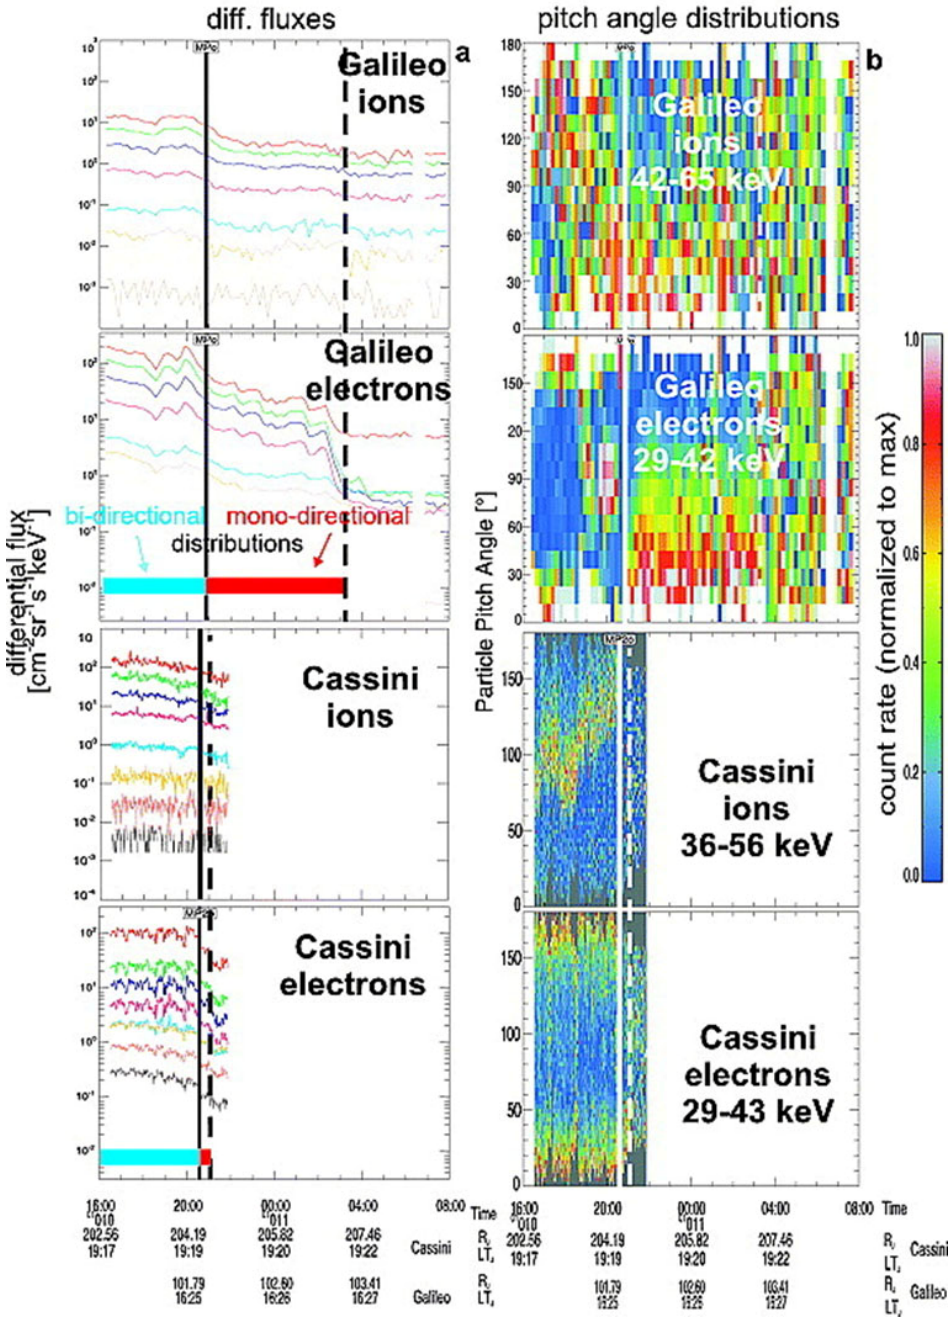

Figure MIMI-6. Differential fluxes and pitch angle distributions of ions and electrons. These ions and electrons are measured with the LEMMS sensors onboard Galileo and Cassini [Krupp et al. 2002] in the vicinity of the magnetopause of Jupiter.

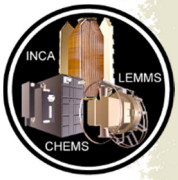


Hanlon et al. [2004] also studied dual spacecraft observations near Jupiter. Cassini data were used as upstream monitors while Galileo was deep inside the Jovian magnetosphere.

Interplanetary Suprathermal and Energetic Particles (Hill)

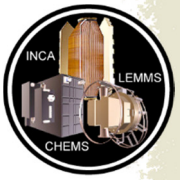
During the cruise to Saturn, the MIMI suite was able to make unique measurements of heliospheric suprathermal particles in the 2–60 keV/nuc range. There has never been an investigation with species separation of this important class of particles, which ties the solar wind plasma to the energetic particles, beyond Jupiter. Hill et al. [2009] made CHEMS measurements that revealed that the radial intensity profiles of He^{+} and He^{++} are very different from both analytical and numerical theory, with the observations showing an increasing intensity with distance from the Sun, while the theory predicts the intensity should fall. This observation remains unexplained.

CHEMS measurements of pickup ions were used to determine solar wind speeds, which enabled a study [Hill and Hamilton 2010] of the spectral index of suprathermal particles. The slopes of the spectra were reported and widely put into and used to create context by the community, but Hill and Hamilton [2010] showed that the expected velocity v dependence was approximately v-5 as reported by Fisk and Gloeckler [2008]. This study was followed up by Kollmann et al. [2019]. They compared Cassini and New Horizons measurements of interplanetary suprathermal ions. This revealed that there is no obvious dependence of the average spectral shape with distance to the Sun but that that the variability at Cassini's location was much larger. They also suggested a mechanism through which the suprathermal ions are accelerated. The data are consistent with acceleration happening largely in corotating interaction regions. Particles leaving these regions and flowing along magnetic field lines are cooled, so that their spectral shape is changing with distance to the emission region.

The solar wind speeds that were derived with CHEMS data are of inherent value for investigating the heliosphere and, near Saturn, as an input to magnetospheric studies. Data from 2001 to 2004, inclusive, at a 12-hour cadence, were published on the Cassini project's MAPSview website in 2014 (mapskp.cesr.fr/index.php).

The energetic particle population was studied by Lario et al. [2004] using LEMMS observations. They found that intensity enhancements up to ~1 MeV were due to the passage of interplanetary shocks while at the highest energy (>25 MeV), the prompt component of solar energetic particle events was responsible. For all but the largest SEP events, the presence of magnetic field structures between the Sun and the spacecraft significantly modulates the intensity enhancements.

Furthermore, the extension of LEMMS's capabilities to monitor galactic cosmic rays, was used to disprove a theory and Earth-based observations that Jupiter contributes up to 5% of the 80 MeV-2.5 GeV proton flux in the heliosphere [Roussos et al. 2019b].

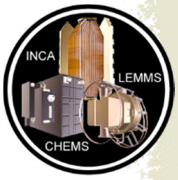


The Heliosphere Imaged with INCA (Dialynas)

The Sun's atmosphere is not static, but expands in the form of a magnetized fluid called the solar wind [Parker 1958], reaching to distances of potentially hundreds of astronomical units (1 AU = 1.5 × 108 km), shaping our local bubble, called the heliosphere, through its interaction with the Local Interstellar Medium (LISM). Voyager 1 and Voyager 2 (hereafter, V1 and V2) crossed the termination shock, where the supersonic solar wind presumably terminates at the shock front, at respective distances of ~94 and ~84 AU in 2004 and 2007 at +35° and −26° ecliptic latitudes [Decker et al. 2005, 2008], pinpointing both the—previously unanticipated—size of the local heliosphere and the scale of the heliospheric asymmetry.

After the discovery of the reservoir of ions and electrons that constitute the heliosheath (a region past the termination shock), V1 passed through an unexpected depletion region, where a decrease in ions of solar origin (by a factor of ~103) and a simultaneous increase of high-energy cosmic rays (~9.3%) occurred, that forms part of the interface between the solar plasma and the galaxy, namely the heliopause [Krimigis et al. 2013], at a distance of ~122 AU. Since August 2012, V1 has continued its journey to the galaxy, measuring the distant and unexplored LISM (V1 is currently located at a distance of ~19 AU past the heliopause), while V2 is still surveying the heliosheath (expected to cross the heliopause in the next few years). Due to the powerful synergy between in situ ions from V1/Low Energy Charged Particle (LECP) instrument and ENAs from INCA (in overlapping energy bands), MIMI, beginning in about 2009, has made key discoveries that altered our past notions on the formation and interactions of the heliosphere, leading to a number of surprises concerning the physics that governs this enormous system, and providing insights on the plasma processes at ~100 AU that were substantially at variance with previous theories and models.

In 2009, the MIMI team published one of the most historic papers, of worldwide appeal, in the field of Heliosphere Physics in Science [Krimigis et al. 2009b]. They showed, for the first time, images of the global heliosphere using >5.2 keV ENA measurements obtained with INCA over the 2003–2009 time period, and identified two striking, previously unexpected, heliospheric signatures: (a) the Belt, a broad band of emission in the sky, identified as a high intensity, relatively wide ENA region that wraps around the celestial sphere in ecliptic coordinates, passing through the nose the anti-nose (tail) and the North and South Heliosphere poles; and (b) the Basins, identified as two extended heliosphere lobes where the ENA minima occur. Interestingly, the ENA measurements are moderately well organized in galactic coordinates, with the Belt presenting a prominent tilt of ~30° with respect to the galactic equator, whereas the Basins were found to roughly coincide with the galactic North and South Poles, although their boundaries were also tilted ~30° to the galactic equator. The same *Science* issue hosted yet another significant publication (with contribution from the then-MIMI PI, S. M. Krimigis), from the Interstellar Boundary Explorer team [McComas et al. 2009], showing, for the first time, images of the heliosphere in <6 keV ENAs. A narrow bright ENA stripe known as the ribbon forms an incomplete circle around the heliospheric nose, most prominent at ~1.1 keV, surrounded by a broad ENA emission that became known as Globally Distributed Flux (GDF).

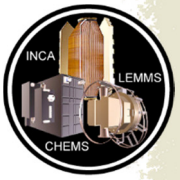


In a later publication, Dialynas et al. [2013a] found that the deviation of the ENA emissions from the equator is effectively minimized in a rotated frame—interpreted as interstellar magnetic field frame (ISMF)—where its North Pole points toward 190° ecliptic longitude and 15° ecliptic latitude. The ENA spectra showed a power-law form in energy, presenting higher spectral slopes in the belt region and lower outside ($3.4 < \gamma < 4.4$), which are almost indistinguishable between the tail and the nose regions, i.e., no noticeable asymmetry was observed. Notably, the morphology of the belt (peak, width, and structure) is nearly energy independent of energy from 5.2 keV to 30 keV. The authors speculated that Interstellar Boundary Explorer (IBEX)-GDF evolves with increasing ENA energy to form the belt at high GDF energies, explaining that the GDF and the ribbon are distinct features that originate from different source plasma populations (heliosheath and outside the heliopause, respectively). This was recently confirmed by the IBEX team [McComas et al. 2017].

Taking into account the local partial pressure over the $\sim 5 < E < 4000$ keV energy range from V1, V2, and INCA (~0.1 pPa), an assumed thickness of the heliosheath (~50 AU) and the simulated PUI (pick-up ion) distribution [Giacalone and Decker 2010] that was used to estimate the $E < 6$ keV contribution (~0.12 pPa), Krimigis et al. [2010] concluded that there is a need for a substantially stronger magnetic field upstream of the heliopause than assumed before, in order to balance the non-thermal PUI pressure against the stagnation pressure of the interstellar plasma and the local ISMF at the heliospheric nose. The interstellar magnetic field was estimated to be ~0.5 nT and have an upper bound of ~0.64 nT. This calculation was confirmed a few years later after V1 crossed the heliopause and measured a strong interstellar magnetic field of ~0.5 nT [Burlaga et al. 2013] that exhibited a jump right outside the heliopause of ~0.6 nT. V1 is currently located at ~19 AU past the heliopause and still measures a magnetic field of ~0.5 nT [Burlaga and Ness 2016], and a relatively dense plasma of $>0.09/cm^3$ that reached densities of $\sim 0.12/cm^3$ [Gurnett et al. 2013, 2015].

A different study, Dialynas et al. [2015] analyzed separately INCA images of the heliosphere and found that the very low (basin) and high (tail) ENA emissions in the heliosheath are separated with a relatively smooth boundary (called transition region), with a spatial width of ~30° in ecliptic longitude, which no theory had predicted to date. The ENA intensity gradient in this transition region was found to be almost invariant as a function of both ecliptic latitude and energy, with an average value of ~2.4% per degree and translates to a corresponding partial pressure gradient that occurs in the transition region, enabling a discussion on the Parker field towards the tail. Bearing in mind that the plasma-β inside the heliosheath showed large fluctuations about an average of ~5–10, i.e., much larger than unity [Decker et al. 2015], this pressure gradient is possibly not consistent with a tail magnetic field configuration that is similar to the measured magnetic fields by the Voyagers in the nose hemisphere. Notably, the pick-up ion populations in the keV range play a dominant role in maintaining the pressure balance in the heliosheath.

In the pre-INCA imaging era, the size of the heliosphere had been estimated using several different models, where the heliosheath varied between 70 and 160 AU. By combining Voyager in situ ion measurements and remotely sensed INCA ENAs in overlapping energy bands, Krimigis et al. [2009b, 2010], calculated that the heliosheath thickness should be ~54 (+30, −15) AU. A more



detailed analysis performed by the MIMI team also included the possible contributions from the Compton-Getting effect due to the radial velocity of the heliosheath plasma and concluded that the heliosheath appears to be twice as thick along the V2 line of sight (LOS) as it is along the LOS to V1: L_{V1} = 31 (+31, −18) AU and L_{V2} = 71 (+30, −15) AU [Roelof et al. 2012]. A breakthrough occurred in 2011 when the MIMI and Voyager teams published a brief report [Krimigis et al. 2011] showing that the radial component of the bulk plasma velocity had been decreasing almost linearly for three years, from 70 km/s to 0 km/s, and then stabilized around this value for ~8 months. This study concluded that the ENA and ion spectra could be brought into agreement at V2 with a heliosheath thickness of L_{V2} ~54 (+30, −15) AU, whereas the same normalization procedure applied to Voyager 1 results in L_{V1} ~27 (+26, −11) AU. Surprisingly, the V1 crossing from the heliopause occurred ~1 month later than anticipated by Krimigis et al. [2011] in August 2012 [Krimigis et al. 2013], showing that the heliosheath thickness towards the nose (at V1 direction) is ~29 AU, i.e., much smaller and more compressed than expected in past models.

Admittedly, one of the milestones in the heliosphere research concerns the shape of this enormous system, because it strongly relates to the interpretation of several phenomena that were either theorized in the literature and/or resulted from measurements performed by modern detectors. For more than five decades, the shape and interactions of the heliosphere with the local interstellar medium have been discussed in the context of either a magnetosphere-like heliotail or a more symmetric bubble shape, posited in 1961 [Parker 1961]. Although past models broadly assumed the magnetosphere-like concept, the accurate heliospheric configuration remained largely undetermined due to lack of measurements.

Building upon previous analyses made by Krimigis et al. [2009b] and Dialynas et al. [2013a], and employing both Voyager in situ and INCA remote measurements, a recent MIMI publication, Dialynas et al. [2017a] used >5.2 keV ENA measurements obtained with MIMI/INCA over the 2003–2014 time period and provided a new paradigm on the heliosphere interaction with the LISM: the belt corresponds to a reservoir of particles that exist within the heliosheath, constantly replenished by new particles from the solar wind, while the ENAs that INCA detects are most likely associated with a region of enhanced particle pressure that is formed inside the heliopause and contributes to balancing the pressure of the ISMF. The authors showed that the heliosheath ions are the source of >5.2 keV ENA and that the heliosphere responds promptly, within ~2–3 years, to outward propagating solar wind changes (controlled by solar sunspot numbers and solar wind energy input) in both the upstream (nose) and downstream (tail) directions. These observations, taken together with the V1 measurement of a ~0.5 nT interstellar magnetic field, plasma density of >0.09/cm^3 and the enhanced ratio between particle pressure and magnetic pressure in the heliosheath, strongly suggest a diamagnetic bubble-like heliosphere with few substantial tail-like features. A follow-up MIMI publication [Dialynas et al. 2017b] discussed the details of these results, and by calculating the recovery times of ENAs in the heliosphere, they found that the rough width of the heliosheath can be ~80–120 AU (or more) towards the tail, due to the ~2–3 year delay after solar minimum (Figure MIMI-7).

Dialynas et al. [2017a] also included two important implications concerning the heliosphere interaction with the LISM: 1) A perfectly symmetric and stable heliosphere in time would not be

possible and/or physically correct, i.e., as the heliosphere cannot be a closed system, the heliosphere bubble can (and must) inflate with time in either the anti-nose direction (tail models) or along the direction of the interstellar magnetic field (note that the polar jets [Opher et al. 2015; Drake et al. 2015], provide one of the possible mechanisms through which the solar wind input is evacuated from the system); and 2) due to the strong interstellar magnetic field, the Mach number of the local interstellar medium can be significantly decreased and the flow can become submagnetosonic, leading to the inability of forming a bow shock, as previously explained by Fahr et al. [1986] and simulated from Kivelson and Jia [2013] using the mini magnetosphere of Ganymede as a rough analogy to the heliosphere.

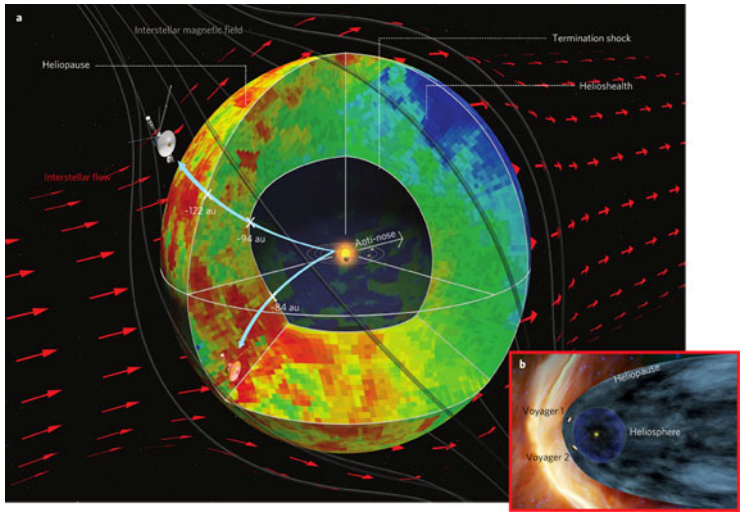


Figure MIMI-7. A conceptual model of the global heliosphere. Adapted from Dialynas et al. [2017b] showing: (a) The gross shape and basic properties of the global heliosphere in three dimensions, summarizing our current understanding, based on both remote ENA and in situ ion measurements from Cassini/INCA and LECP/V1&V2, respectively. It shows a belt of varying ENA intensities surrounding the termination shock and extending to the outer boundary of the heliosphere, called the heliopause, as identified by V1; it is anticipated that the heliopause south of the ecliptic will be crossed by V2 within the next few years. The red arrows represent the interstellar plasma flow deflected around the heliosphere bubble. The termination shock and heliopause are marked at the distances (in AU) observed by the Voyagers from 2004 through 2012 in their traversal of the heliosheath. The cutout illustrates the possible distribution of hot ion plasma in the heliosheath discerned by line-of-sight (LOS) ENA images (E > 5.2 keV); relative scale ranging from 1 (blue) to 12 (red). As the ENA emissions detected by INCA are LOS integrated, the third dimension in this composite, conceptual representation of the global heliosheath (presenting the possible ENA distribution confined between the termination shock and the heliopause) is based on the knowledge of the variation of ion intensities measured at the Voyagers towards the nose hemisphere. These ion intensities are representative of the average ENA intensities along any LOS inside the heliosheath. Note that this concept of the heliosphere does not imply a closed system that cannot change its shape towards the tail to release the solar wind energy input. Inside the termination shock the ion intensities are lower by at least ×100. The orbits of the outer planets are drawn to scale around the Sun. Concept (a) is compared with (b), a magnetosphere-like configuration (http://voyager.jpl.nasa.gov/mission/) widely adopted as one of two possibilities put forward by Parker [1961]. The termination shock is ~10 AU further out in the V1 direction, but the heliosheath (HS) is possibly ~30–50% thicker towards the V2 direction (as detailed in the text), inconsistent with a compressed heliosheath in the Southern Hemisphere. That will be determined when V2 crosses the heliopause (HP), expected in the next few years.

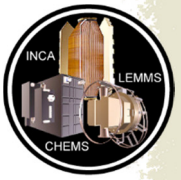
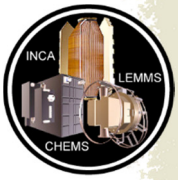


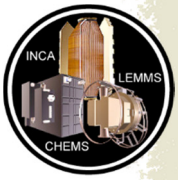
ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AU	astronomical unit
CAPS	Cassini Plasma Spectrometer
CDA	cosmic dust analyzer
CHEMS	Charge-Energy-Mass Spectrometer
CRAND	cosmic ray albedo neutron decay
CSM	Cassini Solstice Mission
ELS	Electron Spectrometer
ENA	energetic neutral atom
ESA	electrostatic analyzer
EUV	extreme ultraviolet
e/Q	energy per charge
GCR	galactic cosmic ray
GDF	Globally Distributed Flux
gEV	giga electron volt
HP	heliopause
HS	heliosheath
HST	Hubble Space Telescope
IBEX	Interstellar Boundary Explorer
INCA	Ion and Neutral Camera
INMS	Ion Neutral and Mass Spectrometer
IR	infrared
ISMF	interstellar magnetic field frame
keV	kiloelectron volt
LECP	Low Energy Charged Particle
LEMMS	Low-Energy Magnetospheric Measurement System
LISM	Local Interstellar Medium
LOS	line of sight
MAG	Magnetometer
meV	megaelectron volt
MIMI	Magnetosphere Imaging Instrument
PI	Principal Investigator
PUI	pick-up ion
QP	quasi-periodic
R_J	Jupiter radius
R_S	Saturn radius
RPWS	Radio and Plasma Wave Science
SEP	solar energetic particle



SKR	Saturn Kilometric Radiation
SOI	Saturn Orbit Insertion
SSD	solid-state detector
TM	Traceability Matrix
TOF	time of flight
UV	ultraviolet



REFERENCES

Disclaimer: The list of references below correspond with in-text references indicated in this report and other articles that rely heavily on MIMI data. Radio and Plasma Wave Science

The Radio and Plasma Wave Science (RPWS) investigation was designed to study radio emissions, plasma waves, thermal plasma, and dust in the vicinity of Saturn. The **science objectives** included improving our knowledge of the rotational modulation of Saturn's intense radio emission (SKR) and hence Saturn's rotation rate, characterizing plasma waves associated with Saturn's icy satellites and characterizing plasma density in the inner magnetosphere. RPWS was able to detect the dust hitting Cassini throughout the Saturn system and characterize lightning in Saturn's atmosphere.

RPWS was composed of an electric field sensor, a magnetic search coil assembly and a Langmuir probe. The electric field sensor consisted of three deployable antennas. The Langmuir probe, which measured electron density and temperature, was a metallic sphere that measured currents and voltages induced in the probe.

ACKNOWLEDGEMENTS

The following investigators contributed to the Final Mission Report Volume 1: Mission Overview, Science Objectives and Results; Section 3.2: Instruments Science Results – Fields, Particles, and Waves Sensing Instruments – Radio and Plasma Wave Science (RPWS).

RPWS Principal Investigator (PI) and Deputy Principal Investigator (DPI):

Executive Summary

The Cassini Radio and Plasma Wave Science (RPWS) investigation was successfully carried out over a seven-year cruise and more than thirteen years in orbit at Saturn. As described elsewhere, the instrument performed almost flawlessly; even some occasional processor hangs were understood to the point that we could anticipate modes that might cause them and sequence commands to allow the instrument to recover without ground intervention. While questions were certainly left to answer with future missions (see section entitled Open Questions for Saturn System Science), all of the RPWS science objectives were addressed and advances were made in areas not anticipated at launch, at least partially due to the long mission extensions and agile orbital mechanics involved in the mission and extended mission design.

Top Scientific Findings

The RPWS team debated the top scientific findings of the investigation at length and it is safe to say that while the following is a representative list, it is by no means a consensus in terms of either completeness or order of priority. It does, however, convey the breadth of the investigation, touching on all of Cassini's disciplines including the magnetosphere, satellites, Titan, rings, and Saturn, itself.

- Confirmation of a variable radio period and the discovery of hemispherically differing radio periods.
- First in situ measurements of Saturn's topside ionosphere and evidence of significant interactions with the ring system.
- Comprehensive study of the occurrence of lightning in Saturn's atmosphere and the evolution of a once-per-Saturn-year Great White Spot storm.
- In situ measurements of the Enceladus plumes and their interaction with Saturn's magnetosphere; in situ studies of a dusty plasma.
- Plasma wave phenomena associated with icy satellites, notably Enceladus and Rhea, revealing their electromagnetic connection to Saturn via its magnetic field.
- First in situ characterization of a non-terrestrial cyclotron maser instability-driven radio source (Saturn kilometric radiation).
- In situ measurements of Titan's extensive ionosphere, including the electron density and temperature, evidence for negative ions, and solar cycle dependencies.
- The development of a plasma density model for Saturn's inner magnetosphere.
- Interdisciplinary studies of Saturn's auroras including Saturn kilometric radiation, ultraviolet (UV) and infrared (IR) observations, energetic particles, and the influence of magnetospheric dynamics and solar wind compression events.

- Imaging of SKR source regions and the confirmation that they align with the UV auroras.
- The discovery of Z-mode waves as the source of ~5 kHz narrowband radio emissions first observed by Voyager.
- Anomalously low plasma densities over the unlit side of the B-ring.
- A new low-frequency radio emission phenomenon consisting of drifting tones.
- Finding Titan ahead of Saturn's bow shock and the realization that a complex shock forms ahead of the Titan-Saturn system as opposed to separate shocks.
- The discovery of a seasonally-dependent source of plasma between the A-ring and Enceladus.
- New insights on high Mach number shocks and upstream phenomena through studies of Saturn's bow shock and foreshock region.

The above list demonstrates that RPWS met and exceeded all of its objectives and made significant progress in areas not anticipated prior to arrival at Saturn.

Open Questions for Saturn System Science

Any mission, however extended, always raises questions based on the new knowledge gained. Here we give a brief list of open questions for radio and plasma wave science at Saturn, after Cassini.

- What is the rotation period of Saturn? How do the multiple, variable magnetospheric periods observed in radio, magnetic fields, energetic particles, plasma, aurora, and other phenomena tie to the internally-generated magnetic field at Saturn?
- Given the extraordinarily axi-symmetric magnetic field, why are there such prominent rotational modulations in Saturn's magnetosphere?
- What drives the episodic lightning on Saturn; why is there ~one Great White Spot storm per Saturnian year?
- How does the dust in the Saturnian system interact with Saturn and its atmosphere? How are the rings coupled to the planet other than through gravity?
- What is the predominant form of the electron distribution function at the source of SKR?
- How does the abundant neutral population in Saturn's magnetosphere make it different from fully or mostly ionized magnetospheres?
- What are the various populations of charged dust and molecules that balance charges in dusty media such as in the plumes of Enceladus and in Saturn's topside equatorial ionosphere?

> … all of the RPWS science objectives were addressed and advances were made in areas not anticipated at launch … .

The key open questions are listed above and in the section entitled Open Questions for Saturn System Science. One of the objectives of Cassini was to understand the rotational modulation of Saturn kilometric radiation in the presence of an axi-symmetric magnetic field. Rather than understanding this, the question became more complex. The rotational modulation of SKR was confirmed to be variable and there are often different periods associated with the northern and southern hemispheres. Furthermore, such multiple, variable periods are seen in many aspects of the magnetosphere including the magnetic field, energetic particles, and even the auroral oval. While models exist that reproduce many of these observations, the fundamental origin of this asymmetric behavior in a symmetric system is not understood.

Another aspect of the Saturnian system which is ripe with follow-on questions is the complex processes involving the magnetized plasma in Saturn's magnetosphere in the presence of a large neutral population and pervaded with charged dust grains with sizes ranging from microns to nanometers.

The Cassini mission provided the first opportunities to observe a cyclotron maser instability (CMI) source (of Saturn kilometric radiation) in situ at a location other than at Earth. While these opportunities allowed for the confirmation of a CMI mechanism, only two such source crossings occurred when the Cassini Plasma Science (CAPS) instrument was functioning. Hence, the multiple additional source crossings in the Ring Grazing and Grand Finale orbits did not have the advantage of the CAPS measurements, meaning we do not have more than a couple samples of the electron distribution function responsible for driving the CMI at Saturn. The theory for CMI allows one to infer the resonant energy of electrons and even something about the form of free energy in the source, but having the plasma measurements for additional sources would be beneficial.

RPWS Instrument Summary

The RPWS instrument is a radio and plasma wave spectrometer with the capability of determining the density and temperature of plasmas. The instrument utilizes seven sensors including three monopole electric field antennas with the ability to use two of them as a dipole antenna, a triaxial search coil magnetometer, and a Langmuir probe. Electric fields in the frequency range of 2 Hz to 16 MHz and magnetic fields in the range of 2 Hz to 12 kHz can be measured by the RPWS. The Langmuir probe can determine plasma densities and temperatures in the range of 10 to 10^5 cm^{-3} and below 8 eV through the analysis of voltage-current sweeps. By using the spacecraft potential as a proxy for the electron density, much lower densities, down to 10^{-5} cm^{-3} can be inferred. The instrument is fully described by Gurnett et al. [2004].

The RPWS utilizes a number of receivers to analyze signals from the various sensors. These include a high frequency receiver (HFR) covering electric fields from 3.5 kHz to 16 MHz with the capability of making full polarization and direction-finding measurements in certain modes. The HFR also includes a sounder which can actively stimulate characteristic frequencies of the plasma that enable an alternate approach to determining the plasma density. The medium frequency receiver (MFR) provides electric and magnetic spectral information in the range of 24 Hz to 12 kHz. The low frequency receiver (LFR) provides spectral information for both electric and magnetic fields in the frequency range of ~1 Hz to 26 Hz. The five-channel waveform receiver (WFR) simultaneously captures waveforms from up to five sensors selected from two electric antennas, three magnetic antennas, and the Langmuir probe. Finally, the wideband receiver (WBR) can collect waveform measurements from a selected sensor in a bandwidth of 60 Hz to 10.5 kHz or 0.8 to 75 kHz. The WBR can also provide a 25-kHz band downconverted from selected frequency bands in the HFR.

A typical temporal resolution for survey measurements (covering the full instrument spectrum) is one spectrum per 8 to 16 seconds. The spectral resolution for survey data are Δf/f of 7 to 13%. The HFR has selectable spectral resolutions of 5 to 20% below 318 kHz and n × 25 kHz at higher frequencies. The typical operation of the Langmuir probe provides a full voltage sweep every 24 seconds and can collect currents at fixed bias at rates as high as 20 Hz. Because of the possibility of interference with other instruments, the sounder is only operated briefly every 10 minutes, or so. The WFR and WBR provide the highest resolution observations because actual waveforms are telemetered to the ground for processing optimized to the wave feature under study. However, because of the tremendous data rate generated by these receivers, only relatively short waveform acquisitions can be afforded. These are typically targeted near satellite flybys or regions of interest in the magnetosphere.

Key Objectives for RPWS Instrument

The key RPWS science objectives listed below are taken from Gurnett et al. [2004] and are discussed in the section entitled Science Results. While they were written with the prime mission in mind, the same objectives flow easily into the mission extensions.

Radio emissions

- Improve our knowledge of the rotational modulation of Saturn's radio sources, and hence of Saturn's rotation rate.
- Determine the location of the SKR source as a function of frequency, and investigate the mechanisms involved in generating the radiation.
- Obtain a quantitative evaluation of the anomalies in Saturn's magnetic field by performing direction-finding measurements of the SKR source.

- Establish if gaseous ejections from the moons Rhea, Dione, and Tethys are responsible for the low frequency narrow-band radio emissions.
- Determine if SKR is controlled by Dione's orbital position.
- Establish the nature of the solar wind-magnetosphere interaction by using SKR as a remote indicator of magnetospheric processes.
- Investigate the relationship between SKR and the occurrence of spokes and other time-dependent phenomena in the rings.
- Study the fine structure in the SKR spectrum, and compare with the fine structure of terrestrial and Jovian radio emissions in order to understand the origin of this fine structure.

Plasma waves

- Establish the spectrum and types of plasma waves associated with gaseous emissions from Titan, the rings, and the icy satellites.
- Determine the role of plasma waves in the interaction of Saturn's magnetospheric plasma (and the solar wind) with the ionosphere of Titan.
- Establish the spectrum and types of plasma waves that exist in the radiation belt of Saturn.
- Determine the wave-particle interactions responsible for the loss of radiation belt particles.
- Establish the spectrum and types of waves that exist in the magnetotail and polar regions of Saturn's magnetosphere.
- Determine if waves driven by field-aligned currents along the auroral field lines play a significant role in the auroral charged particle acceleration.
- Determine the electron density in the magnetosphere of Saturn, near the icy moons, and in the ionosphere of Titan.

Lightning

- Establish the long-term morphology and temporal variability of lightning in the atmosphere of Saturn.
- Determine the spatial and temporal variation of the electron density in Saturn's ionosphere from the low frequency cutoff and absorption of lightning signals.
- Carry out a definitive search for lightning in Titan's atmosphere during the numerous close flybys of Titan.
- Perform high-resolution studies of the waveform and spectrum of lightning in the atmosphere of Saturn, and compare with terrestrial lightning.

Thermal plasma

- Determine the spatial and temporal distribution of the electron density and temperature in Titan's ionosphere.
- Characterize the escape of thermal plasma from Titan's ionosphere in the downstream wake region.
- Constrain and, when possible, measure the electron density and temperature in other regions of Saturn's magnetosphere.

Dust

- Determine the spatial distribution of micron-sized dust particles throughout the Saturnian system.
- Measure the mass distribution of the impacting particles from pulse height analyses of the impact waveforms.
- Determine the possible role of charged dust particles as a source of field-aligned Currents.

RPWS Science Assessment

Tables RPWS-1–RPWS-5 contain assessments of RPWS science based on the objectives in the original Announcement of Opportunity (AO) and the Cassini Traceability Matrix (TM) developed for the Equinox and Solstice missions. Each RPWS science objective is paired with an AO and TM science objective. RPWS objectives span all disciplines addressed by the Cassini mission, to some extent. These include Titan, Icy Satellites, Rings, Saturn, and the Magnetosphere.

Table RPWS-1. RPWS Saturn Science Assessment: AO and TM Objectives are paired with RPWS Science objectives. Objectives are accomplished in terms of acquiring relevant data to address.

Fully/Mostly Accomplished: **Partially Accomplished:**

RPWS Saturn Science Objectives	AO and TM Science Objectives	RPWS Saturn Science Assessment	Comments, if yellow (partially fulfilled)
Saturn Interior Structure and Rotation			
--- Rotation of the Deep Atmosphere	SP3, SN1a		Still unknown
Saturn Ionosphere-Magnetosphere Interaction			
--- Saturn I-M interaction, Auroras	SP4, SC2a		
Saturn Lightning Sources and Morphology			
--- Saturn Lightning	SP6, SN2a, SC1b		
--- Great Storm	SN1b		
Aurorae, Chemistry, and Upper Atmosphere	SC2a		Analysis ongoing

Table RPWS-2. RPWS Rings Science Assessment: AO and TM Objectives are paired with RPWS Science objectives. Objectives are accomplished in terms of acquiring relevant data to address.

Fully/Mostly Accomplished: **Partially Accomplished:**

RPWS Rings Science Objectives	AO and TM Science Objectives	RPWS Rings Science Assessment	Comments, if yellow (partially fulfilled)
Ring Structure and Dynamics			
--- Structure of the dusty rings	RP1, RN1c		
--- Dust in vicinity of F-ring	RC1b, RC2a		
Ring Particle Composition and Size			
--- Size distribution of dust	RP2, RC1a		
Ring-Satellite Interaction			
--- Interaction of Enceladus and E-ring	RP3		
Dust and Meteoroid Distribution			
--- Micron-sized dust within and inside D-ring	RP4		Analysis ongoing
Ring Magnetosphere-Ionosphere Interactions	RP5		Analysis ongoing

Table RPWS-3. RPWS MAPS Science Assessment: AO and TM Objectives are paired with RPWS Science objectives. Objectives are accomplished in terms of acquiring relevant data to address.

Fully/Mostly Accomplished: **Partially Accomplished:**

RPWS MAPS Science Objectives	AO and TM Science Objectives	RPWS MAPS Science Assessment	Comments, if yellow (partially fulfilled)
Saturn Magnetic Field Configuration and SKR			
--- Modulation of SKR	MP1, MN1c		Still do not understand variations
--- Seasonal and Solar Cycle Variations	MC1b		
Magnetosphere Charge Particles	MP2		
--- Enceladus as a source of plasma			
--- Rings as a source of plasma			
Magnetosphere Wave-Particle Interactions	MP3		
--- Upstream waves and waves at shock and magnetopause			
--- Wave-particle interactions in middle magnetosphere			
--- Correlations of SKR and tail reconnection			
Magnetosphere and Solar Interactions with Titan	MP4		
Plasma Interactions with Titan's Atmosphere and Ionosphere	MP5		
Enceladus Plume Variability	MC1a		
Titan's Ionosphere	MC2a		
Magnetotail	MN1a		
Saturn's Ionosphere and Radiation Belts	MN1b		
Ionosphere and Ring Coupling	MN2a		

Table RPWS-4. RPWS Icy Satellite Science Assessment: AO and TM Objectives are paired with RPWS Science objectives. Objectives are accomplished in terms of acquiring relevant data to address.

Fully/Mostly Accomplished: Partially Accomplished:

RPWS Icy Satellite Science Objectives	AO and TM Science Objectives	RPWS Icy Satellite Science Assessment	Comments, if yellow (partially fulfilled)
Icy Satellite Magnetosphere and Ring Interactions			
--- Enceladus plume-magnetosphere interaction	IP5, IC1a, IN1a		
--- Evidence for Dione activity	IN1c		
--- Rhea ring material	IN2a		
--- Tethys contribution to E-ring, magnetosphere	IN2b		
--- Appearance of Hyperion	IN2e		

Table RPWS-5. RPWS Titan Science Assessment: AO and TM Objectives are paired with RPWS Science objectives. Objectives are accomplished in terms of acquiring relevant data to address.

Fully/Mostly Accomplished: Partially Accomplished:

RPWS Titan Science Objectives	AO and TM Science Objectives	RPWS Titan Science Assessment	Comments, if yellow (partially fulfilled)
Titan Meteorology			
--- Search for lightning	TP3		
Titan Upper Atmosphere	TP5		
--- Seasonal variations of Titan's ionosphere	TC1a, TC1b		
Titan-Magnetosphere Interaction	TC2a		
--- Induced magnetic field/magnetosphere interaction	TN1b		

RPWS Saturn System Science Results

Titan Science

The RPWS contributions to Titan science are foremost to map the structure, dynamics and long-term variability of its ionosphere and its induced magnetosphere, both interacting continuously with Saturn's magnetosphere and the solar extreme ultraviolet (EUV) radiation, and occasionally also directly with the enhanced solar wind during more active solar conditions when the magnetopause is pushed back toward Saturn past the orbit of Titan. The RPWS contributions, mostly from the Langmuir probe sensor, were recently reviewed in the Cambridge University Press book Titan, primarily in Chapters 12 and 13 [Galand et al. 2013; Wahlund et al. 2013]. Many more RPWS science results have been produced since then. A total of more than 70 publications with RPWS participation in peer-reviewed journals have resulted regarding Titan science up to 2018. Here we dwell only on the main key results.

The first in situ measurements of Titan's ionosphere and space environment were made by Cassini/RPWS during the Titan A flyby in October 26, 2004 [Wahlund et al. 2005a], and the Langmuir probe sensor has been successfully monitoring the cold plasma, charged aerosol and electron temperature during every Titan flyby since then—a total of 127 flybys. A slight degradation of the Langmuir probe sensitivity was induced by the Saturn radiation belt passes in late 2008, but had no effect on the subsequent science output. The RPWS/Langmuir probe therefore provided good science data from Titan for the full period October 2004 to September 2017 (almost 13 years of data).

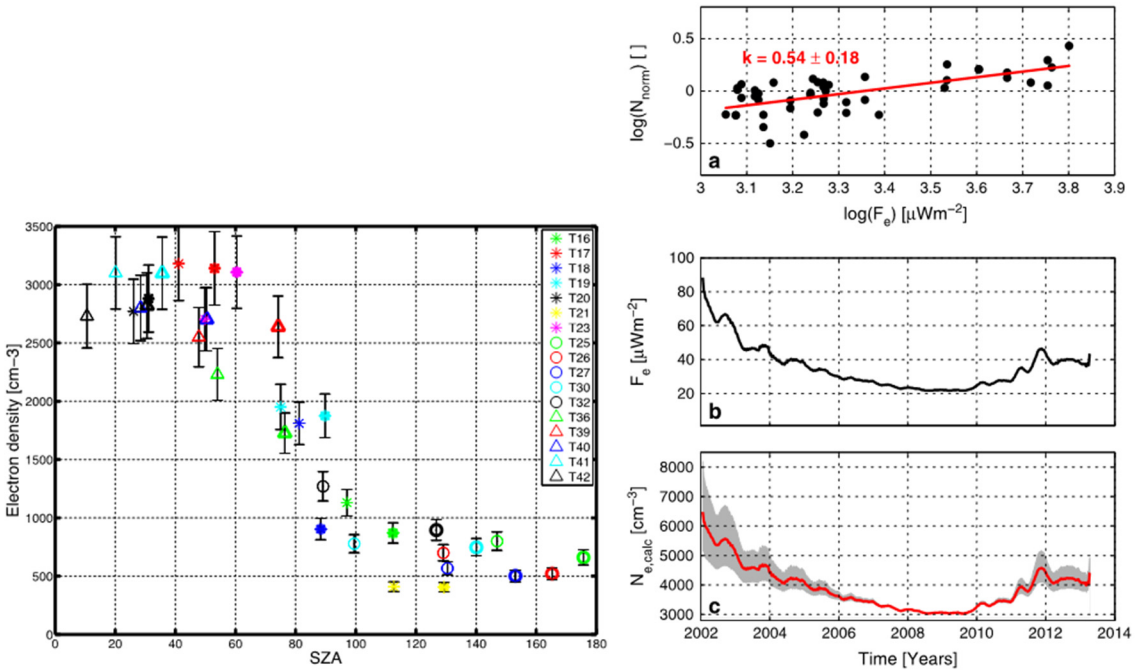

Figure RPWS-1. ***Left*****: Ionospheric peak electron number density versus solar zenith angle [Ågren et al. 2009].** ***Right*****: The variation of the peak electron number density solar EUV flux [Edberg et al. 2013b].**

The main structure of Titan's ionosphere emerged after a few flybys [Ågren et al. 2007, 2009; Robertson et al. 2009] and it became clear that solar EUV radiation dominated the ionization of Titan's upper atmosphere, and varied with the long-term EUV output from the Sun [Edberg et al. 2013b; Shebanits et al. 2017]. Energetic particle precipitation from the magnetosphere is important on the nightside of Titan, but only occasionally makes a significant difference on the dayside [Edberg et al. 2013a]. A most surprising find was the importance of the ionosphere for the production of complex organic chemistry and aerosol particles (dust) below about 1100 km altitude [Coates et al. 2007, 2011; Wahlund et al. 2009b; Vuitton et al. 2009; Ågren et al. 2012; Lavvas et al. 2013; Shebanits et al. 2013, 2016], where the Langmuir probe provided a measure of the detailed amounts of organic ions and charged aerosol particles. The mechanism starts with EUV producing an N_2^+ ion that then reacts primarily with methane, with subsequently more complex C-H-N chemistry and aerosol formation [Lavvas et al. 2013].

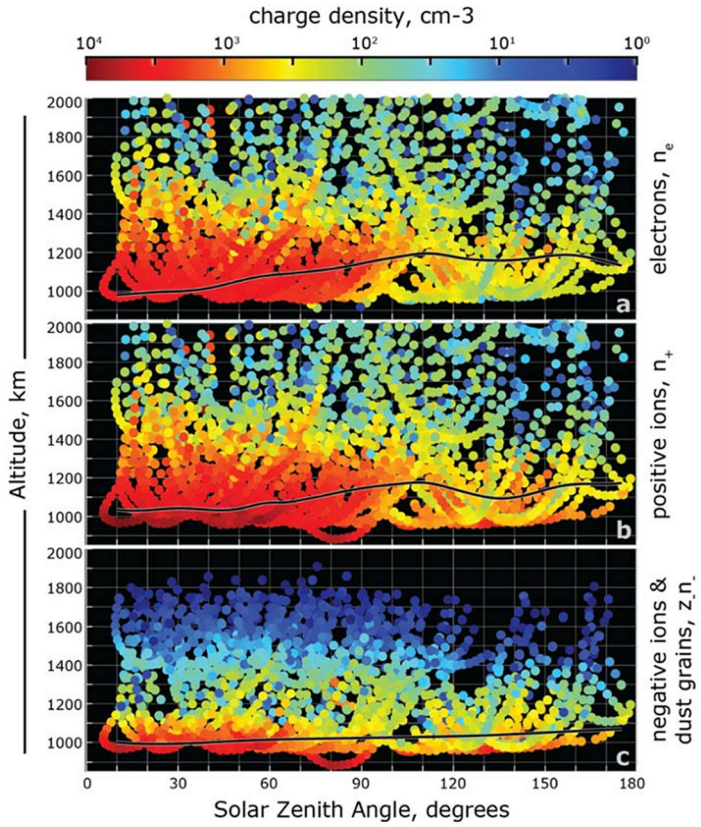

Figure RPWS-2. The ionosphere of Titan. The number densities of electrons (T*op panel*), positively charged ions (*Middle panel*), and negatively charged ions and aerosol particles (*Bottom panel*). Adapted from Shebanits et al. [2013].

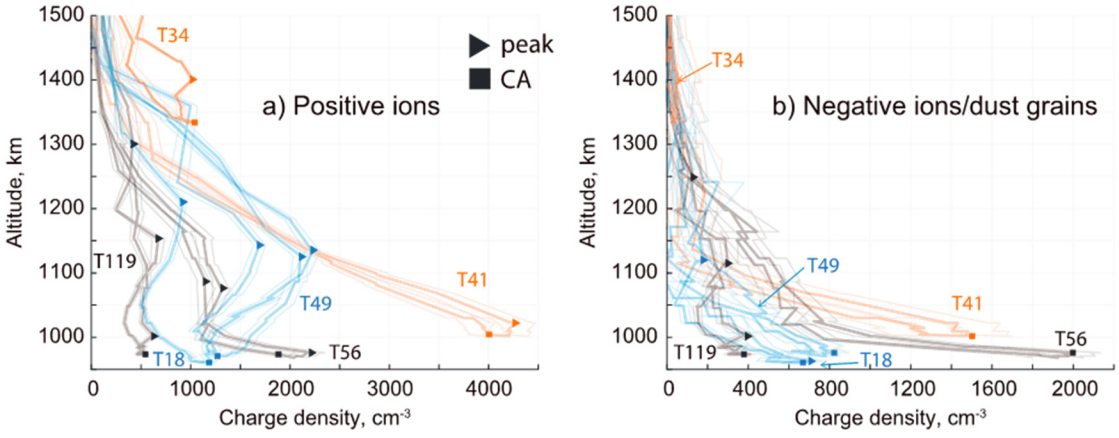

Figure RPWS-3. Examples from six flybys of Titan of altitude profiles of the positive ion and negative ion/aerosol number densities as derived from the RPWS Langmuir probe measurements [Shebanits et al. 2017]. Note the dominance of charged aerosol particles below 1100 km. Dayside flybys are colored in orange, terminator in blue, and nightside in black; the triangles mark the peaks and the squares mark the closest approach (CA) maxima.

Titan's interaction with the magnetosphere of Saturn results in the formation of an induced magnetosphere around Titan. The RPWS sensors have mapped the interaction region [Modolo et al. 2007a, 2007b], proved the existence of cold ionospheric flows from Titan—for example, Edberg et al. [2010, 2011], as well as more energetic ion pickup [Modolo et al. 2007b], and studied how these processes change when Titan enters the magnetosheath [Bertucci et al. 2008; Garnier et al. 2009]. Titan's ionosphere also acts as a conductive medium where electric currents generated in the induced magnetosphere close [Rosenqvist et al. 2009; Ågren et al. 2011]. The escape rate through the cold plasma was determined to be a few kg/s (10^{25} ions/s), which is considered small compared to the exosphere escape rates.

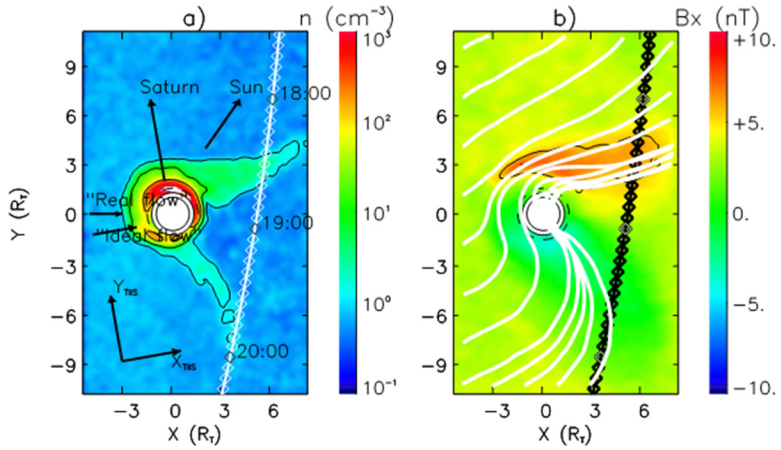

Figure RPWS-4. The induced magnetosphere of Titan as measured and modelled during the T9 flyby through the tail [Modolo et al. 2007b].

Icy Satellite Science

RPWS at Enceladus

PLASMA WAVES

Cassini made 22 close flybys of the icy moon Enceladus which enabled the RPWS to study plasma waves in the moon's near-environment, auroral processes associated with these waves, and the interaction between the magnetospheric plasma and the dust originating in Enceladus' plume. Gurnett et al. [2011a] reported observations of whistler mode auroral hiss emissions produced by magnetic field-aligned electron beams. A ray path analysis of the funnel emission shows the hiss source region within a few moon radii of the Enceladus surface. Figure RPWS-5 is adapted from Figure 2 in Gurnett et al. [2011a] and shows the auroral hiss funnel from the E8 flyby in the top panel and the nearly field-aligned electron beams from the CAPS electron spectrometer (ELS) instrument in the second panel. The magnetometer observations of the field-aligned currents which accelerate the electron beams are shown in the bottom panel. The ramp-like signature of the southward current is associated with a shear-mode Alfven wave excited by the moon-plasma

interaction. Parallel electric fields often associated with the Alfven wave are believed to be accelerated by these waves along magnetic field lines that map to the Enceladus footprint in Saturn's aurora [Gurnett and Pryor 2012].

Leisner et al. [2013] observed northward and southward auroral hiss funnels on both flanks of Enceladus. They found that these funnels are consistently observed on all low-inclination flybys through the Enceladus flux tube, suggesting that the electron beams associated with these auroral hiss funnels are a steady state feature of the Enceladus interaction with the plasma. Sulaiman et al. [2018a] observed an auroral hiss funnel on the ionospheric end of the flux tube connecting the planet to Enceladus.

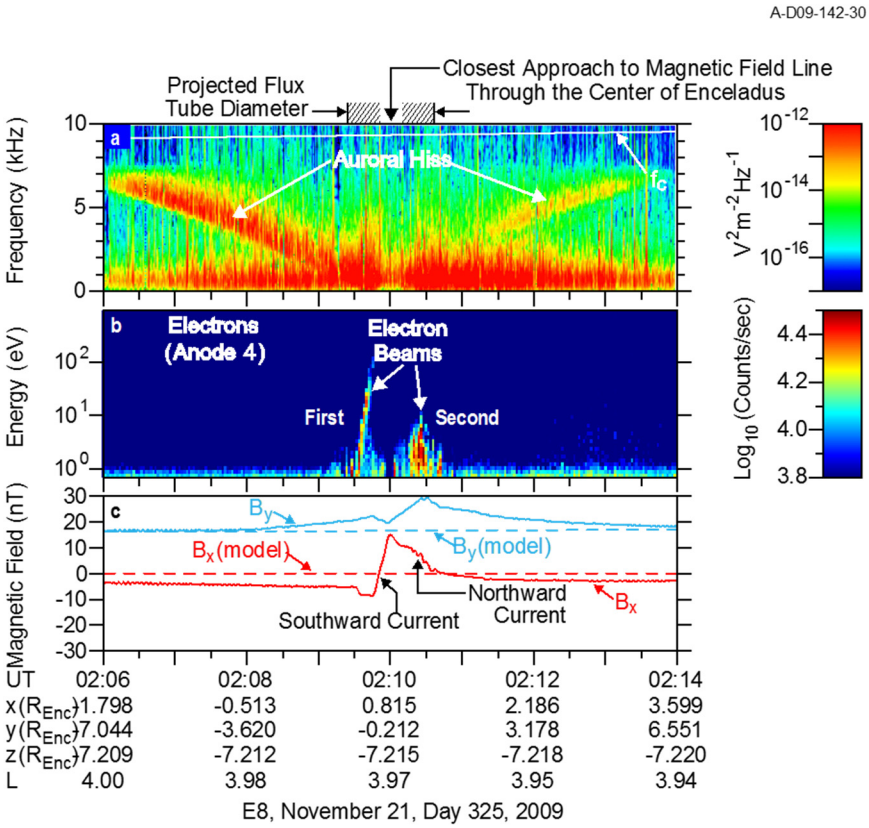

Figure RPWS-5. Evidence of an electrodymanic interaction between Enceladus and Saturn's magnetosphere in the form of auroral hiss generated by electron beams.

PLASMA-DUST INTERACTIONS

The measurement of dust grains in the vicinity of Enceladus and the interaction of these grains with the ambient plasma became a focus of RPWS research. Farrell et al. [2009] presented high-time resolution spectral evidence from the E3 flyby of small water-ice grain impacts on the electric antennas in the vicinity of Enceladus and a sudden, large drop in the electron density in the same region, a density depletion that they attribute to the absorption of electrons by submillimeter-sized

icy particles. Morooka et al. [2011] presented Langmuir probe observations to provide evidence for the presence of dusty plasma in the Enceladus plume region. The data show large increases in the ion and electron densities just south of the equatorial plane in the plume region for four Enceladus flybys in 2008, but there is a two order of magnitude difference in these plasma densities with $n_e/n_i < 0.01$. This plasma signature is attributed to electron absorption by dust grains in the plume, which subsequently become negatively charged. The ion and electron density increases in the plume region just south of the equatorial plane are shown in the top panel of Figure RPWS-6, which is adapted from Figure 5 in Morooka et al. [2011]. No plasma wake signature is observed in this data. The middle panel of Figure RPWS-6 shows the strong drop in the n_e/n_i density ratio in this same region where the presence of dust grains had been previously determined [Farrell et al. 2009]. The bottom panel in Figure RPWS-6 shows almost Keplerian ion speeds measured by the Langmuir probe which are well below the plasma corotation speed, reaching a minimum below Keplerian speeds in the plume region. The interaction between the cold plasma and the negatively charged small dust grains is believed to cause this slowing of the plasma that moves with Enceladus, explaining the lack of a plasma wake behind the moon.

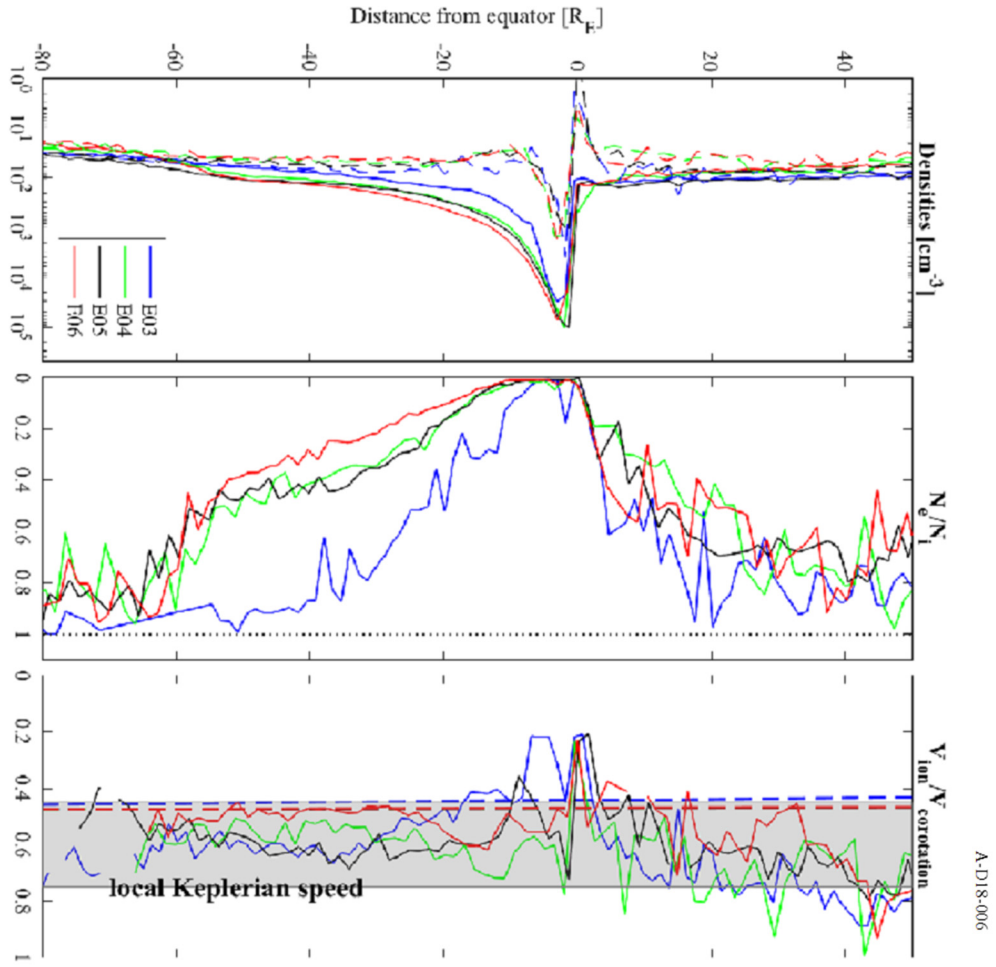

Figure RSWS-6. The variation of electron densities (*Top*), ratio of electron to ion densities (*Middle*) and the ratio of the ion velocity relative to corotation in the vicitnity of Enceladus.

The presence of dust grains inferred by the ion-electron density difference led to a number of research results. Ye et al. [2014a] discovered that, after a dust grain impacted the RPWS electric antennas, a dust ringing effect was observed by the RPWS Wideband Receiver, characterized as periodic plasma oscillations. The frequency of these oscillations was shown to be consistent with the local electron plasma frequency, providing a measurement of the electron density. Densities derived from this method in the Enceladus plume region were found to be consistent with electron densities derived by the Langmuir probe for four consecutive Enceladus flybys in 2008. Shafiq et al. [2011] presented Langmuir probe observations of the E3 flyby to derive estimates of the dusty plasma parameters and found that the dust density would vary depending on the grain size. The submicron-sized dust grains dominate in the plume region with densities of 10^2 cm^{-3}. The micrometer-sized and larger sized grains are estimated to have densities of only 6.3×10^{-5} cm^{-3}.

OTHER RESEARCH

Omidi et al. [2012] used an electromagnetic hybrid simulation to explore the impact of charge exchange between the plasma and the neutral gas and the electron absorption by dust particles on the deceleration of the corotating plasma near Enceladus. They found that the charge exchange between the corotating ions and the neutral gas in the plume played a dominant role in the deceleration of the plasma.

Farrell et al. [2012] found that, in Enceladus' northern hemisphere within ~5 R_E, there is a quasi-time stationary plasma feature, a clear electron density dropout in the RPWS data coincident with a sharp deceleration in the plasma flow. They infer the presence of dust in the northern hemisphere by this plasma feature. They further suggest that the submicron dust population in the northern hemisphere is secondary ejecta, small fast dust grains resulting from surface impacts by larger micron-sized dust grains which originated in, among other possible sources, the moon's plume.

Engelhardt et al. [2015] presented evidence for the existence of a dust trail downstream of Enceladus and extending north of the moon up to 4 R_E. The trail region is characterized by a strong electron density depletion coincident with a nearly constant ion density profile, suggesting that some fraction of the electrons have been absorbed by the dust grains that have been observed in this region.

Farrell et al. [2017a] used a particle-in-cell electrostatic simulation to examine the cold, low-energy ions produced in the Enceladus plume and the development of plasma sheaths about the negatively-charged, submicron dust grains that can act to trap these newly created ions which subsequently exit the plume region at the subcorotational speed of the dust grains. The authors further suggest that only about 3% of the ion population, with energies exceeding the sheath trapping potential, contribute to the ion pickup current and the associated magnetic field perturbations. The Langmuir probe measures both of these ion populations.

Rhea interaction

The moon Rhea orbits at a distance of 8.74 R_S (1 R_S = 60,268 km) from Saturn and is its largest icy satellite, with a radius of 764 km. Since Rhea has essentially no internal geological activity [Pitman et al. 2008] and only a very tenuous exosphere consisting of oxygen and carbon dioxide [Teolis et al. 2010] the moon was expected to be essentially a passive absorber, with little interaction with Saturn's corotating magnetosphere which streams by at a nominal corotational velocity of 85.4 km/s. Nonetheless, Cassini plasma measurements [Wilson et al. 2010] show that the plasma ions in the vicinity of the moon are slowed down by about 30% relative to rigid corotation due to their interaction with the moon. Measurements of the fluxes of energetic (several hundred keV) electrons [Roussos et al. 2012] shows that these electron fluxes have a broad depletion extending out to as much as 5 to 7 times the radius of Rhea. This extended depletion region has been interpreted by Roussos et al. [2012] as possibly being caused by dust or ring particles orbiting Rhea within the Hill sphere which is estimated to have a radius of about 7.7 times the radius of the moon. At lower energies, below about 100 keV, the electron fluxes show sharper depletion boundaries consistent with the geometric wake generated by absorption at the surface of the moon. Curiously, electron density measurements of the cold plasma by the Langmuir probe and by RPWS measurements of the upper hybrid resonance frequency show only a small decrease in the plasma density in the wake region, suggesting that the moon might be a significant source of cold plasma. Measurements of the electric and magnetic fields of plasma waves by the RPWS [Santolik et al. 2011] show that intense plasma waves are generated in the magnetic flux tube connected to the surface of the moon. Three types of plasma waves were observed: (i) bursty electrostatic waves near the electron plasma frequency, (ii) intense whistler-mode waves below one half the electron cyclotron frequency, and (iii) broadband electrostatic waves at frequencies well below the ion plasma frequency. The waves near the electron plasma frequency are believed to be driven by low energy (35 eV) electron beams accelerated in the vicinity of Rhea, and the whistler mode emissions are thought to be generated by the loss-cone anisotropy introduced in the low energy (230 eV) electron distribution by absorption at the surface of the moon. Pitch angle scattering by these waves may be able to explain some of the structure in the flux of energetic electrons reported in the vicinity of the moon.

Dust and Dusty Ring Science

One of RPWS's scientific goals is to detect the micron-sized dust particles that concentrate near the ring plane of Saturn [Gurnett et al. 2004]. In addition to gravity, these particles are also subject to solar radiation pressure and electromagnetic forces, making their orbit dynamics drastically different from the meter-sized main ring particles [Horányi 1996]. The dynamic orbit evolution and plasma sputtering make the lifetime of these particles less than a few thousand years [Burns et al. 2001], which requires these diffuse rings to be replenished continuously. During the Cassini mission, cryovolcanic activity near the south pole of Enceladus was discovered to be the source of E-ring material [Spahn et al. 2006b; Porco et al. 2006]. Other diffuse rings are formed mainly through collisions (meteoroid-moonlet impacts or collisions among the small bodies) and diffusion of collisional debris by non-gravitational forces [Hedman et al. 2007; Williams and Murray 2011].

The longevity of the Cassini mission and good coverage of space by the orbits allowed ample opportunities to explore the dusty rings of Saturn and the plume of Enceladus, providing important in situ measurements of dust density profiles and size distributions in these regions.

During Cassini's Saturn orbit insertion (SOI), RPWS WBR detected micron-sized dust particles at ~500 to 2000 impacts per second around the ring plane crossings [Gurnett et al. 2005]. Due to the high gain antenna (HGA) to ram pointing (protecting the spacecraft from dust hazards), the designated dust instrument Cosmic Dust Analyzer (CDA) [Srama et al. 2004] was not operating during SOI, so RPWS provided the only in situ measurement of dust particles then in this crucial region [Wang et al. 2006]. Based on the power spectrum measured by the monopole antenna, Wang et al. [2006] estimated the root mean square size of the particles detected to be around 2.6 micron. The particles detected near the ring plane were shown to have a power law distribution with power index −2.

In the first few years of the mission, Cassini made a number of inclined and equatorial crossings of the E-ring, particularly near the orbit of Enceladus.

In the first few years of the mission, Cassini made a number of inclined and equatorial crossings of the E-ring, particularly near the orbit of Enceladus. The ice particles detected by RPWS in this region were estimated to be a few microns [Kurth et al. 2006b]. The peak impact rates measured around the orbit of Enceladus were around 50 per second, corresponding to densities of order of 5×10^{-4} m^{-3}. The vertical dust flux profiles could be described by Gaussian function with a scale height of about 2800 km. It was also noted that density peaks could have a vertical offset of a few hundred km. Radial density profiles derived from the equatorial orbit measurements showed a peak near the Enceladus orbit and power law decreases inside and outside the Enceladus orbit, consistent with the previous optical measurements of the ring profile.

Ye et al. [2016a] analyzed the ring plane crossing data (within 6 R_S) collected by RPWS between SOI and equinox (85 crossings). Since the WBR can record the voltage waveform of each individual impact, they were able to derive the dust size distribution based on the sizes of the voltage jumps. It was found that the E-ring particle size distribution can be characterized by a power law function with a power law index around −4. Figure RPWS-7 shows the trajectories of Cassini during 53 high inclination ring plane crossings before equinox. The color code indicates dust density estimated for particles with radius larger than 1 micron. The density profiles derived based on the impact rates showed that dusty ring near the G-ring has a narrow profile (~240 km FWHM). In contrast, E-ring is much thicker. The thickness of E-ring has a minimum ~4000 km FWHM at Enceladus' orbit, and increases with the distance away from Enceladus' orbit. Ye et al. [2016a] constructed an E-ring density model based on fitting the vertical density profiles with Lorentzian functions and radial profiles with power law functions. Near Enceladus' orbit, the vertical dust density profiles showed slight dips around the ring plane, likely due to the gravitational scattering of the particles by the moon. The E-ring peak location was shown to be shifted to the north outside Enceladus' orbit and to the south inside Enceladus' orbit, consistent with optical measurements [Hedman et al. 2012]. The E-ring warp is due to the locking of the pericenters and apocenters of

the dust orbits out of the ring plane by the vertical component of the solar radiation pressure [Hamilton 1993]. So, it was predicted that the E-ring warp would change with time due to the seasonal change of solar radiation pressure normal direction relative to the ring plane.

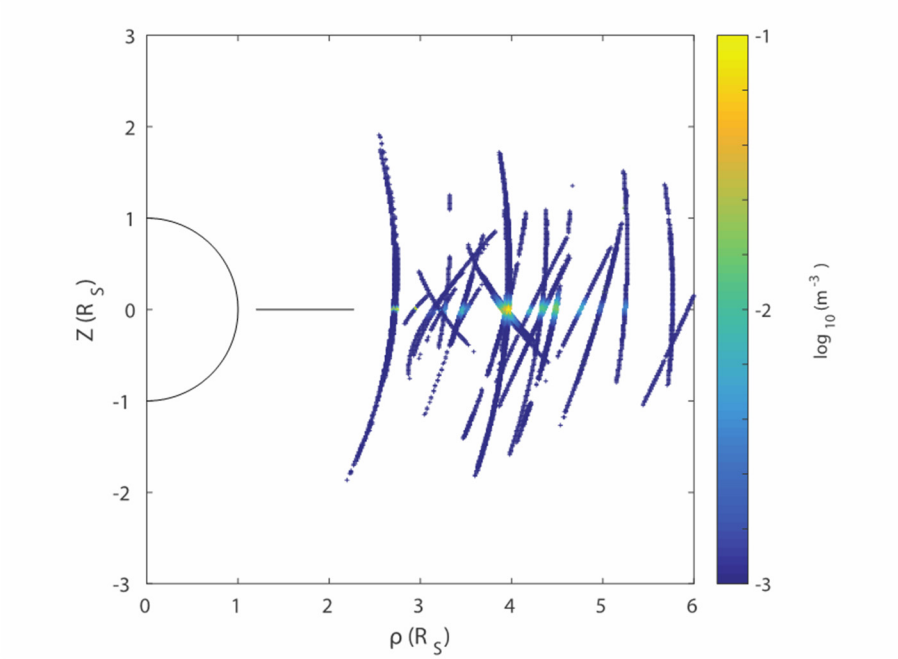

Figure RPWS-7. Trajectories of Cassini during 53 high inclination crossings between SOI and equinox in polar coordinates. The color code shows base ten logarithm of estimated dust density (>1 micron), so that yellow represents 0.1/m^3 and blue represents 0.001/m^3.

Cassini shifted to high inclination orbits and crossed the E-ring multiple times in 2016, providing opportunities to compare the vertical dust density profiles to those measured before equinox. The density profiles showed that the E-ring warp indeed reversed after equinox, with the dust density peak shifting to the south of the ring plane outside Enceladus' orbit and to the north inside Enceladus' orbit. These results confirm the seasonal control of the E-ring warp and role of solar radiation pressure in the dynamics of micron-sized dust particles in the E-ring.

Another asymmetry in the E-ring is the day-night asymmetry, as revealed by both remote sensing [Hedman et al. 2012] and in situ measurements (CDA and RPWS). The E-ring appears to be more compressed and bright on the noon side and more stretched out and faint on the night side. This local time asymmetry is likely related to two factors. One is the dependence of the orbital precession rate on the particles properties like size and charge-to-mass ratio and the other one is the recently discovered noon-to-midnight electric field which is of particular importance in driving the E-ring dynamic evolution.

The plume of water vapor and icy particles ejected from the south pole of Enceladus is perhaps the most exciting discovery of the Cassini mission [Dougherty et al. 2006; Porco et al. 2006]. The ejected material constitutes the major contents of the E-ring and Enceladus torus and

after ionization they become a major source of plasma in the magnetosphere of Saturn. Several instruments onboard Cassini are sensitive to the ice particles in the plume. On the small end of the size spectrum, nanoparticles are directly detected by the CAPS, where nanograins appear as energetic charged particles in the ELS and ion mass spectrometer (IMS) [Jones et al. 2009; Hill et al. 2012; Dong et al. 2015]. In a dusty plasma, electrons are attached to these nanograins, leading to a large difference between the electron and ion densities measured by the RPWS Langmuir probe in and around the plume [Wahlund et al. 2009a; Yaroshenko et al. 2009; Shafiq et al. 2011; Morooka et al. 2011; Engelhardt et al. 2015]. On the large end of the size spectrum, both CDA and RPWS are sensitive to micron-sized dusts [Srama et al. 2006; Kempf et al. 2008; Farrell et al. 2009, 2010; Omidi et al. 2012]. During the plume crossing when both CDA and RPWS were operating, the dust density profiles measured by the two instruments are consistent within the estimated uncertainty range for RPWS [Ye et al. 2014b]. Recently, it has been found that the Magnetospheric Imaging Instrument (MIMI) / Low-Energy Magnetospheric Measurement System (LEMMS) instrument is also sensitive to dust impacts in the plume of Enceladus, and the dust peak matches well with the dust density profile measured by RPWS [Krupp et al. 2017].

The plasma charge balance in the vicinity of Enceladus has been shown by the Langmuir probe measurements to be modified by the presence of dust particles. During the crossings of the Enceladus plume, Cassini RPWS observed sharp frequency decreases of the upper hybrid resonance in the vicinity of the moon, indicating electron density dropouts most likely due to absorption by the dust particles [Farrell et al. 2009]. Inside the plume, however, the dust impact signals are so intense that the upper hybrid resonance is hard to identify. Ye et al. [2014a] presented an independent method of determining the electron density inside the dusty plume of Enceladus, using the plasma oscillations induced by dust impacts and detected by the WBR. The frequencies of these oscillations were shown to be consistent with the local plasma frequency, thus providing a measurement of the electron density. It was proposed that the electrons from the impact plasma constitute a fast beam relative to the background plasma, which will excite Langmuir waves through the bump-on-tail instability.

During the Ring Grazing orbits between December 2016 and April 2017, Cassini crossed through the Janus/Epimetheus ring 20 times. The WBR was scheduled to collect waveform data during the ring plane crossings, from which dust density profiles and size distributions have been derived [Ye et al. 2018a]. Figure RPWS-8 shows the statistics of dust impacts observed during the ring plane crossing on day of year (DOY) 361, 2016. *Panel a* shows the impact counts as a function of voltage and time. *Panel b* shows the gain of the receiver, which is set based on waveform amplitudes to maximize the use of the analog-to-digital converter (A/D) dynamic range while minimizing clipping (exceeding the range of the A/D converter) [Gurnett et al. 2004]. *Panel c* shows the dust density (1 micron size threshold) calculated from the impact rates, assuming an effective impact area of 1 m^2. The red line in *panel c* represents a horizontal cut of *Panel a* situated at 0.034 Volts, the voltage that corresponds to 1 micron dust size. The count rate profile for 1 micron particles has a width (~600 km) similar to the CDA high-rate detector (HRD) density profile. *Panel d* shows the size distribution slope estimated within a 10-second moving window (blue diamonds). The scatter of the blue diamonds indicates the uncertainty of the estimated size distribution slope, increased when the number of impacts detected within the moving window decreases.

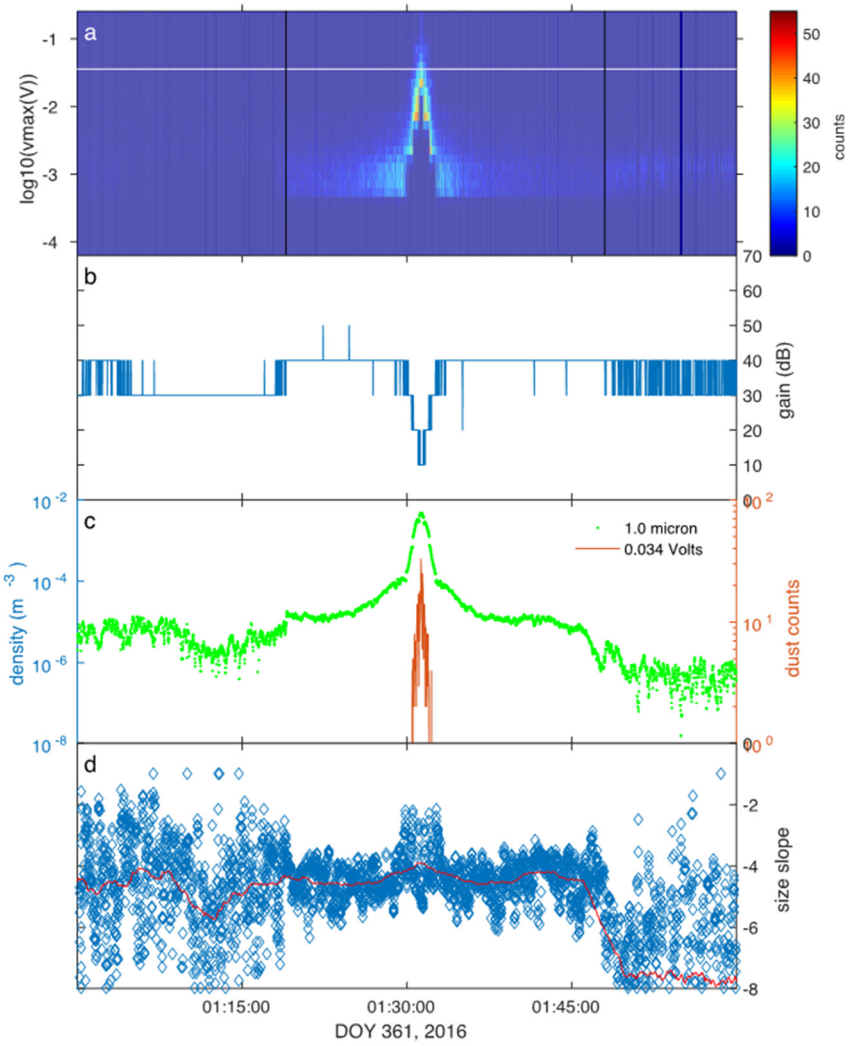

Figure RPWS-8. Dust analysis for the ring plane crossing on DOY 361, 2016. *Panel a*: Impact counts as a function of voltage and time. Black vertical lines mark the times of mode changes, between which the monopole antenna was used. *Panel b*: Gain of the receiver. *Panel c*: Dust density (1 micron size threshold) calculated from the impact rates. The red line shows the horizontal cut of *Panel a* situated at 0.046 Volts (marked with white horizontal line in *Panel a*). *Panel d*: Differential size (radius) distribution slope estimated within a 10-second moving window (blue diamonds, red line shows smoothed value with a 120-second moving window).

For example, when the antenna mode was switched to dipole, fewer impacts were detected, causing higher uncertainty level of the size slope. The red line indicates smoothed values of the individual size slopes (blue diamonds) using a 120-second moving window. This smoothed size slope is also used to scale the density values to the fixed size threshold shown in *Panel c*.

The RPWS dust density profiles were fitted with Lorentzian functions and compared to that measured by the CDA HRD (Figure RPWS-9). There is one order of magnitude difference between the two results, which is within the uncertainty limit estimated for the RPWS measurement.

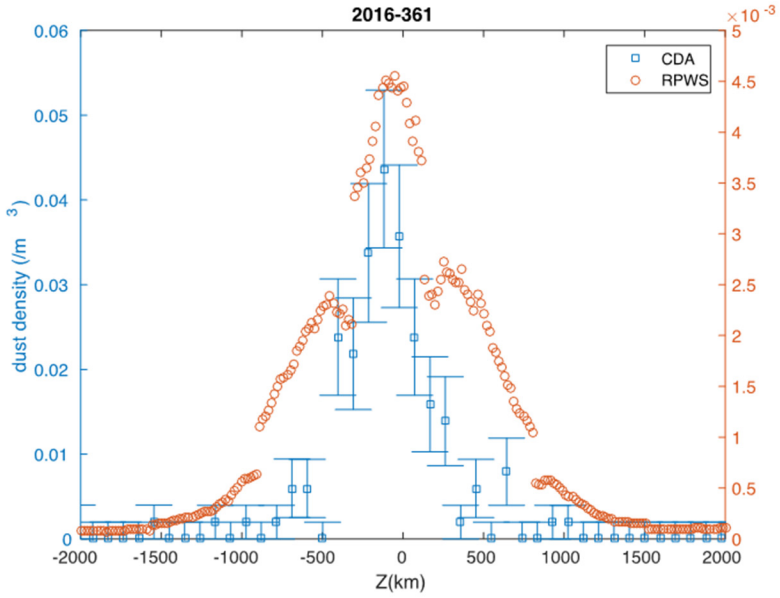

Figure RPWS-9. Comparison of vertical dust density profiles measured by RPWS and CDA HRD during the ring plane crossing on DOY 361, 2016.

The HRD profile also has a slightly narrower peak width. The dust densities inferred from the Langmuir probe sweep data (assuming a differential size distribution slope −4.5) agree with the WBR results [Morooka et al. 2018]. The peak locations of the RPWS dust density profiles shift north and south but are within 100 km of the ring plane (CDA HRD density profiles show a systematic southward shift of 130 km). These peak offsets are within the maximum offsets of the moons Janus and Epimetheus due to their slight orbit inclinations.

On April 26, 2017, Cassini dived into the gap between Saturn's main ring system and its atmosphere starting the 22 Grand Finale orbits. RPWS observed few micron dust impacts during the first five and last ten proximal orbits, not enough for characterizing the size distribution [Ye et al. 2018b]. The lack of micron dust in this region is probably due to the plasma drag in the ionosphere, where the cold density plasma corotate with the planet at a speed lower than the Keplerian speed of the dust particles. So, the micron dusts would lose speed and fall into the planet. During the higher altitude D-ring crossings (rev 276–282), RPWS detected more dust impacts with the density estimated to be about two orders of magnitude lower than F-ring orbits. The monopole antenna measurements near the D-ring indicated that spacecraft was charged positively (the impact signals were mostly positive, whereas at larger radial distances the impacts detected by monopole were mostly negative). The Langmuir probe also measured positive spacecraft potentials and electron bite-outs around the ring plane. The positive potential might be due to kinetic ion impacts, similar to what Langmuir probe (LP) observed in the deep ionosphere. Close inspection of the waveforms indicates a possible dependence of the impact signal decay time on ionosphere plasma density, which showed large variations from orbit to orbit.

RPWS was also able to detect nanoparticles originated from the inner solar system (0.2 AU) [Schippers et al. 2014, 2015] and Jupiter's moons [Meyer-Vernet et al. 2009], based on the bursty noise spectrum measured on the monopole antenna of RPWS. During the cruise phase of Cassini, the RPWS instrument was turned on with setup suitable for dust detection at three different heliocentric distances: 1, 1.6, and 2.9 AU. Signature of nanoparticle impacts were detected during all three operating periods, suggesting ubiquitous presence of these particles in the solar wind. The observed flux distribution is consistent with nanodust produced in the inner heliosphere, picked up by the solar wind, and carried to the outer heliosphere [Mann et al. 2007; Mann and Czechowski 2012]. Meyer-Vernet et al. [2009] analyzed RPWS observations during the Jovian flyby and estimated the flux of streaming nanoparticles ejected by the Jovian moon Io based on the bursty wave spectrum, which is consistent with the flux measured by the onboard dust analyzer CDA and Galileo dust instrument.

Magnetosphere-Ring Interaction Science

The Cassini mission brought about a profound new view the interaction of the amazing Saturnian main ring system with the magnetospheric space environment. During the Voyager era, it was presumed that meteors continually bombarded the rings. The spokes were thought to represent a stunning visual manifestation of these intense impacts. The associated impact-ionized vapor plume then delivered ring water and oxygen ions along connecting magnetic field lines to the ionosphere. These water ions were thought to chemically disrupt the ionosphere hydrogen cycle and deplete the ionosphere locally of electrons. It was also thought that these ring-generated ions possibly modify the color of the cloud tops. In this view, the rings were considered a source of quasi-energetic plasma delivering heavy ions to the exobase above the cloud-tops. Figure RPWS-10

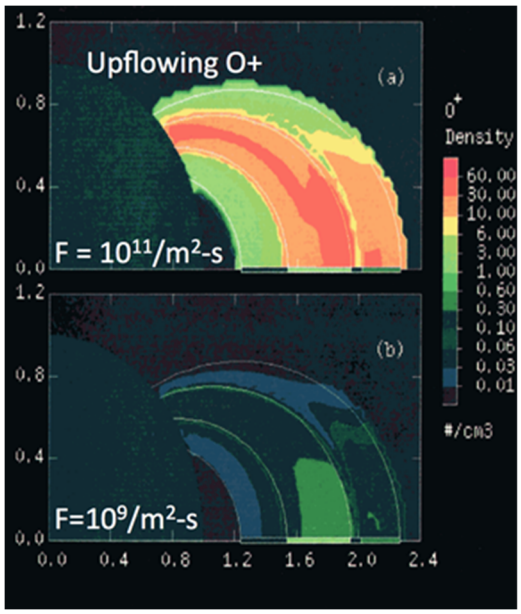

Figure RPWS-10. Impact-driven Ring Plasma Model [Wilson and Waite 1989].

shows the predicted impact-generated plasma flux from the rings, with peak densities over the dense portion of the central B-ring [Wilson and Waite 1989]. Voyager, unfortunately, did not actually fly over the rings and thus confirmation of this impact-driven ring plasma source could only be inferred.

At both the very beginning (SOI) and very end of the Cassini mission, the spacecraft flew directly across magnetic field lines that connect back down to the main rings, and thus obtained unique direct measurements of the plasma environment across the main A-ring, B-ring, and C-ring.

Saturn orbit insertion

Gurnett et al. [2005] presented a new view of the plasma environment over the main rings from the SOI overflight of the shadowed face of the rings. Figure RPWS-11 shows the corresponding plasma density as derived from the narrow-banded upper hybrid waves, electron plasma oscillations, and high frequency edge of the auroral hiss. All of these plasma wave features allow a high resolution direct derivation of the local electron density (see Gurnett et al. [2005] for a more detailed description of that derivation). In the profile, the various plasma wave sources are identified.

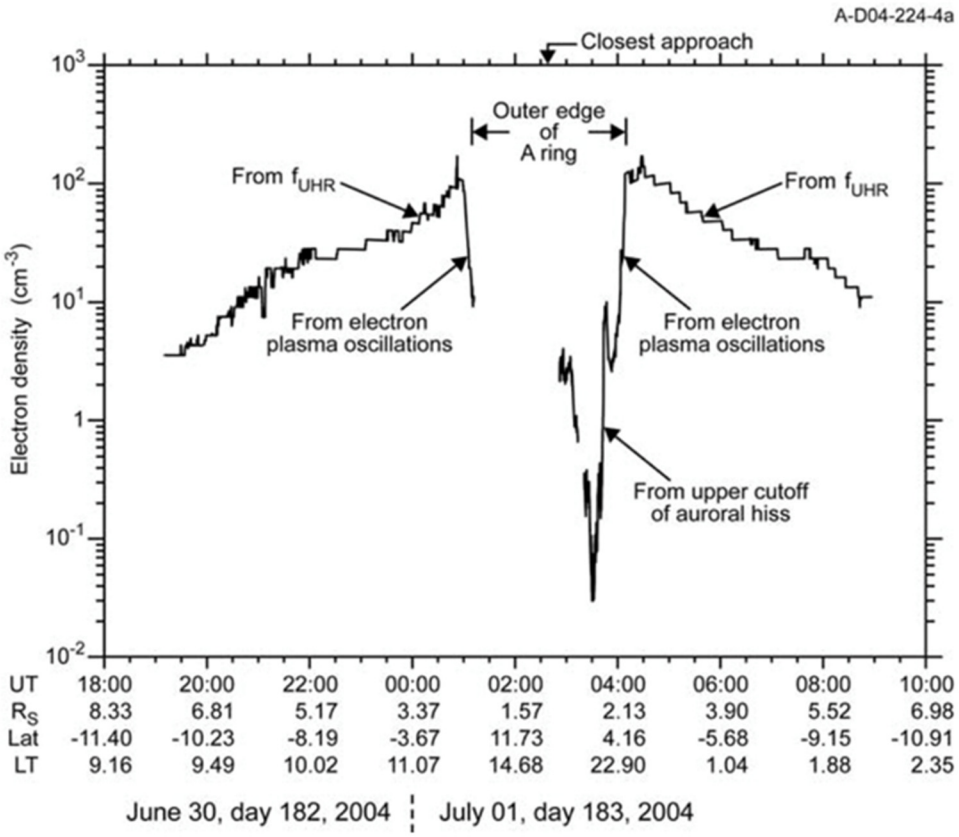

Figure RPWS-11. The electron density over the main rings as derived by the plasma waves detected by RPWS (see Gurnett et al. [2005] for more details).

There are two stunning features to this profile:

1. That immediately adjacent to the dense A-ring, there is an electron density maximum at over 100 electrons/cm^3, with the high density region (>10/cm^3) extending out to beyond L = 5. It would later be found [Persoon et al. 2009, 2015] that this high density region is a plasma torus created by ionization and pickup of new ions born in the Enceladus plume and a seasonal contribution from photo-ionized neutrals originating from the rings themselves. Thus, at equinox, the maximum in plasma density in this torus shifts radially outward to 4 R_S, but at solstice, the Sun-facing rings become a neutral and plasma source shifting the torus plasma maximum closer to the A-ring (see Figure 6 and 7 of Persoon et al. [2015]). The peak density in the torus is about 10% of the Io torus at Jupiter and represents a dominant controlling element in the inner magnetosphere of Saturn [Gurnett et al. 2007].

2. That the region over the main rings is devoid of plasma, with an electron density drop of near 10000 from the outer edge of the A-ring to values of 0.04 electrons/cm^3 at 1.76 R_S over the central portion of the B-ring [Xin et al. 2006; Farrell et al. 2017b]. This void region has been identified as a ring plasma cavity (RPC) with its lowest density near the synchronous location. The profile of electron density over the main rings varied inversely with ring optical depth, with the lowest plasma densities observed over the central dense B-ring and a local maxima sense when passing over field lines connected to the Cassini Division. (In Figure RPWS-11, this Cassini Division plasma maxima is seen near 03:45 spacecraft event time (SCET) with the local peak near 10/cm^3.)

This electron density profile was unexpected and almost diametrically opposite to what would have been predicted from an impact-driven ring plasma system, where the maximum in plasma density is expected in the central B-ring (like in Figure RPWS-10).

Evidence for photolytic-driven rings

RPWS SOI observations confirm the model of Tseng et al. [2013] that the ring-ionosphere-magnetosphere interaction is driven by photolytic processes, not impact processes [Farrell et al. 2017b]. Specifically, the sun-facing side of the main rings are a source of photo-dissociated neutrals that then get ionized to form a relatively low energy exo-ionosphere. This exo-ionosphere cannot directly access the shadowed/unlit side of the rings: the ring particles represent obstacles to their transport. Thus, the plasma density on the unlit side is modulated by ring density, being lowest where the ring obstruction is the highest—in the central B-ring. Local maxima are expected where the local ring particle density is low, like across the Cassini Division. There is little evidence of impact-generated plasma like that predicted during the Voyager era.

New main ring-magnetosphere current system

Xin et al. [2006] reported a strong auroral hiss signal detected at the deepest depletion of the electrons within the RPC near 1.76 R_S. The whistler-mode auroral hiss emission is a classic signature of the presence of energetic-field-aligned electron beams, in this case flowing outward from the rings along field lines connecting to the ionosphere. They reported that the RPC environment had a stunning similarity to plasma cavities found in polar auroral regions, usually associated with field-aligned currents that drive the aurora. The observation suggested that there is a current system driven by the rings-magnetosphere interaction, with the electron beams and currents near the synchronous point at 1.76 R_S possibly being part of the current closure system.

Figure RPWS-12 illustrates the concept of this new ring current system presented in Xin et al. [2006]. While the plasma on field lines over the rings would be corotating, the particles and associated photo-dissociated gas of the rings would be moving in Keplerian motion, creating drag on the plasma. This drag creates an associated change in plasma speed, ΔV. Beyond the synchronous point, the plasma is slowed by the Keplerian-moving particles and gas, creating an outward radially-directed E-field in order to maintain the new subcorotation speed $E' = \Delta V \times B$. This new E-field drives an outward current, J, which acts to then form a magnetohydrodynamic $J \times B$ force to balance the plasma-ring drag force. Inward of the synchronous point, the corotating plasma is accelerated by the ring drag force, creating an inward radial E-field and current that forms a $J \times B$ force to offset the acceleration. At the edges of the rings, these cross-ring currents become field-aligned parallel current that close down to the ionosphere along connecting magnetic field lines at the outer edge of the A-ring near L = 2.25 and inner edge of the D-ring near L ~ 1.11. The rings thus behave as an electrical generator in the plasma, driving currents from the ring surfaces along magnetic field lines down to the ionosphere.

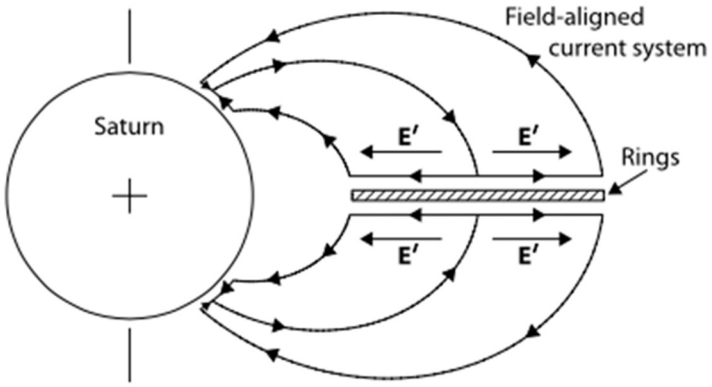

Figure RPWS-12. The proposed large-scale current system that would be induced in Saturn's magnetosphere by the interaction of the rings (including any associated gas) with the corotating magnetospheric plasma. Figure from Xin et al. [2006].

Subsequent RPWS observations confirm the presence of the various elements of this current system:

1. After SOI, Gurnett reported that bursts of auroral hiss emission were observed during SOI at the outer edge of the A-ring by RPWS. These events were initially reported to possibly be from impacts on the rings. However, the burst localization limited to only the very outer edge of the A-ring suggests the non-unique possibility that these auroral hiss emissions are associated with bursty field-aligned electron beams that make up the outer edge of the Xin et al. current system at L ~ 2.2.

2. Farrell et al. [2005b, 2008] reported on z-mode radiation emitted from active plasma hot spots along the outer edge of the A-ring where the rings and corotating magnetospheric plasma disk interact. Newly-born corotating ions created by photo-ionization of neutrals from the Enceladus torus or sunlit side of the rings would be the source of this ring-plasma interaction. Farrell et al. [2005b] and Menietti et al. [2016b] proposed wave generation mechanisms to explain the z-mode emitted from active regions.

3. Kopf et al. [2011] reported on the fine structure of Saturnian Kilometric Radiation from active auroral regions. They found there was a population of events having fine structure emission frequency vs time emission drifts consistent with emission at low latitudes from the L = 2.2 field line. The observation suggests the L = 2.2 field line at the outer edge of the A-ring is active, with parallel currents creating SKR at the field line footprint above the cloud-tops.

4. As discussed in this section, auroral hiss indicative of electron beams and inward flowing currents were detected near the synchronous point at 1.76 R_S [Xin et al. 2006]. This observation was the inspiration for the model of the main ring-magnetosphere current system.

Some added key evidence for this current system is still being derived from the ongoing analysis of the proximal orbit sequence that occurred in 2017.

Proximal orbit analysis and added evidence for the main ring-magnetosphere current system

While detailed analysis of the proximal orbits is still ongoing, Wahlund et al. [2018] reported on a very strong Saturnian ionosphere-D-ring electrical connection, which would represent the current closure of the Xin et al. [2006] model at the inner radial edge of the main rings. Using the RPWS Langmuir probe, they found that Cassini passed through a cold, dense electron region during proximal perigee, which has been interpreted to be entry into the Saturnian ionosphere. Figure RPWS-13 shows an example proximal electron density profile from orbit 271. The peak densities are in excess of $10^3/cm^3$, consistent with passing through the ionosphere. However, as evident in this and other passes, the ionospheric densities had relative maxima and/or unusual fluctuations

on field lines connected to the D-ring (near ±10° latitude). This effect was reported by Wahlund et al. [2018] to be associated with the Keplerian D-ring charged particles driving currents on field lines connected to the corotating ionosphere plasma.

At higher altitude proximal perigee passes, like orbit 277, Cassini passed through the inner edge of the D-ring (also immersed in the outer edge of the ionosphere). In these cases, the electron density had a distinct bite-out or decrease near the equator which is believed to be due to the presence of D-ring particulates that have absorbed the local ionospheric plasma. The RPWS instrument also detected micron-sized dust grain impacts revealing the presence of these D-ring particulates. The complex dusty plasma interactions remain a subject of considerable study even after the end of the mission.

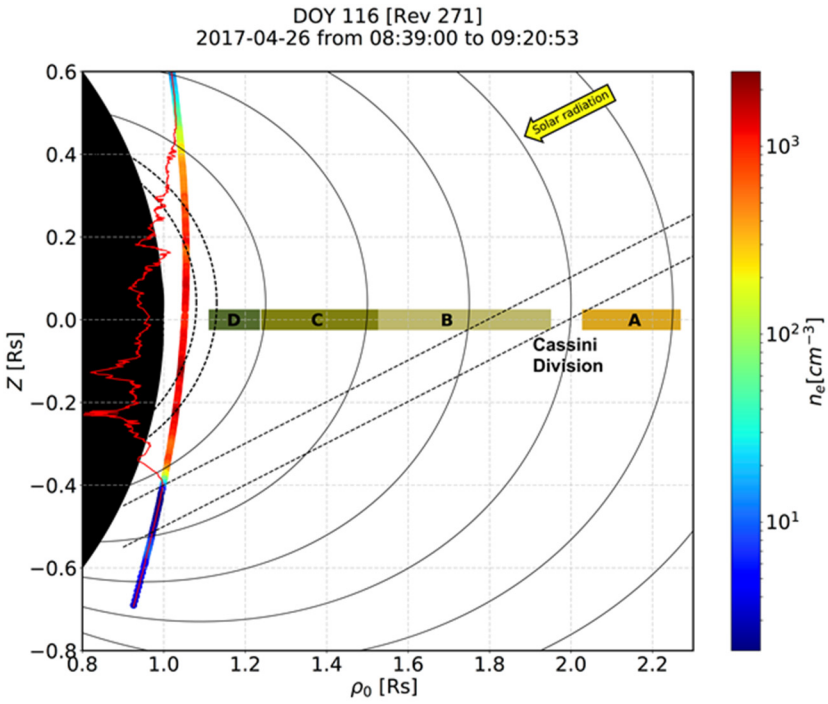

Figure RPWS-13. The Cassini spacecraft trajectory during April 26, 2017, crossed through the gap between the planet Saturn (solid black) and its rings (denoted D, C, B, Cassini Division, A) from north to south. The color code signifies the electron number density as measured by RPWS, which is also shown as a red line (in linear scale, density increases toward the left) where detailed structures can be detected. Four dominant electron density enhancements are connected via Saturn's magnetic field to, or inside, the inner edge of the D-ring (dashed lines). The solar elevation angle was 26.7° during the event, and the shadows of the B- and A-rings result in decreased ionization in the south. From Wahlund et al. [2018].

With repeated sampling of magnetic field lines connected to the main rings during the proximal orbit, Sulaiman et al. [2018b] reported the first observations of VLF saucers originating from Saturn's ionosphere, similar to what was observed at the Earth by the Fast experiment [Ergun et al. 2003]. Furthermore, Sulaiman et al. [2019] found evidence to strongly support the single observation that Xin et al. [2006] reported, hinting a ring-ionosphere current system. This concluded

the existence of a persistent, large-scale, and ordered electrodynamic connection between Saturn and its main rings.

The spokes in the context of the ring-plasma cavity and ring current environmental systems

The enigmatic spokes found near the center of the B-ring (near the synchronous location) were the source of numerous observation and theoretical works during the Voyager era. Their amazing observation captured the imagination since they represented a dynamic, impulsive, modern process occurring on the ring surfaces. Unfortunately, Voyager did not pass over the rings so the space environment associated with the spokes remained unknown until Cassini.

The review by Goertz [1989] described the spokes as being a result of a meteoric impact onto the rings that releases high volumes of charged dust, neutrals, ions, and electrons from the ring surface. Immediately after impact, the plume charged species undergo pickup, with electrons getting picked up immediately, then ions and then the more massive dust. This spatial spread in charged species created by local pickup thus was hypothesized to form an azimuthally-directed transient E-field. The various species then were predicted undergo an ExB drift to migrate radially forming spokes from the central B-ring.

However, during SOI and the proximal orbits, Cassini transited field lines that connect to the spoke locations (although spoke activity was not reported during these times). Farrell et al. [2006] reported that the Voyager spoke occurrences are spatially co-aligned with the ring-plasma cavity observed during SOI. Figure RPWS-14 overlays the SOI observations of the RPC with the Voyager-detected spoke occurrences [Grün et al. 1992]. The stunning spatial coincidence suggests that the spokes might then be some visual manifestation of the larger electrical current system containing the electron beam, auroral hiss, and plasma cavity detected during the Cassini SOI passage.

Any new dusty-plasma plume forming in the central B-ring is thus injected into the low density RPC environment with a radially-directed E-field (see Figure RPWS-12) along the ring surface [Xin et al. 2006]. The radial E-field may then provide the acceleration the spoke's charged dust in the radial direction. This new acceleration process would replace the more complex requirement of having to form a transient azimuthal E-field to create the subsequent radial transport.

HST observations [McGhee et al. 2005] indicated that the spokes on the sun-lit faces of the rings—those visible to Hubble Space Telescope (HST)—tended to disappear when the ring tilt angles exceeded ~15°, under increasing solar UV radiation conditions. Farrell et al. [2006] noted that at these angles the local photo-electron emission from the ring surfaces would exceed the electron densities in the plasma cavity—thus destroying the RPC environment and changing the local surface potential polarity from negative to positive. They suggested this photo-electron effect from solar exposure might explain the reported loss of the spokes at relatively large tilt angles observed by HST.

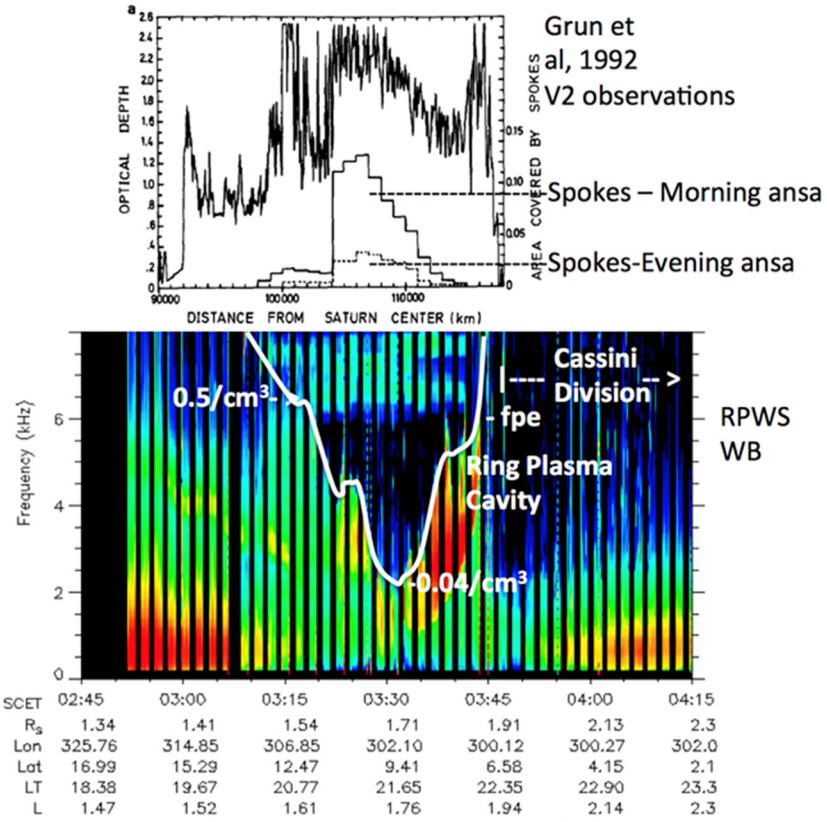

Figure RPWS-14. The ring plasma cavity detected during SOI as evident by the deep minimum in electron plasma frequency (indicated with the white line) in the RPWS wideband spectrogram. *Top panel*: location of the Voyager-observed spokes occurrence from Grun et al. [1992] with the two plots co-aligned by L-shell value. Presented by W. M. Farrell, M. D. Desch, M. L. Kaiser, W. S. Kurth, and D. A. Gurnett at the Joint Juno-Cassini workshop 2015.

Radio Emissions and Periodicities

Saturn's radio emissions started to be observed by Cassini/RPWS over the 10–1000 kHz range (see section entitled Kilometric Radiation) from distances of a few astronomical units. From late 2002 to early 2003, they were embedded in Jovian radio emissions and solar radio bursts. Their signal-to-noise ratio increasing with decreasing distance to Saturn, they became the dominant emission for the mid-2003 to mid-2004 year preceding Saturn's orbit insertion. These emissions divided into three main components, which have been analyzed separately or comparatively, as described below, to address most of the scientific objectives described in previous sections. Figure RPWS-15 shows examples of Saturn Kilometric Radiation (SKR), 5- and 20-kHz narrowband (NB) emissions and Saturn Drifting Bursts (SDBs) along with Saturn Electrostatic Discharges (SEDs) at the higher frequencies.

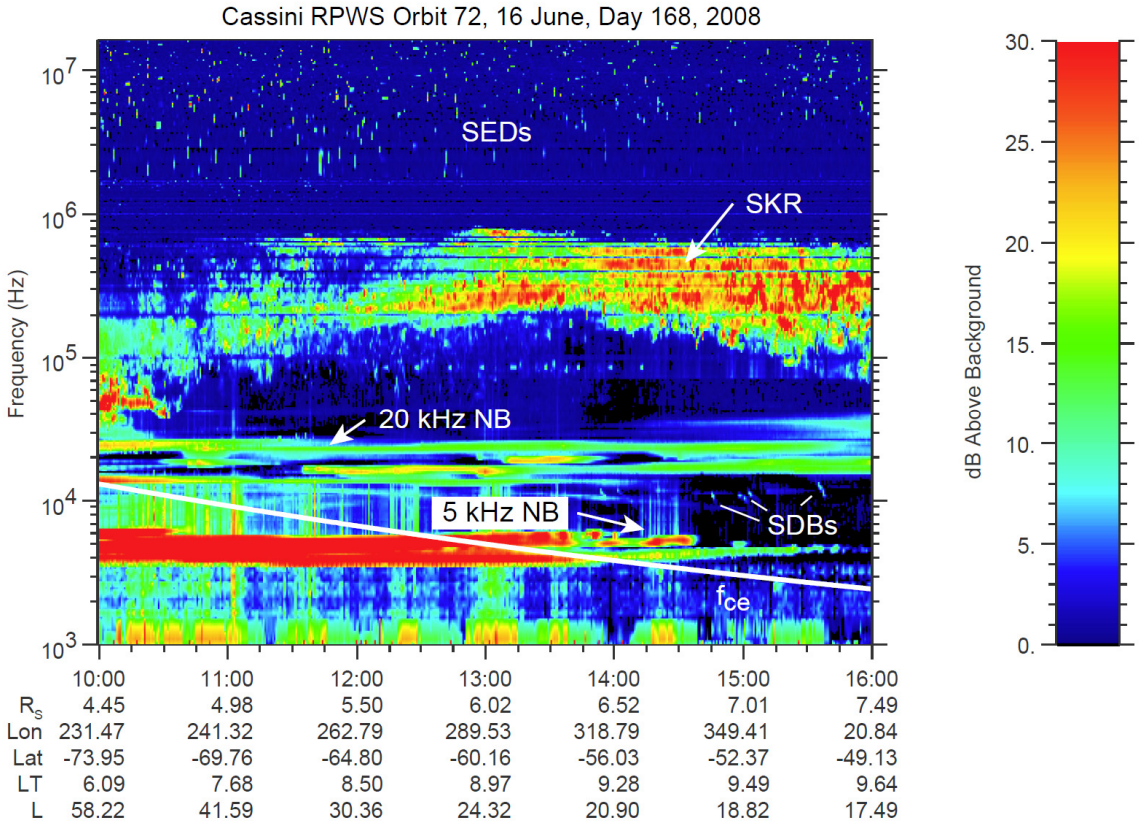

Figure RPWS-15. An illustration of the the major Saturnian radio emissions. From highest frequencies: SEDs, Saturn electrostatic discharges from lightning; SKR, Saturn Kilometric Radiation, 20- and 5-kHz NB, emissions, and SDBs, Saturn drifting bursts.

Kilometric radiation

Saturn's Kilometric Radiation is the most intense radio emission component, produced in the auroral regions. Several reviews of SKR properties have accompanied the Cassini mission [Kurth et al. 2009; Badman et al. 2014], the most recent one summarizing our current knowledge before Cassini Grand Finale [Lamy 2017] (see in particular Figure 1 of Lamy [2017] which plots all RPWS observations of SKR over the course of the Cassini mission).

REMOTE PROPERTIES

- The SKR spectrum was studied statistically with RPWS observations from a wide variety of Cassini's positions. It extends from a few kHz to 1 MHz and appears to be most intense when observed from the dawn-side at mid-latitude [Lamy et al. 2008a; Kimura et al. 2013]. Southern SKR was predominant up to 2010 to mid-2011 (slightly after the equinox of 2009), while the northern SKR was predominant after,

consistent with a seasonal control of field-aligned currents driving auroral emissions by solar illumination of Saturn's ionosphere.

- The SKR sources were routinely located by RPWS/HFR direction-finding (goniopolarimetric analysis, which additionally provided the apparent wave beaming angle. The radio sources were observed to be hosted by magnetic field lines at all longitudes whose footprints map to the circumpolar auroral oval [Farrell et al. 2005a; Cecconi et al. 2006; Lamy et al. 2009]. The emission is strongly anisotropic, with a beaming angle decreasing with frequency, which produces arc-shaped emissions in the t-f plane [Lamy et al. 2008b; Cecconi et al. 2009; Lamy et al. 2013].
- SKR is a right-handed (RH) fully elliptically polarized emission. It is seen predominantly in the R-X (and marginally in the L-O) mode, with RH/LH (LH/RH) polarization witnessing emissions coming from the northern/southern (southern/northern) hemispheres, respectively. SKR was remotely found to display quasi-purely circular polarization at latitudes below 30° and strongly linearly polarized above [Cecconi and Zarka 2005a; Masters et al. 2009].
- SKR displays several types of dynamics. At timescales of a few minutes, SKR displays fine structures drifting in frequency and reminiscent of auroral kilometric radiation (AKR) fine structures observed at Earth. Multiple origins accounting for the slow drifts of a few kHz/min are debated [Kurth et al. 2005b]. At timescales of hours, active flux tubes hosting anisotropic radio sources produce isolated arcs in the time-frequency plane, whose characteristics relate to the wave beaming angle and the position/motion of the source with respect to the observer. At timescales of 11 h, the emission is strongly rotationally modulated (see section entitled Radio Periodicities). At longer timescales, SKR strongly brightens episodically, indicating auroral storms driven or not by the solar wind and thus probing large-scale magnetospheric dynamics [Kurth et al. 2005a, 2016; Clarke et al. 2005; Crary et al. 2005; Jackman et al. 2005, 2009, 2010; Badman et al. 2008a, 2016; Nichols et al. 2009; Lamy et al. 2013; Reed et al. 2018].

In situ characteristics:

SKR sources were crossed twice at 10–20 kHz before the Cassini Grand finale. Their detailed study revealed that SKR is fully consistent with the Cyclotron Maser Instability (CMI) developed for AKR at Earth. It is radiated perpendicular to the magnetic field-lines from shell-like electron distribution functions of 6–9 keV [Lamy et al. 2010a; Mutel et al. 2010; Bunce et al. 2010; Schippers et al. 2011; Kurth et al. 2011; Menietti et al. 2011a, 2011b]. SKR polarization turned to be strongly linearly polarized at the source, as expected for perpendicular emission, and was found to be circularized along its propagation through the surrounding environment in agreement with expectations from the magneto-ionic theory in a cold, weakly inhomogeneous, plasma [Lamy et al. 2011a]. A statistical survey of the ring-grazing orbits revealed three additional passes of the spacecraft within low frequency dawnside northern SKR sources. The amplified waves were again

found to be strongly linearly polarized, radiated quasi-perpendicularly from the field lines through the CMI from 6-12 keV unstable electrons. Additionally, the SKR source region was interestingly seen to be only partially colocated with the UV auroral oval as the local plasma density was surprisingly variable and sometimes high enough to quench the CMI [Lamy et al. 2018a]. Cassini proximal orbits will provide further insights to the statistical characterization of SKR high frequency sources.

Narrowbanded emissions

At the lower edge of SKR spectrum, narrowbanded (NB) emissions have been observed between 3 and 70 kHz, and divide in two main components around 5 kHz and 20–40 kHz. Their observation by RPWS has been reviewed by [Ye et al. 2011].

The 5 kHz emissions, early labelled n-SMR for NB myriametric emissions in analogy with narrowband kilometer (nKOM) at Jupiter, were observed to rise in association with sudden SKR intensifications and related to ejection events from the plasma disk [Louarn et al. 2007]. The 5 kHz component was found to be intense and weakly circular polarized while the 20–40 kHz component, proposed to be referred to as n-SKR, appeared to be weaker and highly circularly polarization, both being better observed from high latitudes [Lamy et al. 2008a].

The source locus, dynamics, and wave growth of NB emissions were investigated in depth through a series of statistical and case studies [Menietti et al. 2009, 2010b, 2016b; Ye et al. 2009, 2010a; Wang et al. 2010; Gu et al. 2013]. Both components were found to propagate in the L-O ordinary mode. The 20–40 kHz component was proposed to be generated by mode conversion of electrostatic upper hybrid waves on the boundary of the plasma torus. The 5 kHz component is produced on the Z-mode from the lower density region near the inner edge of the Enceladus torus and possibly from the auroral regions as well by a generation mechanism not unambiguously identified yet.

Saturn Drifting Bursts

Another type of low frequency radio emissions called Saturn Drifting Bursts (SDBs) was detected with RPWS below 50 kHz [Taubenschuss et al. 2011]. These bursty emissions are highly circularly polarized, propagating in R-X and L-O modes and display emission at the fundamental and first harmonic frequencies. They last for a few minutes and occur intermittently as slowly drifting events in the time-frequency spectrogram. Possible generation mechanism include CMI and linear or nonlinear mode conversion.

Radio periodicities

RPWS brought crucial observations to the study of the rotational modulation of Saturn's magnetosphere through measurements of periods of SKR and NB emissions (see reviews in Gurnett [2011]; Lamy et al. [2011a]; Lamy [2017]; Carbary and Mitchell [2013]; Szego et al. [2015]).

The first SKR periodicity measured by RPWS witnessed a value differing by 1% to the SKR period identified from Voyager/Planetary Radio Astronomy (PRA) observations 25 years earlier [Gurnett et al. 2005]. Such a large variation implies that the SKR period does not probe the internal rotation rate. The measured SKR period was then found to display weak variations associated with those of solar wind speed [Cecconi and Zarka 2005b; Zarka et al. 2007].

The major discovery brought by RPWS was then the identification of two SKR periods [Kurth et al. 2008] corresponding to the two kronian hemispheres, differing by ~1%. These periods were found to both vary with time in anti-correlation over yearly timescales and crossed closely after equinox, a trend which was interpreted as a seasonal driving of solar illumination [Gurnett et al. 2009a, 2010b, 2011b; Lamy 2011]. These dual periods were later noticed in NB emissions and auroral hiss as well [Gurnett et al. 2010a; Ye et al. 2010b; Ye et al. 2017] and more generally observed in numerous magnetospheric observables including magnetic oscillations, energetic neutral atom (ENA) emissions, aurorae [Mitchell et al. 2009c; Carbary et al. 2010, 2011; Nichols et al. 2010; Andrews et al. 2010, 2011; Provan et al. 2011; Badman et al. 2012a, 2012b]. It is now accepted that these dual rotational modulations all originate from two rotating hemispheric systems of field-aligned currents, whose origin may be atmospheric vortices [Jia et al. 2012].

The post-equinox period displayed a confused situation with poorly determined radio and magnetospheric periods. Over 2010–2012, they remained close to each other at locked phases, suggesting retro-interaction between both currents systems [Garnier et al. 2014], while sudden jumps of periods were tentatively attributed to Saturn's great whit spot activity [Fischer et al. 2014b] or to variable solar wind conditions [Provan et al. 2015]. Both periods eventually merged between mid-2013 and mid-2014 before crossing and diverging from each other after mid-2014 up to September 2017 [Provan et al. 2016; Ye et al. 2016b, 2017; Lamy 2017]. Figure RPWS-16 summarizes the variation of northern and southern SKR periods found by Ye et al. [2018c].

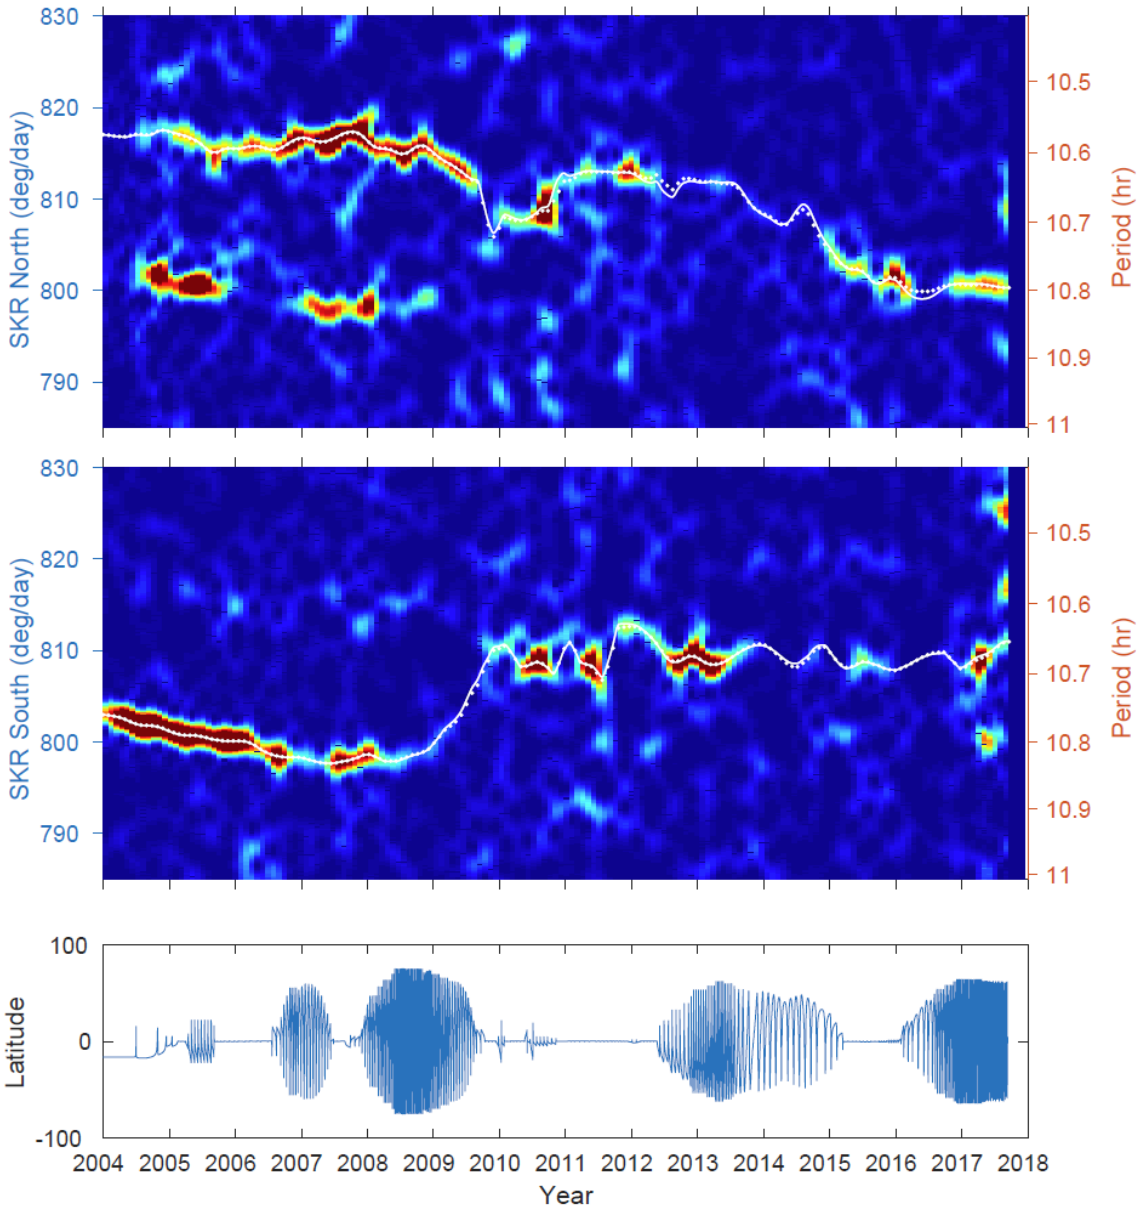

Figure RPWS-16. Rotational modulation spectrograms for SKR. *Top panel*: northern, *Middle panel*: southern hemispheres. The spectrograms show normalized modulation power (calculated using the least-squares spectral analysis) as a function of rotation rate and time. The white dotted lines show the automatically traced rotation rates (zeroth order) of north/south SKR. The white solid lines are corrected SKR rotational modulation rates (based on the zeroth-order rates and corrected by the phase drifts traced in Figure 1 of Ye et al. [2018c]). *Bottom panel*: is the latitude of Cassini.

Magnetosphere and Solar Wind Interactions Science

The Cassini RPWS instrument has helped investigate many different effects due to the interaction of the solar wind and the Saturnian magnetosphere, … .

The Cassini RPWS instrument has helped investigate many different effects due to the interaction of the solar wind and the Saturnian magnetosphere, how shock to the variations in the SKR intensity and frequency range, the presence of upstream Langmuir waves in the solar wind, and the detection of lion-roar like emissions in the magnetosheath. The following sections briefly discuss these observations and the various studies that RPWS has contributed to.

Solar wind influence on the Saturnian magnetosphere and aurora

The exact nature and importance of the solar wind influence on the Saturnian magnetosphere has long been debated. At Earth, the solar wind is the primary source of plasma in the magnetosphere and solar wind dynamics drive changes in the magnetosphere, including magnetic storms that lead to magnetic reconnection, plasma transport, and aurora. At Jupiter, the rapid rotation, large spatial scales, and internal source of plasma from the moon of Io, cause the magnetospheric dynamics to be primarily driven by centrifugal stresses rather than solar wind dynamics. The solar wind influence on the Saturnian magnetosphere has generally been considered to have both internal and solar-wind-driven processes. For example, the Voyager results suggested that the SKR pulsed at a period close to the planetary rotation period, but also that the emitted intensity was correlated with the solar wind dynamic pressure. This possible solar wind influence on the magnetospheric dynamics was an active area of research throughout the Cassini mission.

The approach to Saturn and the many orbits in which Cassini was located in the solar wind during apogee allowed in situ measurements of the solar wind while remote sensing measurements of the Saturn system were obtained. The remote sensing included Saturnian auroral imaging from the Hubble telescope and Cassini, plus observations by RPWS of the auroral radio emissions. During the approach to Saturn in early 2004, the Hubble Space Telescope took a number of ultraviolet images of the Saturn aurora and the comparison of these images to the Cassini observations were reported in a series of papers [Clarke et al. 2005; Crary et al. 2005; Kurth et al. 2005a]. During these observations, Saturn's auroras respond strongly to solar wind conditions, with the main controlling factor being solar wind dynamic pressure and electric field, with the orientation of the interplanetary magnetic field playing a much more limited role [Crary et al. 2005]. Clarke et al. [2005] reported that Saturn's auroral emissions varied slowly, with some features appearing to be related to corotation, and others are fixed to the solar wind direction. The auroral oval shifts quickly in latitude and is often not centered on the magnetic pole. In response to a large increase in solar wind dynamic pressure Saturn's aurora brightened dramatically, the brightest auroral emissions moved to higher latitudes, and the dawn side polar regions were filled with more intense emissions. The SKR emissions were also found to increase in intensity and drop in frequency

during the dynamic pressure increase and this intensity was correlated with the intensity of the aurora as shown in Figure RPWS-17 [Kurth et al. 2005a].

The relationship between solar wind dynamics, SKR, other magnetospheric properties, and the variation in the aurora continued in a number of different studies. During the SOI period, Jackman et al. [2005] suggested a major compression of Saturn's magnetosphere took place. Bunce et al. [2005] examined the in situ affects measured by Cassini that the corotating interaction region (CIR)-related compression had on Saturn's magnetospheric dynamics. For example, at ~02:00 UT on day 184, a burst of SKR emission is observed which disrupts the existing pattern of planetary modulated emission seen both upstream of the magnetosphere and during the inbound pass [Jackman et al. 2005; Kurth et al. 2005a]. Simultaneously, inside the magnetosphere, Cassini experienced a region of depressed and variable magnetic field. In addition, ion and electron observations show that this occurs as the spacecraft is engulfed by a hot, tenuous plasma population. They proposed that this behavior is indicative of a major episode of tail reconnection, triggered by the impact of the compression region on Saturn's magnetosphere.

The MIMI Ion and Neutral Camera (INCA) on the Cassini spacecraft also detected abrupt increases in energetic neutral atom flux coming from the general direction of Saturn's magnetotail that are well correlated with the enhancements in the Saturn kilometric radiation. Given the similarities between these events and substorm activity on Earth, including their dependence on interplanetary conditions, Mitchell et al. [2005] concluded that Earth-like substorms occur within Saturn's magnetosphere.

Taubenschuss et al. [2006b] examined the external control of SKR by the solar wind in the frame of the Linear Prediction Theory (LPT). Four basic solar wind quantities (solar wind bulk velocity, the solar wind ram pressure, the magnetic field strength of the interplanetary magnetic field (IMF) and the y-component of the IMF) were found to exert a clear influence on the SKR intensity profile. All four inputs exhibit nearly the same level of efficiency for the linear prediction indicating that all four inputs are possible drivers for triggering SKR, but all showed different lag times, ranging from ~13 hours for the ram pressure to ~52 h for the bulk velocity.

In contrasts to these earlier observations of direct correlations between solar wind magnetospheric dynamics, Gérard et al. [2006] reported results from a coordinated Hubble Space Telescope-Cassini campaign that took place between October 26 and November 2, 2005. During this period, Saturn's magnetosphere was in an expanded state and the solar wind was quiet, as indicated by the location of the magnetopause, in situ particle measurements, weak auroral SKR emission, and the generally low brightness of the aurora. The aurora exhibited considerable longitudinal structure and time variations over intervals of a few hours, in spite of the absence of observable external triggers and generally low intensity. In particular, enhancements of the dawn-morning oval were seen while no apparent indication of solar wind activity was observed. These features rotated at a speed corresponding to about 65% of the planet's angular velocity. Also, an ENA acceleration event occurred in the magnetotail on October 26 without any measured signature of solar wind activation. These observations suggest an intrinsically dynamical magnetosphere where injection of hot plasma occasionally takes place in the night or dawn sector during quiet

magnetospheric conditions, possibly connected with either the Dungey or the Vasyliunas convection cycle.

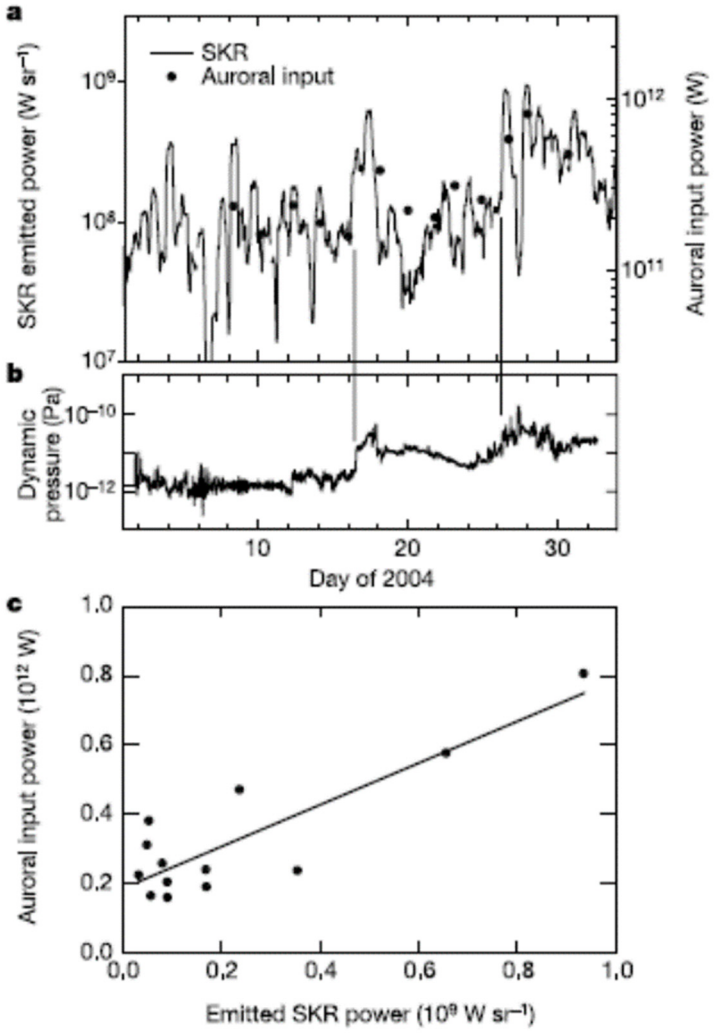

Figure RPWS-17. Correlations between auroral input power and emitted SKR power. *Panel a*: shows the time-averaged power emitted as SKR over plotted with the estimated auroral input power based on the ultraviolet aurora integrated intensity. *Panel b*: shows the solar wind dynamic pressure determined from Cassini measurements of the solar wind density and speed, and propagated to Saturn with a simple radial magnetohydrodynamic model. *Panel c*: compares the auroral input power and emitted radio power. Based on Figure 1 of Kurth et al. [2005a].

Louarn et al. [2007] reported on radio signatures observed at Saturn which are strikingly similar to the Jovian energetic events observed by Galileo. These radio signals consist of a sudden intensification of the SKR followed by the detection of a periodic narrowband radiation at about 5 kHz which most likely originates with plasma evacuation from Saturn's plasma disk. These radio signatures suggest that although Saturn's auroral activity is largely triggered by the solar wind,

energetic processes developing in the plasma disk are also involved, possibly associated with plasma transports and consequent releases of rotational energy.

In a study with a slightly different emphasis, Zarka et al. [2007] examined the possible role of the solar wind on the SKR radio period. As discussed in detail in the section entitled Radio Periodicities, as Cassini approached Saturn, the SKR period was measured to vary on the order of ~1% [Gurnett et al. 2005], and measurements over the first few years of the mission found that it actually exhibits two different periods [Kurth et al. 2008], and that each auroral polar region has its own dominate period that also varied with time [Gurnett et al. 2009a]. Zarka et al. [2007] found that the SKR period varied systematically by about ±1% with a characteristic timescale of 20–30 days, and that these fluctuations were correlated with solar wind speed at Saturn, suggesting that SKR is controlled in part, by conditions external to the planet's magnetosphere. No correlation was found with the solar wind density, dynamic pressure or magnetic field; suggesting that the solar wind speed therefore has a special role in this variation.

Rucker et al. [2008] reexamined the relationship between the SKR intensity and solar wind dynamics (both measured by Cassini and measured by Ulysses at ~5 AU and propagated to Saturn) for the year 2004. This study also found that the SKR intensity is positively correlated with solar wind pressure, and suggested that it may be possible to use the measured SKR properties as a monitor for the solar wind conditions.

Badman et al. [2008a] looked for variation of the SKR power observed by Cassini following arrival of thirteen solar wind compression event and investigated the phasing of the intensified or reduced emission peaks during the compression event, and the relative phasing and intensity of the emission peaks before and after the compression compared to the predictions of the drifting SKR period [Kurth et al. 2007]. They found that even though the behavior of the SKR following the compressions was somewhat variable, they confirmed that there was an overall positive correlation between the change in solar wind dynamic pressure and the change in emitted SKR power, and that the timings of the initial SKR intensifications following the compressions could be independent of the long-term phasing of the SKR bursts, but during the disturbed interval the SKR continues to pulse close to the expected times. Distinct extra bursts of SKR emission were also detected both before and during the compressions. The intensity of the detected emissions during the disturbed intervals was variable, sometimes remaining intense for several days, sometimes reducing, and in rare cases it disappeared. This variability showed that the SKR emissions cannot be simply used as a diagnostic of the prevalent solar wind conditions (e.g., when Cassini is inside Saturn's magnetosphere), without careful consideration of other influencing factors.

Clarke et al. [2009] built on the Cassini approach observations by using more aurora imaging data from a large campaign of observations in 2007 and 2008 of Saturn using the Hubble Space Telescope, in association with measurements from Cassini and determining solar wind conditions both by propagating measurements from 1 AU and by using Cassini observations when it was in the solar wind. The data found a one to one correspondence between the arrival of solar wind shocks at Saturn and increases in Saturn's auroral power and SKR emission, plus a decrease in the auroral oval radius. At the times of two reverse shocks, the SKR emission appeared to increase,

and possibly also the UV emission although the statistics were poor. These data are consistent with a causal relationship between solar wind disturbances and auroral and SKR emission increases as suggested in the earlier studies.

Mitchell et al. [2009c] adds to the above Clarke et al. [2009] results by examining the MIMI ENA results in conjunction with the auroral images and SKR observations. In the ENA observations, recurrent ring current oxygen intensity enhancements are usually detected that begin near midnight and increase in intensity and area as they rotate through the dawn meridian toward noon, and there is a close temporal association between recurrent ring current enhancements and recurrent SKR enhancements. For the single example of this recurring phenomenon for which continuous UV auroral imaging was available, bright corotating auroral emissions distributed in latitude from about 70 to 80 degrees tracked the ring current ion enhancement as it moved in local time from post-midnight to late morning. It was suggested that these recurrent events are caused by recurrent reconfiguration of the thin night-side current sheet in the 15–20 R_S region, probably associated with Vasyliunas-cycle reconnection and plasmoid release in the tail initiated relatively close to Saturn. The energy in such events presumably derives from Saturn's rotation, in combination with the mass loading of the cold plasma produced from Enceladus' extended gas cloud. However, a strong correlation was also found to exist between a solar wind pressure pulse resulting in magnetospheric compression and a ring current event, a sudden SKR power increase, and dawn-side auroral brightening. This correlation suggest a link between the asymmetric ring current enhancements and a rotating field aligned current system that drives both SKR enhancements and auroral displays. Such a relationship is implied for both the recurrent events with the Saturn rotation period and the solar wind pressure induced events.

The exploration of the nightside magnetosphere is reported in a series of papers by Jackman and coauthors. Jackman et al. [2009] revealed evidence of plasmoid-like magnetic structures and other phenomena indicative of the Saturnian equivalent of terrestrial substorms. In general, there was a good correlation between the timing of reconnection events and enhancements in the auroral SKR emission. Eight of nine reconnection events studied occur at SKR phases where the SKR power would be expected to be rising with time. Thus, while the recurrence rate of substorm-like events at Saturn is likely much longer than the planetary rotation timescale, the events are favored to occur at a particular phase of the rotation. Three examples were found in which the SKR spectrum extended to lower frequencies than usual. These low frequency extension SKR events were labeled low frequency extension (LFE) and were interpreted as an expansion of the auroral particle acceleration region to higher altitudes (lower radio frequency) along magnetic field lines as a direct consequence of an increase in the magnetosphere-ionosphere current density driven by substorm-like events. Saturnian substorms are likely a much more prevalent phenomenon than this small number of observations suggests, but the statistics in this study were hampered by viewing geometries, primary the small amount of time that Cassini spent in the deep magnetotail near the nominal current sheet location. Many examples of LFEs are observed by

In general, there was a good correlation between the timing of reconnection events and enhancements in the auroral SKR emission.

Cassini from a wide set of vantage points, but the spacecraft is only in the right position to observe the corresponding magnetic signature (if any) a fraction of the time.

Jackman et al. [2010] explored the dynamic response of Saturn's magnetotail to an episode of solar wind compression that took place while Cassini was sampling Saturn's nightside equatorial magnetosphere in 2006. Following an initial increase in solar wind dynamic pressure, the magnetosphere was compressed and became more streamlined, with an elevated lobe field strength as external pressure compressed the tail. Then, assuming a favorable IMF direction (for at least part of the interval, as seems entirely plausible), dayside reconnection may have been ongoing, leading to an increase in the amount of open flux inside the magnetosphere, flaring of the magnetotail, and continued elevated lobe field strength. Because of the longer time scales involved at Saturn for loading of the tail with open flux, it can take several days for the tail to be inflated to a point where reconnection is likely to occur, and this study suggested that the time scale observed in this case was of order ~6–7 days. No strong evidence for magnetotail reconnection events during this loading phase were detected, however, toward the end of this period a sharp decrease in lobe field strength and what appears to be significant current sheet deflection toward the equator from its previously hinged position was observed. Several days later the current sheet was displaced southward from its previously hinged position, and magnetic signatures consistent with the passage of a plasmoid were observed. These field signatures are closely correlated with intense radio emission, evidenced by LFEs of radio emission, corresponding to radio sources detected at higher altitudes. All of the above features are believed to be a common consequence of the impact of a solar wind compression on Saturn's magnetosphere.

Jackman et al. [2015] presented a rare observation of strong planetward flow following a reconnection episode in Saturn's tail from August 2006, when the Cassini spacecraft was sampling the region near 32 R_S and 22 h LT. Cassini observed a strong northward-to-southward turning of the magnetic field, which is interpreted as the signature of dipolarization of the field as seen by the spacecraft planetward of the reconnection X line. This event was accompanied by very rapid (up to ~1500 km s^{-1}) thermal plasma flow toward the planet. At energies above 28 keV, energetic hydrogen and oxygen ion flow bursts were observed to stream planetward from a reconnection site downtail of the spacecraft. Meanwhile, a strong field-aligned beam of energetic hydrogen was also observed to stream tailward, likely from an ionospheric source. SKR radio emissions enhancements similar to ones previously associated with plasmoid formation and release were detected slightly more than an hour after the observation of the dipolarization. The reconnection episode as inferred from the planetward directional flow duration lasts on the order of ~1.5 h, a significant fraction of a planetary rotation. The continuing presence of energetic O+ ions throughout the event demonstrates that this must be a case of long-lasting Vasyliunas-type reconnection occurring beyond 32 R_S in the premidnight region, perhaps indicating quasi-steady reconnection of the type. Because of the persistent presence of O+, we find little evidence for lobe involvement in the reconnection.

Kimura et al. [2013] investigated the very long-term (six years of measurements) variations of northern and southern SKR spectra, separated by polarization. This study confirms the prominent

role of solar wind pressure over one solar cycle, and additionally identified a seasonal dependence of the SKR activity, with a maximum in summer.

Kurth et al. [2016] reports on the SKR measurements obtained during a Saturn auroral campaign carried out in the spring of 2013 which used multiple Earth-based observations, remote-sensing observations from Cassini, and in situ-observations from Cassini. Saturn kilometric radiation was remotely monitored nearly continuously providing a measure of the auroral activity and a means of understanding the temporal relationships between the sometimes widely spaced remote sensing observations of the auroral activity. While beaming characteristics of the radio emissions are known to prevent single spacecraft observations of this emission from being a perfect auroral activity indicator, a good correlation between the radio emission intensity and the level of UV auroral activity was observed, when both measurements are available, similar to what the previous studies had shown. Given the known influence of solar wind dynamics on both SKR intensity and auroral activity as discussed above, the SKR integrated power is also a proxy for solar wind activity. This study found that there is a good correlation between the 10-h averages of SKR power flux and the power estimated input to the aurora on the basis of the UV brightness, justifying the SKR as a simple proxy for auroral activity through the campaign. The SKR emissions also give evidence for a recurrent pattern of solar wind interaction with Saturn's magnetosphere, suggesting a two-sector structure and associated corotating interaction regions influencing the level of auroral activity on Saturn. However, there are other SKR intensifications that may be due to internal processes.

Bunce et al. [2014] presented an unusual case in January 2009, where Ultraviolet Imaging Spectrograph (UVIS) observes the entire northern UV auroral oval during a 2 h interval while Cassini traverses the magnetic flux tubes connecting to the auroral regions near 21 LT, sampling the related magnetic field, particle, and radio and plasma wave signatures. The motion of the auroral oval evident from the UVIS images was found to be consistent with the appropriate phase of the magnetosphere oscillations in the northern hemisphere, whereas previous interpretations have assumed a static current system. Concurrent observations of the auroral hiss (typically generated in regions of downward directed field-aligned current) support this revised interpretation of an oscillating current system.

Thomsen et al. [2015b] presented observations that suggest that under some conditions the solar wind governs the character of the plasma sheet in the outer magnetosphere. Observations from September 2006, near local midnight at a radial distance of 37 R_S, showed a planetward flowing ion population for ~5 hours, which was accompanied by enhanced SKR emissions. This ion beam was interpreted as the outflow from a long-lasting episode of Dungey-type reconnection, i.e., reconnection of previously open flux containing magnetosheath material. The beam occurred in the middle of a several-day interval of enhanced SKR activity and lobe magnetic field strength, likely caused by the arrival of a solar wind compression region with significantly higher than average dynamic pressure (magneto-hydrodynamic (MHD) propagation models of the solar wind from 1 AU observations to Saturn during this period suggest the presence of higher density solar wind). There was also a change in the composition of the plasma-sheet plasma, from water-group-dominated material clearly of inner-magnetosphere origin to material dominated by light-ion composition,

consistent with captured magnetosheath plasma. This event suggests that under the influence of prolonged high solar wind dynamic pressure, the tail plasma sheet, which normally consists of inner-magnetospheric plasma, is eroded away by ongoing reconnection that then involves open lobe field lines. This process removes open magnetic flux from the lobes and creates a more Earth-like, Dungey-style outer plasma sheet dominantly of solar wind origin. This behavior is potentially a recurrent phenomenon driven by repeating high-pressure streams (corotating interaction regions) in the solar wind.

During a coordinated auroral observing campaign on April 21–22, 2013, instruments onboard Cassini and the Hubble Space Telescope observed Saturn's northern and southern aurora while Cassini traversed Saturn's high latitude auroral field lines [Badman et al. 2016]. Signatures of upward and downward field-aligned currents were detected in the nightside magnetosphere, with the location of the upward current corresponded to the bright ultraviolet auroral arc seen in the auroral images, and the downward current region located poleward of the upward current in an aurorally dark region. In the area poleward of the auroral oval, magnetic field and plasma fluctuations were identified with periods of ~20 and ~60 min. During April 21, 2013 the northern and southern auroral ovals were observed to rock in latitude in phase with the respective northern and southern planetary period oscillations. A solar wind compression impacted Saturn's magnetosphere at the start of April 22, 2013, identified by the intensification and extension to lower frequencies of the SKR. At this time, a bulge appeared along the pre-dawn auroral oval, which appeared to have moved sunward when this region was next observed. The midnight sector aurora remained a narrow arc at this time. Subsequently, the post-midnight aurora broadened in latitude and contracted towards the pole. The motion in this sector was in the opposite direction to that expected from the planetary period oscillation. There was also an intensification of the auroral field-aligned currents. These observations are interpreted as the response to tail reconnection events instigated by solar wind compression, initially involving Vasyliunas-type reconnection of closed mass-loaded magnetotail field lines, and then proceeding onto open lobe field lines, causing the contraction of the polar cap region on the post-midnight sector.

Felici et al. [2016] presented a case study of data from Saturn's magnetotail, when Cassini was located at ~22-hour Local Time at 36 R_S from Saturn that suggests for the first time that a low-energy ionospheric outflow event has been detected at planets other than Earth. During several entries into the magnetotail lobe, tailward flowing cold electrons and a cold ion beam were observed directly adjacent to the plasma sheet and extending deeper into the lobe. The electrons and ions appear to be dispersed, dropping to lower energies with time. The composition of both the plasma sheet and lobe ions show very low fluxes (sometimes zero within measurement error) of water group ions. The magnetic field has a swept-forward configuration which is atypical for this region, and the total magnetic field strength is larger than expected at this distance from the planet. Ultraviolet auroral observations show a dawn brightening, SKR is enhanced and extends down to lower frequencies, and upstream heliospheric models suggest that the magnetosphere is being compressed by a region of high solar wind ram pressure. This event is interpreted as the observation of ionospheric outflow in Saturn's magnetotail, with the active atmospheric regions most likely the main auroral oval.

The majority of the previously discussed studies involved periods where Saturn's magnetosphere encountered a high density solar wind. The study by Kinrade et al. [2017] discusses observations during a period that Saturn's magnetosphere was in a rarified solar wind region. During this period on June 14, 2014 (day 165), the Hubble Space Telescope observed an unusual auroral morphology, where for 2 h, the Saturn's far ultraviolet (FUV) aurora faded almost entirely, with the exception of a distinct emission spot at high latitude. The spot remained fixed in local time between 10 and 15 LT and moved poleward to a minimum colatitude of ~4°. Interestingly, the spot constituted the entirety of the northern auroral emission, with no emissions present at any other local time—including Saturn's characteristic dawn arc, the complete absence of which is rarely observed. Solar wind parameters from propagation models, together with a Cassini magnetopause bow shock crossing, indicate that Saturn's magnetosphere was in an expanded magnetosphere configuration during the interval, suggesting it was likely embedded in a rarefaction region. The spot was possibly sustained by reconnection either poleward of the cusp or at low latitudes under a strong component of interplanetary magnetic field transverse to the solar wind flow. The subsequent poleward motion could then arise from either reconfiguration of successive open field lines across the polar cap or convection of newly opened field lines. The spot's fixed LT position may be attributed to the negative IMF BY conditions incident at the time, combined with increased subcorotation of open flux toward higher latitudes. The emission intensity was also possibly enhanced by a sector of upward planetary period oscillation (PPO) current rotating through the region. These observations show conclusively that the mechanisms producing noon auroral spots and the main oval auroras (i.e., the dawn arc) are distinct, since in this case the cusp spot occurred without the arc. These observations also suggest that reconnection can occur in an expanded magnetosphere, in agreement with the cusp observations of Arridge et al. [2016a, 2016b], who found evidence of reconnection under a range of upstream solar wind conditions.

Solar wind parameters from propagation models, …, indicate that Saturn's magnetosphere was in an expanded magnetosphere configuration during the interval, suggesting it was likely embedded in a rarefaction region.

A recent study by Roussos et al. [2018] uses a novel technique to overcome the lack of an upstream solar wind monitor at Saturn. Cassini MIMI/LEMMS observations of solar energetic particle (SEP) and galactic cosmic ray (GCR) transients, that are both linked to energetic processes in the heliosphere such us interplanetary coronal mass ejections (ICMEs) and CIRs, are used to trace enhanced solar wind conditions at Saturn's distance. A survey of the MIMI/LEMMS dataset between 2004 and 2016 resulted in the identification of 46 SEP events. Most events last more than two weeks and have their lowest occurrence rate around the extended solar minimum between 2008 and 2010, suggesting that they are associated to ICMEs rather than CIRs, which are the main source of activity during the declining phase and the minimum of the solar cycle. Also, 17 time periods (> 50 days each) are identified where GCRs show a clear solar periodicity (~13 or 26 days). The 13-day period that derives from two CIRs per solar rotation dominates over the 26-day period in only one of the 17 cases catalogued. This interval belongs to the second half of 2008 when

expansions of Saturn's electron radiation belts were previously reported to show a similar periodicity. That observation not only links the variability of Saturn's electron belts to solar wind processes, but also indicates that the source of the observed periodicity in GCRs may be local. In this case GCR measurements can be used to provide the phase of CIRs at Saturn. The survey results also suggest that magnetospheric convection induced by solar wind disturbances associated with SEPs is a necessary driver for the formation of transient radiation belts that were observed throughout Saturn's magnetosphere on several occasions during 2005 and on day 105 of 2012. Also, an enhanced solar wind perturbation period that is connected to an SEP on day 332 of 2013 was the definite source of a strong magnetospheric compression (enhanced SKR and LFEs were also detected at this time) which led to open flux loading in the magnetotail. This event lists can a guide to better constrain or identify the arrival times of interplanetary shocks or solar wind compressions for single case studies or statistical investigations on how Saturn and its moons (particularly Titan) respond to extreme solar wind conditions or on the transport of SEPs and GCRs in the heliosphere.

OTHER AURORAL OBSERVATIONS

X-ray aurorae are detected at Jupiter, but no detection has been made at Saturn. Saturnian X-ray aurorae may be expected to be powered by charge exchange between energetic ions and the planet's atmospheric neutrals. If the ions are of solar origin, the emission should be brightest during episodes of enhanced solar wind activity. Using propagating SW parameters measured near the Earth to Saturn to estimate the timing of solar wind enhancements to reach Saturn, a number of Chandra observations were obtained in April–May 2011. Cassini in situ measurements confirm that two of the observations were carried out at the time when a significant SW disturbance reached Saturn. Variability was observed between the two Chandra datasets, but no evidence for X-ray brightening in the auroral regions were detected during this period, suggesting that the strength of any charge exchange auroral X-ray emission on Saturn was below Chandra's detectability threshold [Branduardi-Raymont et al. 2013].

Upstream Langmuir waves

Langmuir waves are often detected by Cassini in the foreshock region upstream of the Saturnian bow shock [Hospodarsky et al. 2006]. In planetary foreshocks, electrostatic Langmuir waves at frequencies close to the local plasma frequency (f_{pe}) are generated by electrons reflected from the bow shock via the beam-plasma instability. The fact that the Langmuir waves are generated near f_{pe} allows an estimate of the solar wind electron plasma density (n_e) to be determined from the frequency of the waves when they are present. This ability to estimate the density was used in a study by Bertucci et al. [2007a] to compared low frequency (<<1 Hz) waves detected by the Magnetometer instrument to similar variations observed in ne as determined from the Langmuir wave frequency. Langmuir wave derived solar wind density measurements have also been used in a number of studies investigating the bow shock shape and stand-off distance. These studies are discussed in the section entitled Bow Shock Shape and Location.

Using the RPWS Wideband Receiver measurements, Píša et al. [2015, 2016] examined the characteristics of the Langmuir waves detected upstream of Saturn. Typical Langmuir wave amplitudes observed by the RPWS at Saturn are in a range of 0.01 to 1 mV/m, with the largest amplitudes detected ~10 mV/m. The estimated energy density for the largest measured amplitudes at Saturn does not exceed the threshold for strong turbulence processes, suggesting that weak turbulence saturation processes are more important in the Langmuir wave saturation inside Saturn's foreshock. The maximum wave intensity is observed around the upstream foreshock boundary with a slight shift behind the tangent magnetic field line toward the downstream position and with a decrease in intensity along the solar wind direction deeper in the foreshock. The wave amplitude also decreases with distance along the tangent field line, but decreases more slowly compared to the dependence on the depth. This dependence shows an amplitude decrease of almost one order of magnitude over the distance of 100 R_S.

The typical Langmuir wave spectrum at Saturn exhibits a single intense peak (62% of all selected waveforms). However, spectra with a superposition of two (25%) or more (13%) intense peaks are also observed [Píša et al. 2016]. Using magnetic field observations and a model of the bow shock, plasma wave activity across Saturn's foreshock has been mapped. The single peak spectra are observed across the entire foreshock, while more complicated spectra are more likely measured deeper inside the foreshock and closer to the bow shock. A gap in wave occurrence and intensity at the tangent point delimits two foreshock regions similar to those observed at Venus and Earth. In the case of Saturn's foreshock, this gap is caused by the larger radius of curvature of the shock.

Lion Roar emissions

Electromagnetic waves with similar properties known as “lion roars” have been reported by numerous missions in the terrestrial magnetosheath.

Píša et al. [2018] presented an observation of intense electromagnetic emissions in Saturn's magnetosheath as detected by the Cassini spacecraft in the dawn sector (magnetic local time ~06:45) over a time period of 11 hours. The waves were narrow-banded in frequency with a peak frequency of about 0.16 f_{ce}, where f_{ce} is the local electron gyrofrequency. Using plane wave propagation analysis, the waves were found to be right hand circularly polarized in the spacecraft frame and propagate at small wave normal angles (<10°) with respect to the ambient magnetic field. Electromagnetic waves with similar properties known as “lion roars” have been reported by numerous missions in the terrestrial magnetosheath. These Cassini observations are the first evidence of such emission outside the terrestrial environment.

Bow shock shape and location

Studying the global shape, location, and dynamics of the bow shock offers important insights into the physics governing its formation and the magnetospheres response to solar wind dynamics. A

number of authors [Achilleos et al. 2006; Masters et al. 2008; Went et al. 2011] have used the Cassini data to develop models of the average shape of Saturn's bow shock as well as the response of this surface to changes in the dynamic pressure of the upstream solar wind. RPWS data has contributed to these studies by detecting the occurrence of bow shock crossings and by providing upstream solar wind densities from the frequency of the Langmuir waves near these crossings. The solar wind density has been used both as an in situ verification of solar wind propagation models [Hansen et al. 2005; Zieger and Hansen 2008] and to estimate the solar wind dynamic pressure.

A number of studies have investigated the properties of the bow shocks themselves at Saturn [Masters et al. 2013a, 2013b, 2017; Sulaiman et al. 2015; Sundberg et al. 2017], and the particles and regions associated with the bow shock, including hot flow anomalies [Masters et al. 2009], superthermal electrons [Masters et al. 2016], and upstream whistler mode waves [Sulaiman et al. 2017a]. The T96 Titan encounter (see the section entitled Titan Science for more details) occurred during a period of high solar wind pressure that caused Saturn's bow shock to be pushed inside Titan's orbit, exposing the moon and its ionosphere to the solar wind. Omidi et al. [2017] using electromagnetic hybrid (kinetic ions and fluid electrons) simulations and Cassini observations, showed a formation of a single deformed bow shock for the Titan-Saturn system.

Saturn Science—Lightning

The first indication of lightning in Saturn's atmosphere was obtained in November 1980 by the radio instrument on-board Voyager 1. Strong impulsive signals in the frequency range of a few MHz were detected and termed Saturn electrostatic discharges (SEDs) [Warwick et al. 1981]. The Voyager SEDs were thought to stem from an atmospheric source in the equatorial region of Saturn, and a source in Saturn's B-ring was excluded by Kaiser et al. [1983] with an argument of visibility. However, no storm clouds in the equatorial region could be identified in the Voyager images. The Cassini mission has greatly enhanced our knowledge about Saturn lightning, and combined radio and imaging observations have clearly established the atmospheric origin of the SEDs. This is discussed in the first subsection below, and the subsequent subsections will describe the occurrence of SED storms in the Cassini era, the fascinating great white spot (GWS) event of 2010/2011, the physical parameters of the SEDs, the usage of the SEDs as a tool to investigate Saturn's ionosphere, and the scarcity of lightning whistler observations. Finally, we will mention that the new discoveries by Cassini will enable limited future ground-based observations of Saturn's thunderstorm and lightning even without a spacecraft in Saturn's orbit.

New discoveries by Cassini will enable limited future ground-based observations of Saturn's thunderstorm and lightning even without a spacecraft in Saturn's orbit.

Radio and imaging observations of Saturn lightning storms

The first link between SEDs and cloud features in Saturn's atmosphere was found in 2004: Cassini Imaging Science Subsystem (ISS) imaged the so-called dragon storm, and the RPWS instrument detected SEDs at the same time [Porco et al. 2005; Fischer et al. 2006a]. These combined observations revealed consistent longitudes and longitudinal drift rates of the cloud feature and the SED source. Later, the white storm clouds were also found to be brighter when the SED rates were high [Dyudina et al. 2007; Fischer et al. 2007a]. Finally, Saturn lightning flashes were first detected optically on the nightside of Saturn around equinox, when the reflected light from the rings towards the planet (ring-shine) was minimized. The Cassini cameras spotted flash-illuminated cloud tops with a diameter of about 200 km, suggesting that the lightning comes from 125–250 km below [Dyudina et al. 2010], and most likely from the water-cloud layer. At Earth, the charging of water cloud particles in thunderstorms is most effective in a temperature range of −10° C to −25° C. At Saturn this temperature range is located at a level of 8–10 bars, about 200 km below the cloud tops, i.e., consistent with the altitude range found by Dyudina et al. [2010]. Another indication that the Saturn lightning source is in the water cloud layer comes from Cassini Visual and Infrared Mapping Spectrometer (VIMS) near-infrared spectra of the Great White Spot. They revealed spectroscopic evidence for ammonia and water ices [Sromovsky et al. 2013] brought up to higher altitudes by strong vertical convection. So it is thought that the same particle charging mechanisms are at work on Saturn and Earth. As most of the sunlight is absorbed above 2 bars, Saturn's weather and thunderstorms at deep pressure levels should be powered by the planet's internal energy [Desch et al. 2006]. It drives the vertical convection which brings up the water cloud to the visible atmospheric level where it is observed as a bright eruption by Cassini ISS and VIMS. Dyudina et al. [2010] also measured the optical flash energy to be about 10^9 J, which suggests that Saturn lightning is superbolt-like with total energies of about 10^{12} J [Fischer et al. 2011a], and not a fast and weak discharge as hypothesized by Farrell et al. [2007].

The left side of Figure RPWS-18 shows an image made by Cassini ISS of a Saturn lightning storm with two outbreaks, separated by about 25° in longitude [Fischer et al. 2018]. They are both located at the same planetocentric latitude of 35°South, a region nicknamed storm alley since many SED storms occurred there. They can be easily seen as the bright white features with a size of about 2000 km. Saturn's thunderstorms could also be imaged with the backyard telescopes of amateur astronomers as the right side of Figure RPWS-18 shows. The observations of amateur astronomers turned out to be very useful: they provided information on the location and the morphological evolution of the thunderstorms when the Cassini cameras were not looking [Fischer et al. 2011d; Mousis et al. 2014]. On the other hand, the Cassini optical instruments were able to study Saturn's thunderstorms in a very high spatial resolution [e.g., Dyudina et al. 2007; Sayanagi et al. 2013] revealing their exact sizes and dynamics. In the Cassini images, one can also see dark ovals that spew out of the stormy regions over the course of weeks [Dyudina et al. 2007] (see also Figure RPWS-18). These dark ovals show no SED activity since they are still visible for several weeks after the end of an SED storm. Baines et al. [2009] believe that their dark color originates from carbon soot particles that could have been produced by the dissociation of methane in the high-temperature lightning channels.

Figure RPWS-18. Two outbreaks of a Saturn lightning storm during the year 2008. The left image was obtained by Cassini ISS on June 18, 2008; and the right image was made by the amateur astronomer Christopher Go on May 1, 2008 (cloud features marked with white arrows).

Occurrence of SED storms

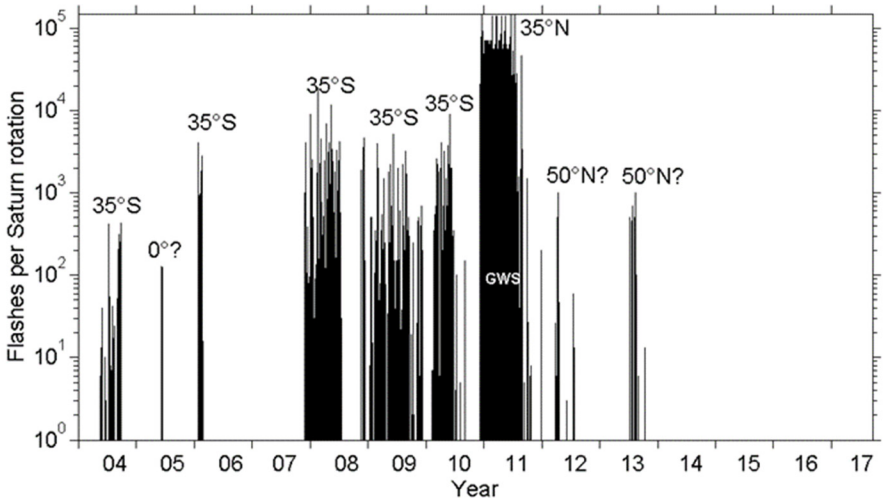

Figure RPWS-19. Number of flashes/SEDs per Saturn rotation detected by Cassini RPWS as a function of time (years from 2004 until 2017). The text in the figure denotes the planetocentric latitudes of the thunderstorms, and GWS marks the SEDs from the Great White Spot.

Figure RPWS-19 shows the number of SEDs per Saturn rotation as a function of time (year from 2004 until 2017) throughout Cassini's orbital tour around Saturn. Some bursty SED-like emissions recorded in July 2003 at a distance of 1.08 AU from Saturn [Gurnett et al. 2005] turned out to be Jovian decametric arcs [Fischer et al. 2006c]. The first SEDs were detected by Cassini RPWS in May 2004, and the last SEDs were seen in October 2013.

Figure RPWS-19 shows that Saturn lightning storms can last from a few days up to several months, and there was one storm that almost lasted throughout the year 2009. There are also long

time intervals with no SED activity, especially from February 2006 until November 2007 and during the last four years of the mission. The absence of SEDs after October 2013 could be explained by a kind of convective inhibition state of the atmosphere after the GWS of 2010/2011 [Li and Ingersoll 2015]. The flash rate during the GWS was about 1–2 orders of magnitude higher than during the other regular 2000 km-sized SED storms. For the GWS the flash rate was about 10 SEDs per second [Fischer et al. 2011c], whereas the regular storms typically have flash rates of a few SEDs per minute [Fischer et al. 2008]. Saturn's thunderstorms only raged at specific latitudes, preferentially at the so-called storm alleys around 35° South (regular storms) and 35° North (GWS). At those latitudes there are broad minima in wind speed with small westward velocities with respect to the Voyager Space Launch System (SLS). Only a few smaller storms were potentially located at different latitudes (equator or 50° N). Since Cassini RPWS could not exactly determine the locations of the thunderstorms on Saturn, a good collaboration with the Cassini imaging team and ground-based amateur astronomers was essential as pointed out in the previous subsection. Most SEDs occurred ±2 years around equinox (August 2009), and the SED storms switched from the southern hemisphere to the northern hemisphere one year after equinox, suggesting a seasonal influence [Fischer et al. 2011c].

The Great White Spot

There are two different classes of thunderstorms on Saturn [Aplin and Fischer 2017], (i) regular 2000 km-sized storms, and (ii) the rare and giant GWS that usually occur only once per Saturn year (29.5 Earth years). The previous GWS on Saturn broke out in 1990 and was located in the northern equatorial region [Sanchez-Lavega et al. 1991].

The 2010/2011 GWS was located around a planetocentric latitude of 35° N, and it reached a latitudinal extension of about 10,000 km about three weeks after it started in early December 2010 (first SEDs detected on December 5). The storm developed an elongated eastward tail with additional storm cells that wrapped around the whole planet (a distance of 300,000 km) by February 2011 [Fischer et al. 2011c]. In Figure RPWS-20, one can see an image of the GWS from March 2011. The main lightning activity took place in the so-called head of the storm (westernmost bright white clouds on the left side in the top panel of Figure RPWS-20), which drifted westward with a velocity of −27 m/s (westward motion w.r.t. Voyager SLS). The head spawned the largest anticyclonic vortex ever seen on Saturn that drifted with −8 m/s [Sayanagi et al. 2013]. The different drift velocities led to a collision between the head and the anticyclonic vortex in mid-June 2011, which caused a significant drop in SED activity. After the collision, the SED activity became intermittent and SEDs finally disappeared at the end of August 2011.

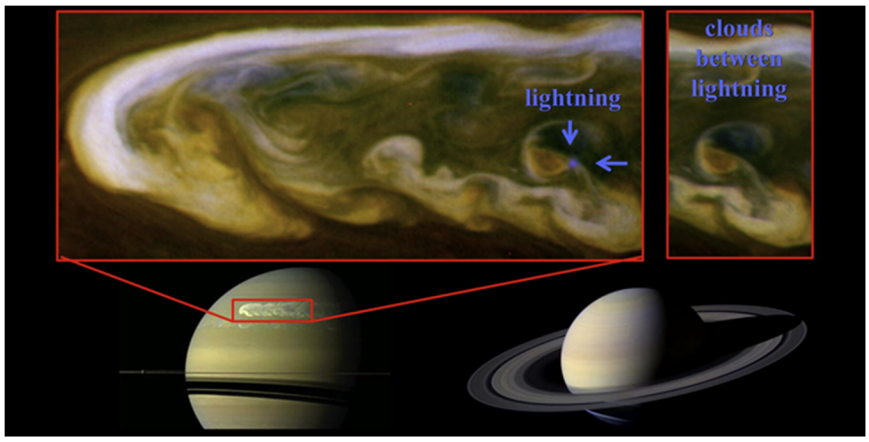

Figure RPWS-20. The upper part of this figure shows two Cassini images taken on March 6, 2011. The *left panel* shows a blue spot attributed to a lightning flash which is absent in the *right panel* image taken half an hour later. The lower part of this figure displays two Saturn images to show the large extent of the Great White Spot. Figure from Dyudina et al. [2013].

Dyudina et al. [2013] could also identify visible flashes in blue wavelengths on Saturn's dayside, which is also shown in Figure RPWS-20. The optical flashes appeared in the cyclonic gaps between anticyclonic vortices where the atmosphere looked clear down to the level of deep clouds. Dyudina et al. [2013] also estimated the optical power of the flashes to be about 10^{10} W, and the total convective power of the GWS to be of the order of 10^{17} W. Since this power is similar to Saturn's global power radiated to space, storms like the GWS should be important factors in the thermal balance of Saturn's atmosphere. Fischer et al. [2014b] suggested that the powerful storm was an intense source of gravity waves that may have caused a global change in Saturn's thermospheric winds via energy and momentum deposition. These changes might have also influenced the periodicity of SKR, which should be driven by the upper atmosphere. The GWS also caused a large stratospheric vortex with temperatures of 80 K above the normal level and an enhanced abundance of stratospheric acetylene [Fletcher et al. 2012].

Physical parameters of SEDs in comparison to Earth lightning

The radio emissions of Saturn lightning are stronger by a factor of 10^4 than the radio emissions from terrestrial lightning in the frequency range of a few MHz. Zarka et al. [2006] and Fischer et al. [2006b] found spectral radio powers of the order of 10 to 100 W/Hz, confirming previous Voyager measurements by Zarka and Pedersen [1983]. RPWS detected the first SEDs from beyond 300 Saturn radii [Fischer et al. 2006a] in May 2004. This corresponds to a staggering distance of about 3000 Earth radii compared to only 14 Earth radii, within which RPWS detected terrestrial lightning during its Earth flyby [Gurnett et al. 2001]. Similarly, the total energy of one superbolt SED is about 10^{12} J, a factor of 10^4 larger than the typical total energy of a terrestrial flash with 10^8 J. The large SED energy could be related to the fact that the breakdown voltage increases with pressure, and the SED source should be located at a pressure level of 8–10 bars. Higher breakdown fields would allow more charges to accumulate before it comes to a powerful breakdown [Fischer et al. 2008].

Similar to terrestrial intracloud lightning, an SED consists of many subpulses, and the total duration of one SED can be as long as a few hundred milliseconds. Most SEDs are somewhat shorter, and the average SED duration is around 60–70 ms [Zarka et al. 2006]. The SED duration can be well described by a distribution with an exponential decrease in SED numbers with increasing burst duration. Such distributions are characterized by a so-called e-folding time, and for SEDs this e-folding time is in the range from 35–50 ms [Fischer et al. 2007a]. The RPWS instrument had a millisecond mode with which the signal amplitude could be measured at a fixed frequency with a high temporal resolution of 1 ms. However, it turned out that this time is still too long to resolve the substructures of an SED. High temporal resolution observations were provided by ground-based SED observations (see the section entitled Ground-based Saturn lightning observations for the future), and Mylostna et al. [2013] found substructures with a duration of the order of 100 microseconds. The temporal structure of a burst should be related to its frequency spectrum. The frequency spectrum of terrestrial lightning shows a roll-off with $1/f^2$ or even steeper above 1 MHz. Zarka et al. [2006] and Fischer et al. [2006b] found a distinctly different spectrum for SEDs which is almost flat or with a slight roll-off of $1/f^{0.5}$ from 4–16 MHz. The reason for such a flat spectral behavior of SEDs is unknown.

Lightning as a tool to investigate Saturn's ionosphere

SEDs usually occur in episodes of a few hours when the thunderstorm is on the side of Saturn facing Cassini, whereas the SEDs are absent when the storm is on the backside of the planet. However, some SEDs can propagate from beyond the visible horizon due to ducted ionospheric propagation, and we call this the over-the-horizon effect [Zarka et al. 2006].

Figure RPWS-21 shows an SED episode that lasts for about six hours. The SEDs are the short vertical bursts, which appear as narrow-banded signals due to the frequency sweeping receiver, although they are intrinsically broadband. Assuming straightline SED propagation, the peak electron plasma frequency of Saturn's ionosphere can be easily determined from the low frequency cutoff denoted by the white line [Fischer et al. 2011b]. Therefore, it is necessary to know the exact location of the storm cloud, and it is indicated in Figure RPWS-21 when the storm cloud was appearing at the horizon, passing the central meridian (CM), and disappearing again. Fischer et al. [2011b] found peak electron densities of 10^4 cm^{-3} at midnight and 10^5 cm^{-3} at noon for the storms at the kronocentric latitude of 35° S. This diurnal variation of about 1 order of magnitude is still too large to be explained by ionospheric models [Moore et al. 2012]. The SED measurements are still the only technique to obtain the electron densities of Saturn's ionosphere at all local times, since radio occultation only works for local times at dawn and dusk. Figure RPWS-19 shows the different SED behavior when the storm cloud is close to the horizon: SEDs get weaker when the cloud comes near the day-side horizon due to the oblique angle of propagation leading to absorption in Saturn's ionosphere. On the other hand, SEDs were detected about one hour before the cloud reached the visible night-side horizon, and the over-the-horizon SEDs are denoted in the figure. This effect not only exists when Cassini is on the morning side, but also with Cassini on the evening side with an SED storm that disappears towards the night-side [Fischer et al. 2018]. The typical over-the-horizon effect extends 30° to 45° beyond the night-side horizon and has been modelled by ray tracing [Gautier et al. 2011].

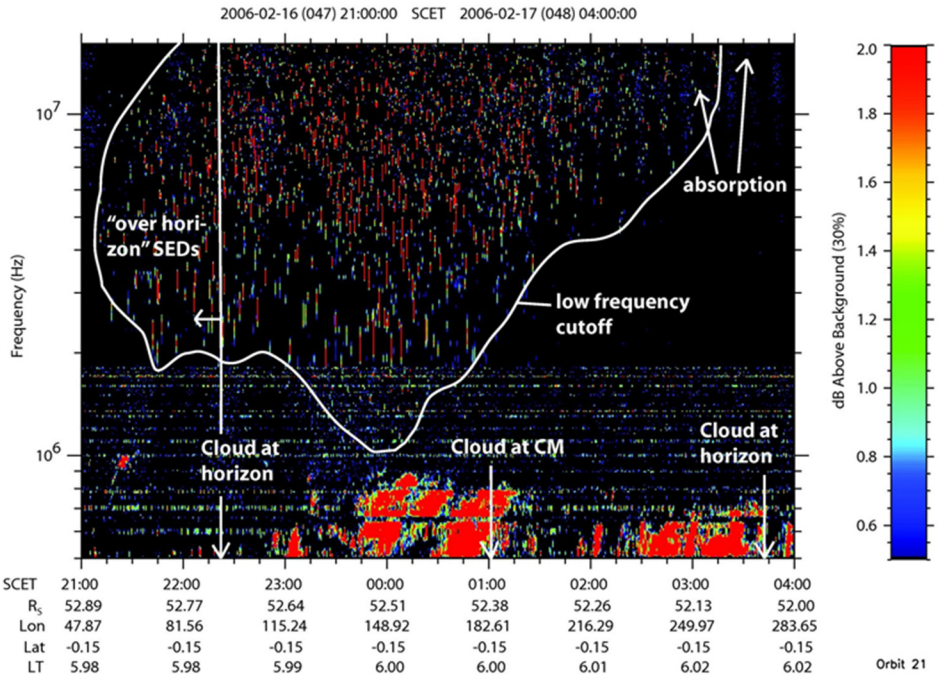

Figure RPWS-21. Dynamic spectrum (color-coded radio wave intensity as function of time and frequency) of an SED episode as measured by RPWS on February 16–17, 2006. The white line denotes the low frequency cutoff and other features are described in the text. The bottom numbers show the Spacecraft Event Time (SCET), the distance of Cassini to Saturn's center in Saturn radii, and the longitude, latitude, and local time of Cassini. Figure from Fischer et al. [2008].

The wave polarization of SEDs has been measured below 2 MHz (in the so-called quasi-static frequency range), and it is thought that it is fixed in Saturn's ionosphere. Fischer et al. [2007c] found SEDs to be highly polarized (80%) with just one sense of rotation, which was right-handed with respect to the wave propagation direction for SEDs originating from the southern hemisphere. They explained this by the dominance of the ordinary mode and the absorption of the extraordinary mode in the ionosphere. Consequently, SEDs from the northern hemisphere were found to be left-hand circularly polarized [Fischer et al. 2011c], since the magnetic field and the wave propagation vector point to the same direction in the northern hemisphere, whereas they are opposite to each other in the southern hemisphere.

Saturn lightning whistlers

Lightning is known to emit whistler waves at very low frequencies which propagate along magnetic field lines from the source to the observer. For Saturn the detection of only one lightning whistler has been reported in the literature. Akalin et al. [2006] detected one whistler signal in the frequency range of 200–400 Hz that lasted for 2 seconds. It was detected by the RPWS wideband receiver on October 28, 2004, on a magnetic field line with an L-shell value of 6.5. They concluded that the whistler originated from the northern hemisphere from a latitude of 67°, but no corresponding SED activity was seen. The scarcity of whistler observations by Cassini can be explained by Cassini's trajectory, since the stormy regions at latitudes around 35° N and S are connected to low magnetic

L-shells which were traversed by Cassini only during orbit insertion and the proximal orbits of 2017. However, an intense search for lightning whistlers led to the detection of only three tentative events during the proximal orbits. This is probably due to the absence of lightning storms in 2017 as shown in Figure RPWS-17.

Ground-based Saturn lightning observations for the future

We already mentioned that SEDs are typically 10,000 times stronger than terrestrial lightning in the frequency range of a few MHz. This has led to their first detection with an Earth-based radio telescope, which was achieved by the giant UTR-2 facility (effective area of 150,000 m²) in the Ukraine [Zakharenko et al. 2012; Konovalenko et al. 2013]. At Earth, the SEDs have a radio flux of a few hundred Jansky (1 Jy = 10^{-26} W/m²/Hz), and the sensitivity of UTR-2 is a few Jansky. The new discoveries about Saturn's thunderstorm by Cassini will enable some limited future observations of Saturn's lightning and thunderstorms even without a spacecraft in Saturn's orbit. During the times of Saturn apparition we should be able to identify thunderstorms in Saturn's atmosphere with a high confidence from the images of the ground-based amateurs, since we now know what they should look like. Saturn can be well-observed from Earth for roughly 6–9 months per year, and a confirmation of a storm's SED activity is now possible with large Earth-based radio telescopes. It is interesting to know when the next SED storm will take place after the long inactivity of more than four years at the end of the Cassini mission.

Search for Titan lightning

The existence of lightning on Saturn's enigmatic moon Titan has been suggested soon after the Voyager 1 flyby in 1980, although no corresponding radio emissions were detected by Voyager [Desch and Kaiser 1990]. The potential effects of lightning on Titan's atmospheric chemistry have been widely investigated up to the production of organic compounds that could be essential precursors for the evolution of life [Plankensteiner et al. 2007]. Furthermore, the Cassini cameras observed convective cloud activity in Titan's atmosphere. However, no radio bursts that would clearly indicate the existence of Titan lightning were found by RPWS during the numerous flybys [Fischer et al. 2007b; Fischer and Gurnett 2011]. Hence, Titan lightning is a very rare event if it exists at all.

Saturn Science—Ionosphere

The ionosphere of Saturn is still a work in progress, and the first in situ measurements by RPWS of the cold ionosphere properties have just been reported [Wahlund et al. 2018]. Several other manuscripts have been submitted, and they all show a very strong interaction between the D-ring and the ionosphere of Saturn, causing the ionosphere to become extremely variable with more than two orders of magnitude and trigger a dust-ionosphere layer near the equator.

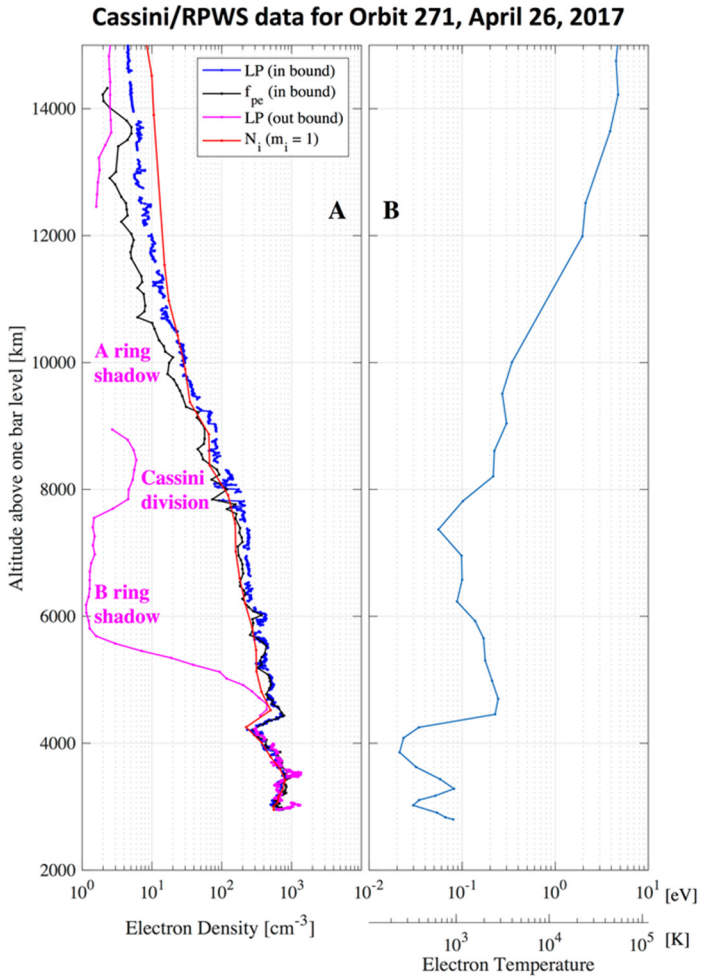

Figure RPWS-20. Cassini/RPWS altitude profiles of the ionosphere number density (*Panel A*) and inbound electron temperature (*Panel B*) during the crossing on April 26, 2017. Two independent methods for estimating the inbound electron density (blue and black) gave almost identical results, confirming their validity. The Langmuir probe ion density (N_i, assuming H^+) also produces values in agreement with the estimated electron densities, confirming that hydrogen ions dominated during this first flyby. The lower LP electron densities over the outbound sector (magenta) indicate that much of the A- and B-rings are opaque to ionizing extreme ultraviolet radiation.

Sulaiman et al. [2017c] reported the first observations of lower hybrid resonance waves in Saturn's ionosphere. They are believed to be generated through the interaction of whistler-mode waves and density gradients present in the ionosphere.

Plasma Waves

The almost 300 orbits by Cassini have allowed the RPWS to study a variety of plasma and radio waves in the magnetosphere of Saturn. See Gurnett et al. [2005]; Mauk et al. [2009]; Kurth et al. [2009]; Hospodarsky et al. [2012, 2016] for overviews of the Saturn magnetosphere and some of the wave observations.

In the inner magnetosphere (<10 R_S), whistler mode chorus [Hospodarsky et al. 2008; Menietti et al. 2013a, 2013b, 2014a, 2014b], quasi-periodic (QP) whistler mode emissions [Hospodarsky et al. 2012], electron cyclotron harmonic (ECH) emissions [Menietti et al. 2008a, 2008b, 2012; Tao et al. 2010], and upper hybrid resonance (UHR) emissions [Persoon et al. 2005, 2006a, 2006b, 2009, 2013, 2015] are observed. At higher magnetic latitudes (> ~25°), auroral hiss is detected [Mitchell et al. 2009a; Gurnett et al. 2009b; Kopf et al. 2010]. RPWS observations of ion cyclotron waves have also been made in the Saturn downward auroral current region. Menietti et al. [2011c] showed that these waves can be generated by the observed upward electron beams and modeling suggested that they can produce significant ion heating as has been observed in the terrestrial auroral region.

Evidence of lightning in Saturn's atmosphere is shown from observations of lightning whistlers [Akalin et al. 2006] and from observations of Saturn Electrostatic Discharges (SEDs) (see the section entitled Saturn Science—Lightning for detailed discussion of the lightning observations). A number of radio emissions are also observed, including Z- and O-mode narrowband emissions [Louarn et al. 2007; Ye et al. 2009, 2010a, 2011; Menietti et al. 2009, 2010b, 2012; Wang et al. 2010], and SKR [Kurth et al. 2005a, 2005b, 2011; Cecconi et al. 2006; Lamy et al. 2008a, 2010a; Fischer et al. 2009; Mutel et al. 2010; Menietti et al. 2011b]. Plasma waves have also been detected in association with many of the Saturnian moons, including Enceladus [Tokar et al. 2006; Gurnett et al. 2011a; Leisner et al. 2013; Pickett et al. 2015] and Rhea [Santolik et al. 2011]. The RPWS instrument also detects dust impacts on the Cassini spacecraft, providing information on the properties of dust [Kurth et al. 2006b; Wang et al. 2006; Ye et al. 2014a] and sometimes information on the electron density [Ye et al. 2014b] (see the section entitled Dust and Dusty Ring Science for a more detailed discussion of the RPWS dust results].

Whistler mode chorus emissions

Whistler mode emissions are often observed in Saturn's inner magnetosphere with many characteristics similar to chorus detected at Earth and Jupiter. Due to these similar characteristics, the majority of the literature on these emissions has called the whistler mode emission chorus even though some of the emissions lack discrete elements or fine structure [Hospodarsky et al. 2008; Menietti et al. 2013b, 2014a]. Hospodarsky et al. [2008] performed an initial survey of these emissions and characterized them into two types based on their spectral characteristics and where they were observed. The most common type was defined as magnetospheric chorus that was observed within ~30 degrees of the magnetic equator between L shells of about 4.5 to 10. This emission usually has a bandwidth of a few hundred Hz and is detected below 1/2 f_{ce} as Cassini crosses through the inner magnetosphere. A variety of fine structure is associated with the chorus, from a structureless, hiss-like emission to narrowband frequency tones rising in frequency. The rising tone structure is similar to structures associated with chorus detected at Earth and Jupiter, but the timescales of the structure detected at Saturn are usually longer than those observed at Earth or Jupiter [Hospodarsky et al. 2008].

There is a subset of the magnetospheric chorus that have rising tones with periods on the order of many minutes. These emissions have been referred to as rising whistler mode emission, QP whistler emission, or sometimes as worms. They are observed about 5% of the time when Cassini is near the magnetic equator within 5.5 R_S of Saturn, and appear to be related to electrons with energies of a few keV. The cause of the many-minute periodicity is not well understood [Hospodarsky et al. 2016]. Although Hospodarsky et al. [2008] included these many-minute period rising tone whistler mode emissions with the magnetospheric chorus emissions, their spectral characteristics are more similar to the QP whistler mode emissions detected at Earth. However, it is currently unclear if the same type of source generation can explain the Earth and Saturn QP emissions.

The second type of whistler mode chorus emission reported by Hospodarsky et al. [2008] is detected in association with local plasma injections and were defined as injection event chorus. Local plasma injection events are injections of hot, less dense plasma produced by the interchange instability in rapidly rotating magnetospheres such as Saturn. These injections flow towards the planet while the colder and denser plasma from the inner magnetosphere flows outward [Mauk et al. 2009; Rymer et al. 2009; Mitchell et al. 2009b; Paranicas et al. 2016]. Young injection events are usually easy to detect with RPWS due to the changes in the spectral properties of the plasma waves associated with the injection compared to the waves detected outside of the events [Menietti et al. 2008a, 2008b; Hospodarsky et al. 2008; Kennelly et al. 2013]. Specifically, the frequency of the UHR usually decreases due to the lower electron plasma density inside of the injection and the ECH and chorus emissions are enhanced. Injection event chorus is often observed in two bands located above and below 1/2 f_{ce}, with a gap in the emission intensity at 1/2 f_{ce}, very similar to chorus detected at the Earth. The injection event chorus often contains fine structure (primarily rising tones) at a much smaller timescale (less than a second to a few seconds) than the magnetospheric chorus, again more similar to chorus at Earth and Jupiter [Hospodarsky et al. 2008]. Menietti et al. [2008a] showed that the chorus emissions observed inside the injection region can be at least partially generated by the measured temperature anisotropies in the electron population.

The occurrence, intensity, local time, and latitude variations of both types of chorus emission at Saturn have been examined by Hospodarsky et al. [2008, 2012] and in a series of papers by Menietti et al. [2012, 2013b, 2014a, 2014b]. These studies found that the peak in chorus intensity is detected at about ±5 degrees in magnetic latitude, with the intensity decreasing at the magnetic equator. The emissions are observed at all LT, but display maximum intensity on the nightside between L of 4.5 to 7. The small scale fine structure is more likely to be observed at higher frequencies and at latitudes greater than ~5°. The injection event chorus was typically found to be more intense than the chorus outside of the injection events [Menietti et al. 2014a], and the amplitude and structure of the rising tones was found to reasonably match predictions from non-linear theories of chorus generation [Menietti et al. 2013a]. Calculations of the wave normal and Poynting vector using the WFR data show that the chorus emissions propagate away from the magnetic equator at Saturn—see Figure 7 of Hospodarsky et al. [2008]—similar to results obtained for chorus at Earth.

Intense whistler mode waves were also detected in the magnetic flux tube connected to the surface of the Saturnian moon Rhea during a close flyby on March 2, 2010 [Santolik et al. 2011]. The whistler mode emission was observed below 1/2 f_{ce}, had peak amplitudes >0.5 nT, and was found to be propagating toward Rhea. Santolik et al. [2011] showed that these waves could be generated by the loss-cone anisotropy caused by absorption of electrons by the surface of the moon. Strong, bursty electrostatic waves near the electron plasma frequency and broadband electrostatic waves at frequencies well below the ion plasma frequency were also detected during this flyby. The waves near the electron plasma frequency have many of the characteristics of Langmuir waves observed in the solar wind and are believed to be produced by a low energy (~35 eV) electron beam propagating away from Rhea. The low-frequency waves may be related to the higher frequency waves through a nonlinear three-wave interaction.

Whistler mode auroral hiss emission

Auroral hiss is produced by electron beams and, when plotted on a time-frequency spectrogram, usually exhibits a funnel shaped spectrum.

Cassini also observes at magnetic latitudes greater than about 25° at Saturn a whistler mode emission that has many of the characteristics of auroral hiss [Mitchell et al. 2009a; Gurnett et al. 2009b; Kopf et al. 2010]. Auroral hiss is produced by electron beams and, when plotted on a time-frequency spectrogram, usually exhibits a funnel shaped spectrum. Auroral hiss has only been detected by Cassini propagating away from the auroral zone of Saturn and the emission is often observed out to distances of many tens of Saturn radii (R_S). Before 2008, the emission often exhibited a modulation in its intensity with a period of about 10.6 hours in the northern hemisphere and about 10.8 hours in the southern hemisphere, very similar to the periods of the SKR emission [Gurnett et al. 2009a, 2009b]. Shorter scale periodicity on the order of one hour is also often detected, and these short scale structures are often correlated with ion conics [Mitchell et al. 2009a, 2016; Palmaerts et al. 2016]. Kopf et al. [2010] analyzed electron beams detected by the CAPS during a Cassini high latitude pass and found that the detected beams coincided with observations of auroral hiss emissions. Examination of the predicted emission growth rate demonstrated that each of the measured beams possessed large whistler-mode growth rates, sufficient to produce the observed emission intensities.

Similar auroral hiss-like emissions have also been detected near Saturn's B-ring during the SOI period [Xin et al. 2006], and near the Saturnian moon Enceladus [Gurnett et al. 2011a]. Using ray tracing and the observed spectral funnel characteristics of the emission observed on seven different Enceladus flybys, Leisner et al. [2013] found two possible source regions near the moon, the quadrant upstream of the Saturnward flow terminator and the quadrant downstream of the anti-Saturnward flow terminator. The result of similar source regions for multiple flybys separated by over five years suggests that the electron beam acceleration near the moon is a quasi-time-stationary feature of the plasma interaction.

Electrostatic ECH and UHR emissions

Electrostatic emissions detected in Saturn's inner magnetosphere include ECH and UHR emissions. ECH emissions usually occur in frequency bands at $(n + 1/2)f_{ce}$, where n is an integer. Just like the chorus emissions discussed earlier, the ECH emissions are observed on most orbits when Cassini crosses the inner magnetosphere [Menietti et al. 2017]. The ECH waves also exhibit very different spectral characteristics inside and outside of injection events. ECH emissions observed outside of injection events are primarily found in the first harmonic band centered at ~1.5 f_{ce}, with higher harmonic bands being weaker and more sporadic. Inside of injection events the ECH emissions usually increase in both intensity and the number of harmonic bands present. A number of studies have attempted to explain the characteristics of the ECH waves using the electron plasma distributions measured by CAPS [Rymer et al. 2009] both outside [Menietti et al. 2008b] and inside [Menietti et al. 2008a; Tao et al. 2010] of an injection event. Menietti et al. [2008a, 2008b] found that phase space distributions with an assumed narrow, empty loss cone of the lower energy (< 100 eV) electron populations both inside and outside the injection event could generate the observed ECH emissions. However, Tao et al. [2010] found that inside the injection events, assuming a non-empty loss cone for electrons with energy near a few hundred eV and a few keV (higher than those predicted by Menietti et al. [2008b] could produce ECH waves with the observed harmonic structure. The precise ECH wave gain in the Tao et al. [2010] and Menietti et al. [2008b] models is very sensitive to the electron distribution used, which for this event is not measured at the smallest pitch angles. These uncertainties in modeling the actual cold electron components may explain the differences in these studies.

The UHR emissions are detected on most orbits in the inner magnetosphere [Moncuquet et al. 2005; Schippers et al. 2013] and during close flybys of Saturn's moons—for example, Farrell et al. [2009], especially Titan [e.g., Modolo et al. 2007a]. Because the frequency of the UHR emissions (fuhr) is related to the electron plasma frequency (f_{pe}) by $f_{uhr}^2 = f_{pe}^2 + f_{ce}^2$, determining f_{uhr} and obtaining f_{ce} from the magnetic field strength provides the electron plasma density (n_e) from $f_{pe} = 8980\ n_e^{1/2}$. By measuring f_{uhr} for each pass through the inner magnetosphere, Persoon et al. [2009, 2013] have developed an empirical plasma density model for the Saturnian system.

Open Questions for Saturn System Science

Any mission, however extended, always raises questions based on the new knowledge gained. Here we give a brief list of open questions for radio and plasma wave science at Saturn, after Cassini.

- What is the rotation period of Saturn? How do the multiple, variable magnetospheric periods observed in radio, magnetic fields, energetic particles, plasma, aurora, and other phenomena tie to the internally-generated magnetic field at Saturn?
- Given the extraordinarily axi-symmetric magnetic field, why are there such prominent rotational modulations in Saturn's magnetosphere?

- What drives the episodic lightning on Saturn; why is there ~one Great White Spot storm per Saturnian year?
- How does the dust in the Saturnian system interact with Saturn and its atmosphere? How are the rings coupled to the planet other than through gravity?
- What is the predominant form of the electron distribution function at the source of SKR?
- How does the abundant neutral population in Saturn's magnetosphere make it different from fully or mostly ionized magnetospheres?
- What are the various populations of charged dust and molecules that balance charges in dusty media such as in the plumes of Enceladus and in Saturn's topside equatorial ionosphere?

RPWS Non-Saturn Science Results

Cruise Science

The bulk of science carried out in the cruise phase by the RPWS was at planetary targets as detailed in the following sections, although there were considerable efforts employed during cruise to check out the instrument and exercise and improve various observing modes planned for use at Saturn. However, Schippers et al. [2014, 2015] reported nanograins in the solar wind detected by the RPWS and Meyer-Vernet et al. [2009], reported nanograins originating from Jupiter's moons.

Venus

During two Cassini very close gravity-assist flybys of Venus, the first on April 26, 1998, and the second on June 24, 1999, the RPWS instrument conducted a search for high-frequency (0.125 to 16 MHz) radio impulses from Venus lightning. Despite the excellent sensitivity of the high-frequency RPWS receiver (down to the cosmic background), no impulses were detected [Gurnett et al. 2001]. During a subsequent close gravity-assist flyby of Earth on August 18, 1999, radio signals from lightning were observed essentially continuously at all radial distances inside of about 14 Earth radii, with maximum occurrence rates up to about 30 pulses per minute. If Venus lightning exists then it must be much weaker and at much lower frequencies than terrestrial lightning.

Earth

Cassini executed a flyby of Earth on August 18, 1999, in order to gain sufficient energy to get to Saturn. However, the flyby also offered an opportunity to understand how some of the instruments, including RPWS, perform in a planetary magnetosphere nearly five years prior to arrival at Saturn [Kurth et al. 2001b]. The Earth flyby provided the opportunity to test a number of observation modes and capabilities to determine their efficacy in time to make adjustments prior to the prime mission.

In addition, the flyby provided a swift flyby of Earth that allowed a unique set of observations of terrestrial magnetospheric radio and plasma wave phenomena.

Figure RPWS-21 shows an overview of the RPWS observations during the Earth flyby. The trajectory brings Cassini into the magnetosphere just past noon local time and carries it down the magnetotail in the post-midnight sector. Closest approach to Earth was just under 1200 km. As one would expect, the RPWS observed broadband electrostatic waves at the bow shock, electron cyclotron harmonics and whistler mode chorus in the outer radiation belts and emissions between the plasma frequency and upper hybrid frequency in the ionosphere. Evidence for electron phase space holes was found in the near-Earth plasma sheet. At higher frequencies auroral kilometric radiation was observed on the night side indicating a series of auroral substorms and fixed frequency narrowband lines from man-made terrestrial radio stations were observed. Even Jovian hectometric radiation was observed from a position far downstream from Earth.

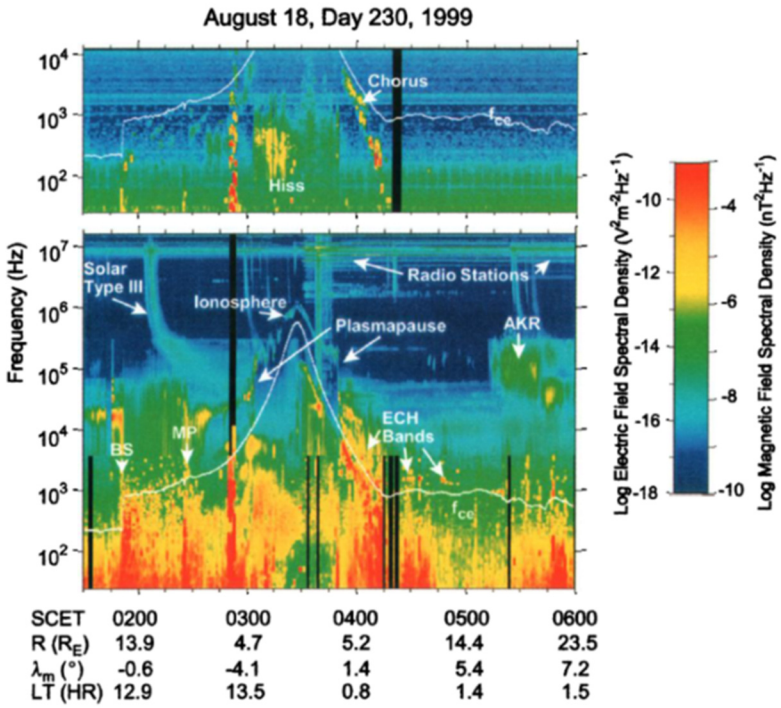

Figure RPWS-21. An overview of RPWS observations of the Earth flyby with magnetic fields shown in the *Top panel* and electric fields below. The white trace is the electron cyclotron frequency fce derived from |*B*|. *BS* refers to the bow shock, *MP* refers to the magnetopause, *ECH* refers to electron cyclotron harmonics, and *AKR* refers to auroral kilometric radiation.

Using a number of techniques, the plasma density was measured. The electron plasma frequency and upper hybrid resonance frequency are characteristic frequencies of the plasma dependent on the electron density. RPWS also includes a Langmuir probe that can determine the electron density and temperature. Finally, a relaxation sounder was used to stimulate the plasma frequency.

Wideband waveform measurements were used in various regions of the magnetosphere to acquire examples of chorus and ECH bands. These are also necessary to identify solitary-like structures associated with electron phase space holes.

Another feature of the RPWS instrument that was tested during the Earth flyby was the capability of determining the wave normal angle of whistler mode waves using 5-channel WFR measurements of three magnetic and two electric sensors. Hospodarsky et al. [2001b] used the WFR measurements to examine the propagation characteristics of a lightning whistler, chorus, and electromagnetic emissions in the magnetosheath, presumably lion roars.

Hospodarsky et al. [2001b] determined that the whistler analyzed was also detected at Palmer Station in Antarctica. The chorus waves were observed near the magnetic equator and appeared to reverse their direction of propagation at the equator, consistently propagating away from the equator where it is assumed the chorus source is located. The lion roars were found to consistently propagate nearly along the magnetic field but varied from burst to burst with some propagating near parallel and others near antiparallel to the field, suggesting multiple sources.

As mentioned above, Cassini detected intense, fixed frequency emissions at close range to Earth in the frequency range above about 1 MHz that are attributed to man-made radio transmissions. Fischer and Rucker [2006] studied the occurrence of these in detail and demonstrated that most of the emissions could be identified with shortwave radio bands. A few brief detections of scientific transmitters including the High-frequency Active Auroral Research Program (HAARP) and the Russian SURA station—see also Tokarev et al. [2006]. Fischer and Rucker point out an interesting quiet period when Cassini was near closest approach over the Pacific Ocean where a combination of the rarity of transmitters in this location and ionospheric propagation characteristics effectively shielded Cassini from the radio transmission for a period of about 20 minutes.

Jupiter

Cassini flew by Jupiter on December 30, 2000, on its way to Saturn. Arriving from the pre-noon sector, closest approach occurred in the afternoon sector at 138 Jovian radii ($\sim 10^7$ km) from the planet, and was followed by an exploration of the dusk flank of the Jovian magnetosphere. In spite of the large distance of the flyby, several Cassini- Magnetospheres and Plasma Science (MAPS) instruments including RPWS recorded high-quality data for about 6 months around closest approach. These observations benefited from the simultaneous presence of Galileo in orbit around Jupiter, enabling two-point measurements, and were complemented by remote observations by HST, Chandra, and ground-based radio observations (e.g., with the Nançay decameter array, France). This resulted in a very rich data set that was the basis of many publications and will be further exploited in the coming years.

The distant observations were well adapted to the study of the complex zoo of Jupiter's magnetospheric radio emissions, nicely covered by the Kronos receiver of RPWS, an example of which is given in Figure RPWS-22. An early overview is given in [Lecacheux 2001]. The intensity

spectrum of all Jovian radio components was accurately measured [Zarka et al. 2004a] through calibration on the Galactic background and Nançay observations, demonstrating in particular the absence of peak at 10 MHz in the decameter spectrum. The beaming of the decametric (DAM) and hectometric (HOM) components (a widely opened hollow cone of a few degrees thickness) were measured via two point Cassini-Wind measurements [Kaiser et al. 2000] as well as frequency-longitude statistics and modelling [Imai et al. 2008, 2011a, 2011b]. The HOM low-frequency cutoff measured by Ulysses and Cassini provided constraints of its source location, in the outer regions of the Io plasma torus [Zarka et al. 2001a].

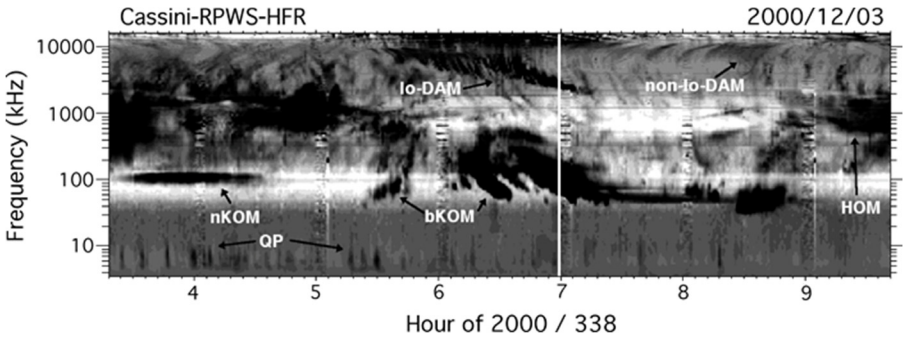

Figure RPWS-22. Jovian low-frequency radio emissions detected on December 3, 2000, by the RPWS experiment onboard Cassini approaching Jupiter. Frequency range is 3.5 kHz to 16.1 MHz. The Io-induced decameter emission (Io-DAM) appears here down to about 2 MHz, while weaker Io-independent (non-Io-DAM) arcs merge with the HOM component detected down to ~400 kHz. The auroral broadband kilometer (bKOM) component is detected down to ~40 kHz. The narrowband emission (nKOM) about 100 kHz is generated at or near the plasma frequency f_{pe} in Io's torus. The QP bursts, spaced by 5 to > 15 min, are detected in the ~5 to 20 kHz range. Distance to Jupiter was 383 R_J (2.7×10^7 km) at the time of this observation.

The six month series of continuous homogeneous measurements provided unique measurements of time variations of the radio emission. Burst of auroral (non-Io) DAM emission were found to reoccur at a period slightly longer than the system III rotation period [Panchenko et al. 2010, 2013; Panchenko and Rucker 2011]. Gurnett et al. [2002] found from Cassini and Galileo observations that Jupiter's auroral radio and UV emissions were triggered by interplanetary shocks inducing magnetospheric compressions, in disagreement with theoretical predictions [Southwood and Kivelson 2001]. Hess et al. [2014] reconciled these views by a finer analysis of dawn and dusk radio emissions seen by Cassini, Galileo and Nançay, only dusk emissions being driven by both compressions and dilatations of the magnetosphere. They also used radio observations to deduce the subcorotation velocity of the magnetospheric plasma. Clarke et al. [2009] compared the effect of solar wind compressions on radio and UV aurora at Jupiter and Saturn, and found a weaker effect at Jupiter. Radio (non-Io-DAM, HOM, and bKOM) and UV comparisons are used quite systematically in the study of Jupiter's aurora [Clarke et al. 2004, 2005; Pryor et al. 2005]. Comparison of Galileo/Jupiter and Cassini/Saturn observations also revealed similar energetic events where auroral radio intensifications are related to centrifugal plasma ejections, from the Io torus at Jupiter and from the equatorial plasma sheet at Saturn [Louarn et al. 2007].

Cassini, Galileo, and Voyager radio observations were used to try to demonstrate the influence of satellites other than Io on DAM emissions. Marginal results were obtained statistically [Hospodarsky et al. 2001a], whereas clear evidence was obtained for Europa and Ganymede by comparison of observations with modelled dynamic spectra [Louis et al. 2017a]. The ExPRES simulation tool developed in Meudon [Hess et al. 2008] and the experienced gained with Cassini on Jupiter's radio emissions were used to build simulations preparing the re-exploration of the Jovian magnetosphere by the electrostatic energy analyzer (ESA) Juice mission [Cecconi et al. 2012].

Fast recording modes of RPWS (spectral and waveform) allowed us to characterize the fine structure of Jovian radio emissions in the kilometer (bKOM) to decameter range [Kurth et al. 2001a; Lecacheux et al. 2001], including zebra-like patterns in the bKOM emission. Those were tentatively interpreted by bubble-like plasma inhomogeneities [Farrell et al. 2004] or the double plasma resonance mechanism involving ion cyclotron waves [Zlotnik et al. 2016]. Similar patterns have been observed at decameter wavelengths [Panchenko et al. 2016, 2018].

At the very low-frequency end of the radio spectrum (below a few 10s of kHz), Cassini together with Ulysses and Galileo characterized the Jovian Quasi-Periodic bursts [Kaiser et al. 2001, 2004], stereoscopic observations demonstrated their strobe-like behavior and wide beaming [Hospodarsky et al. 2004], and direction-finding techniques localized their sources at high latitude regions of the magnetopause, implying complex propagation [Hospodarsky et al. 2004; Kimura et al. 2012]. QP bursts were tentatively related to the so-called Jovian anomalous continuum radiation [Ye et al. 2012]. Propagation of radio waves near the edges of the Io plasma torus were shown to generate the HOM attenuation lane, an intensity gap oscillating between ~1 and ~3 MHz, described by Boudjada et al. [2011] and modelled by Menietti et al. [2003] and Imai et al. [2015]. Occultations of Jovian radio emissions were used to probe the Io plasma torus [Boudjada et al. 2014a].

Analysis of local low-frequency plasma waves recorded by RPWS was used to study the Jovian dust flank magnetopause and bow shock [Kurth et al. 2002; Szego et al. 2003], magnetosheath [Bebesi et al. 2010, 2011] and pre-shock [Szego et al. 2006]. The magnetopause was found to be in the process of being compressed by a solar wind pressure increase at the time of the Cassini flyby [Kurth et al. 2002]. Langmuir waves were detected upstream of the bow shock, and their level compared with that at other planets: the ratio of the energy density of the waves electric field to the plasma was found to increase with distance from the Sun [Hospodarsky et al. 2006].

Z-mode radiation and electron cyclotron harmonics (at low latitudes) and whistler-mode chorus (at higher latitudes) were measured [Menietti et al. 2012, 2016a] and their effect on electron acceleration was evaluated [de Soria-Santacruz et al. 2017]. RPWS spectral and waveform measurements also permitted to detect nanodust particles in the interplanetary medium, of likely Jovian origin [Meyer-Vernet et al. 2009; Schippers et al. 2014, 2015].

Observations of Jupiter radio emissions were used to calibrate the Direction-Finding (actually Gonio-Polarimetric) capability of RPWS/Kronos [Vogl et al. 2001, 2004], which proved extremely successful at Saturn. Early use of this directional capability permitted to check the origin of lightning-like signals observed in Cassini's inbound leg to Saturn, which proved to be Jovian radio bursts [Fischer et al. 2006c].

Overall, the Cassini RPWS experiment was very successful at Jupiter. The obtained results were reported in several review papers about comparisons of radio waves [Zarka 2000, 2004; Zarka and Kurth 2005; de Pater and Kurth 2007; Rucker et al. 2014] and plasma waves [Hospodarsky et al. 2012] at the magnetized planets, as well as in reviews about auroras [Badman et al. 2014], magnetospheric processes [Blanc et al. 2002; Seki et al. 2015], or dust detection [Meyer-Vernet et al. 2017]. They greatly helped to prepare the magnetospheric measurements of the Juno mission in Jovian polar orbit [Bagenal et al. 2017]. Two PhD theses were largely based on Cassini RPWS measurements at Jupiter [Cecconi 2004; Imai 2016].

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

A/D	analog-to-digital converter
AKR	auroral kilometric radiation
AO	Announcement of Opportunity
AU	astronomical unit
bKOM	broadband kilometer
CA	closest approach
CAPS	Cassini Plasma Science
CDA	Cosmic Dust Analyzer
CIR	corotating interaction region
CM	central meridian
CMI	cyclotron maser instability
DAM	decametric
DOY	day of year
ECH	electron cyclotron harmonic
ELS	electron spectrometer
ENA	energetic neutral atom
ESA	electrostatic energy analyzer
EUV	extreme ultraviolet
FUV	far ultraviolet
FWHM	full width at half-maximum
GCR	galactic cosmic ray
GWS	great white spot
HAARP	High-frequency Active Auroral Research Program
HFR	high frequency receiver
HGA	high gain antenna
HOM	hectometric
HRD	high-rate detector
HST	Hubble Space Telescope
ICME	interplanetary coronal mass ejection
IMF	interplanetary magnetic field
IMS	ion mass spectrometer
INCA	Ion and Neutral Camera
IR	infrared
ISS	Imaging Science Subsystem
LEMMS	Low-Energy Magnetospheric Measurement System
LFR	low frequency receiver
LP	Langmuir probe

LPT	Linear Prediction Theory
LT	local time
MAPS	Magnetospheres and Plasma Science
MFR	medium frequency receiver
MHD	magneto-hydrodynamic
MIMI	Magnetospheric Imaging Instrument
NB	narrowbanded
nKOM	narrowband kilometer
PPO	planetary period oscillation
PRA	Planetary Radio Astronomy
QP	quasi-periodic
RH	right-handed
RPC	ring plasma cavity
RPWS	Radio and Plasma Wave Science
RS	Saturn radii
SCET	spacecraft event time
SED	Saturn electrostatic discharges
SEP	solar energetic particle
SKR	Saturn kilometric radiation
SLS	Space Launch System
SOI	Saturn orbit insertion
TM	Traceability Matrix
UHR	upper hybrid resonance
UT	universal time
UV	ultraviolet
UVIS	Ultraviolet Imaging Spectrograph
VIMS	Visual and Infrared Mapping Spectrometer
WBR	wideband receiver
WFR	waveform receiver

REFERENCES

Disclaimer: The partial list of references below correspond with in-text references indicated in this report. For all other Cassini references, refer to Attachment B – References & Bibliographies; Attachment C – Cassini Science Bibliographies; the sections entitled References contributed by individual Cassini instrument and discipline teams located in Volume 1 Sections 3.1 and 3.2 Science Results; and other resources outside of the Cassini Final Mission Report.

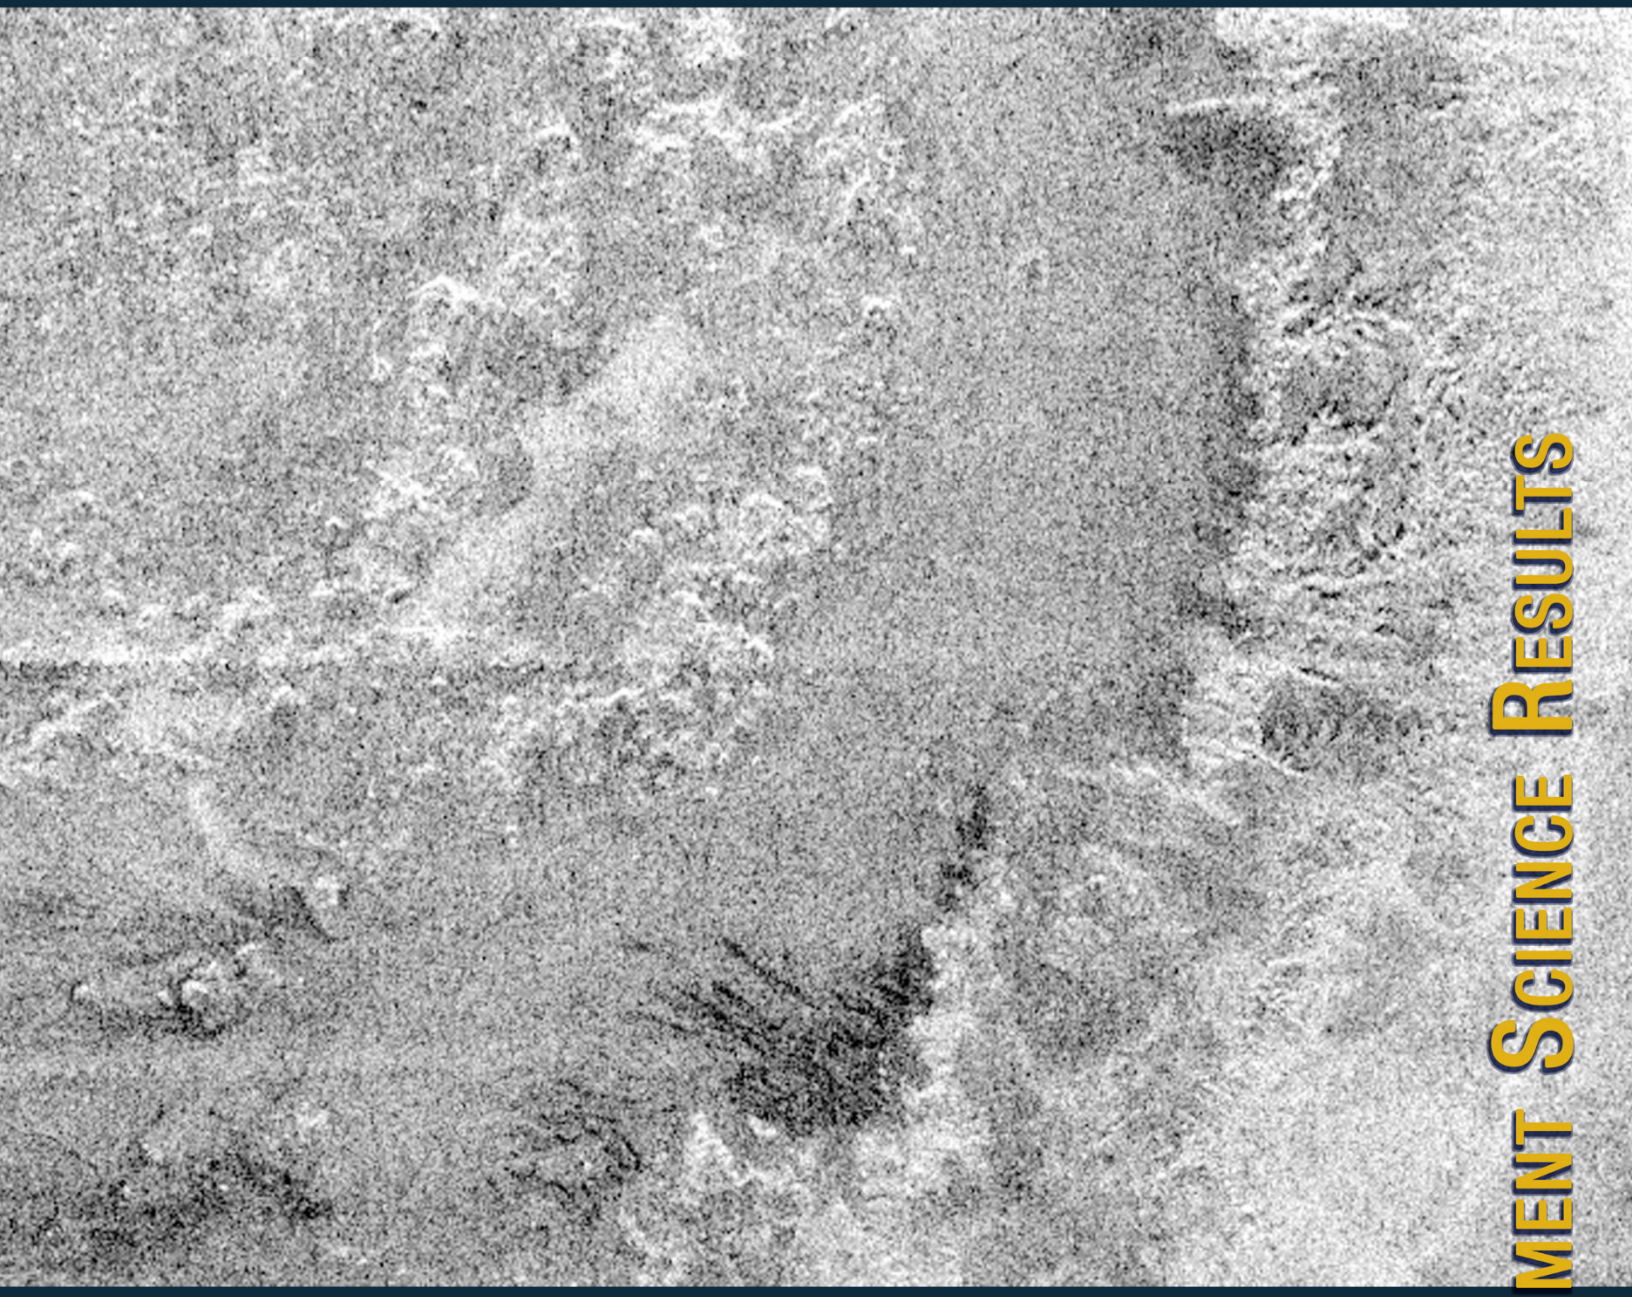
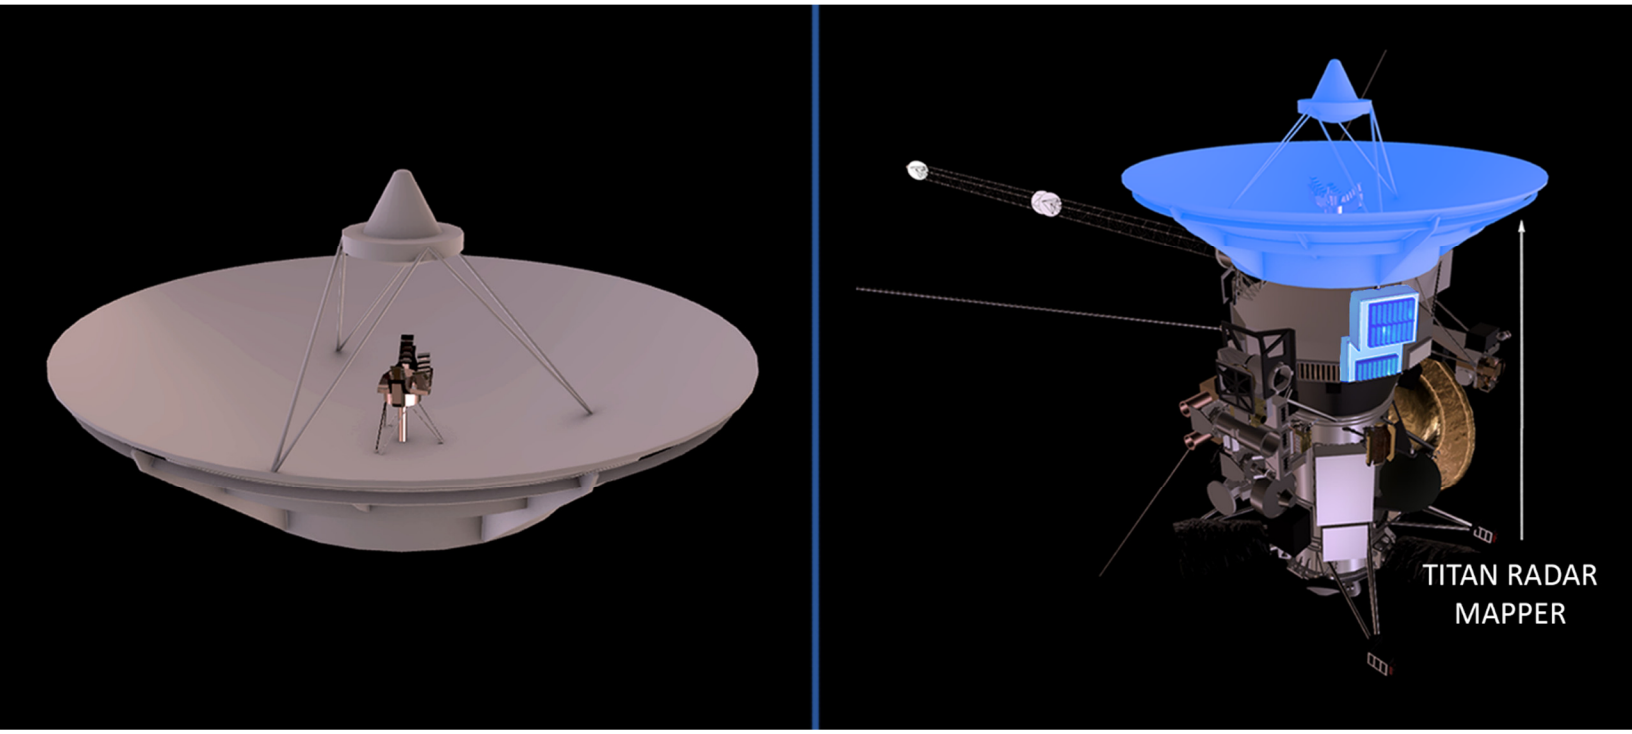
Microwave Remote Sensing Instruments



– Titan Radar Mapper (RADAR)

– Radio Science Subsystem (RSS)

INSTRUMENT SCIENCE RESULTS



TITAN RADAR MAPPER

The Titan Radar Mapper (RADAR) Instrument investigated Saturn, its rings and moons, but it was primarily built to study Saturn's moon Titan, which has a thick atmosphere that hides its surface. The **science objectives** of RADAR were to perform Synthetic Aperture Radar (SAR) imaging, altimetry, scatterometry, and radiometry of Titan's surface to determine the distribution of lakes and seas, investigate the geologic features and topography of the solid surface of Titan, and acquire data on non-Titan targets (Saturn, rings, icy satellites). RADAR bounced radio waves at microwave frequencies off Titan's surface, and created images of the surface by recording slight differences in the reflected signal's arrival time and wavelength back at the spacecraft. RADAR detected how smooth or rough surfaces are, making it useful for studying Titan's methane seas.

The RADAR used the spacecraft's high-gain antenna (HGA) and its associated five-beam Ku-band feed assembly to send radar transmissions (at a wavelength of 2.2 cm, equivalent to a frequency of 13.8 GHz) toward targets and capture reflected radar signals and blackbody radiation. In its altimetry mode, the RADAR could also measure the height profile of terrain beneath the spacecraft.

EXECUTIVE SUMMARY

Throughout the Cassini mission, Titan Radar Mapper (RADAR) obtained Synthetic Aperture Radar (SAR) images, altimetry, scatterometry, and (passive) radiometry of Titan, Saturn, some of the icy satellites, and Saturn's rings. Over the course of the mission, the Radar Science Team planned, commanded, processed, and archived these datasets. Taken together with other Titan-observing Cassini instruments' data, their analysis has produced many scores of discoveries: we have revolutionized our understanding of Titan, which despite its low temperatures has shown its surface to be unexpectedly Earth-like, both in terms of observed features and the geologic processes that formed them. These include mountains, sand dunes, oceans and lakes, rivers, and a complex hydrologic system where the working fluid is primarily methane. Analysis of repeat SAR coverage was a major contributor to the conclusion that there is a subsurface ocean within Titan. Radar observations of Saturn have improved microwave observations by nearly an order of magnitude and revealed deeper structure than was previously thought possible. Icy satellite data have been used to explore hemispheric dichotomies or regional anomalies and, where higher spatial resolution was possible, to examine specific areas of interest—in particular of Enceladus. Microwave scans of Saturn's rings suggest that particles in the A-ring, B-ring, and C-ring may be highly porous, and that the rings may be very young—perhaps less than 150 million years. Both passive and active radar data from Cassini's last orbits of Saturn, still under analysis, promise to provide new information about particle size distribution and its variation across the rings.

Radar observations of Saturn have improved microwave observations by nearly an order of magnitude and revealed deeper structure than was previously thought possible.

To rank the team's discoveries is difficult, both because of their wide variety and because discoveries often involve analyses of more than one instrument's data. After some debate we have developed these top ten major new facts resulting at least in part from radar data. The body of this report explains these in detail.

1. Titan's surface is dynamic and Earthlike, with an active hydrological cycle that includes several large seas, hundreds of lakes, and numerous rivers and channels.

2. Titan's surface is relatively young, perhaps hundreds of millions of years, with few impact craters identified.

3. A band of linear sand dunes, likely made of organic material, stretches across most of Titan's equator.

4. Titan's seas have depths of 100s of meters; the liquid in them is remarkably pure methane-ethane-nitrogen.

5. A large, previously identified feature known as Xanadu is not elevated relative to surrounding terrain as previously suspected. It seems to be younger and rougher than the rest of Titan and it likely has a high content of highly fractured water ice bedrock.

6. Titan is internally differentiated, and has an outer ice shell, a subsurface ocean, a high pressure layer at the base of the ocean, and a deep rocky interior.

7. Liquid is transported from one Titan hemisphere to the other, resulting in more lakes that are currently dry in the south.

8. Cryovolcanism exists or has recently existed on Titan. Several surface features have been identified as likely cryovolcanic vents.

9. By probing its ammonia at depth, radiometric data have revealed deeper structure in Saturn than was previously thought possible.

10. The south pole of Enceladus has the brightest radar backscatter of any planetary surface in the solar system, suggesting a retroreflective near surface, for reasons that remain puzzling but appear to be linked in some way to the presence of the E-ring.

RADAR Instrument Summary

The Titan Radar Mapper (henceforth RADAR[1] [Elachi et al. 2004]) was one of twelve instruments aboard the Cassini spacecraft. It was developed by NASA's Jet Propulsion Laboratory (JPL), the Italian Space Agency (ASI), and the Cassini Radar Science Team, primarily to reveal the surface of Titan but also to explore Saturn, its rings and the icy satellites. Nearly opaque at most visible and near-infrared wavelengths, Titan's atmosphere is transparent at RADAR operating wavelength of 2.17 cm (Ku-band). RADAR had four operating modes: SAR imaging, altimetry, scatterometry, and radiometry. In its SAR mode, used at altitudes under ~4,000 km, RADAR imaged surfaces of Titan and Saturn's icy satellites and rings in various modes, including SAR at incidence angles from 15 to 35 degrees and spatial resolutions varying as low as 350 m, sufficient to identify major structures and to make geologic maps. SAR images characterize the surface roughness at scales near the radar wavelength, to surface slopes at the scale of the radar resolution, and to dielectric properties of the constituent materials. In addition, microwaves can penetrate many wavelengths into some materials on Titan. But for the most part, SAR images are observationally similar to optical images and allow us to identify major structures and geomorphologic units. Altimetry results when the antenna is pointed within a fraction of a beam width (0.35 deg) of nadir resulting in a range resolution of approximately 30 m and spatial resolution depending on altitude. The altimetry data have two broad applications. First, the aggregate of all data define an absolute geoid for Titan and constrain any rotational or tidal bulge. Second, relative topographic profiles from each RADAR

[1] In this report, we distinguish radar, a microwave sensing technique, and RADAR, an instrument aboard the Cassini spacecraft.

pass characterize landforms (e.g., impact craters, mountains), yielding important constraints on geophysical models. Altimetry was obtained over 2% of Titan's surface, in some cases measuring the depth and absorption of liquids.

An amplitude monopulse comparison technique called SARTopo [Stiles et al. 2009] added an additional 5% topographic coverage using SAR data [Corlies et al. 2017]. The SARTopo technique depends on the precise manner in which the location and magnitude of each SAR pixel are affected by variation in surface height between each of the five antenna beams (feeds) [Elachi et al. 2004]. The technique estimates surface heights from observed differences between beams. Cassini's antenna had multiple beams, so that some points on the ground were observed from two different beams. For different beams, the mislocation error due to surface height is the same, but the miscalibration error is different and of opposite sign. Nonzero surface heights, therefore, result in apparent differences in pixel positions between overlapping single beam SAR images. In addition, altimetry was able to obtain depths of several lakes and seas [Mastrogiuseppe et al. 2014]. Scatterometry is obtained by pointing the transmitter off-nadir, but processing the echoes using the real aperture rather than the synthetic aperture. The data indicate the backscatter efficiency at various incidence angles at relatively low resolution (real aperture resolution depends on range to

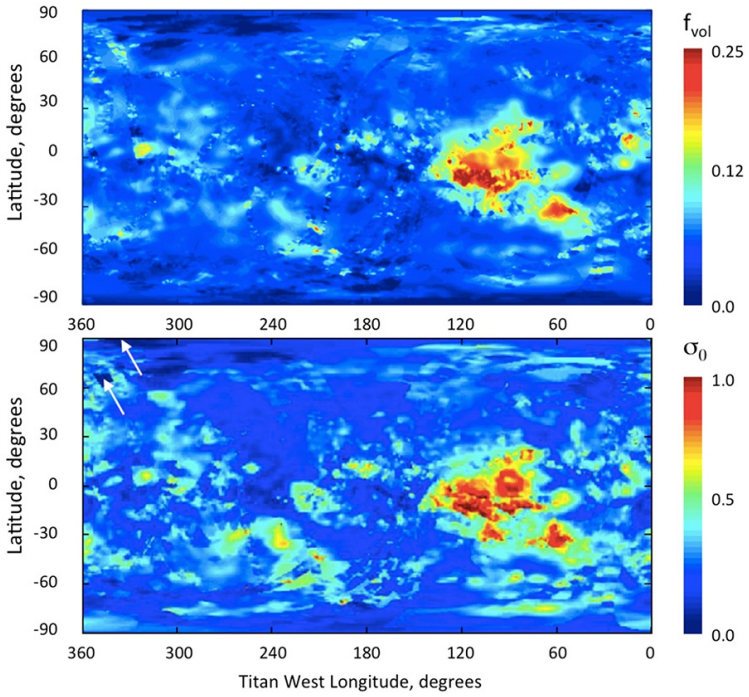

Figure RADAR-1. Predicted and observed maps of scattering from Titan's surface. The upper panel is a map of the volume scattering parameter f_{vol} for a simple surface model composed of a smooth dielectric interface separating free space from an inhomogeneous and isotropically scattering subsurface. The f_{vol} is the probability that a photon entering the surface (as determined by the effective dielectric constant) scatters and escapes from the subsurface before it is absorbed. The map of f_{vol} reconciles the maps of effective dielectric constant and emissivity and predicts the overall magnitude of the scattering. The lower panel is a global mosaic of Titan's normalized radar cross-section from all real aperture data through T71 [Wye 2011], showing the actually observed scattering. The white arrows in the upper left-hand corner indicate two small regions that were not mapped.

surface). Scatterometry coverage is near-global (Figure RADAR-1); it can be used as a basemap for SAR and as a broad characterization of global terrains. As an independent constraint on surface roughness, scatterometry data are an important complement to radiometry data in order to constrain surface composition. Used as a passive microwave radiometer, RADAR collected near-global measurements (Figure RADAR-2) of Ku-band brightness temperature with an accuracy of 1 K [Janssen et al. 2016]. Radiometry data produce polarized brightness temperatures of the observed scene, obtained from the antenna temperature measurements. The microwave brightness temperature of a solid surface depends on many properties besides physical temperature; e.g., emission angle, polarization, dielectric constant, porosity, surface, and subsurface roughness, etc.

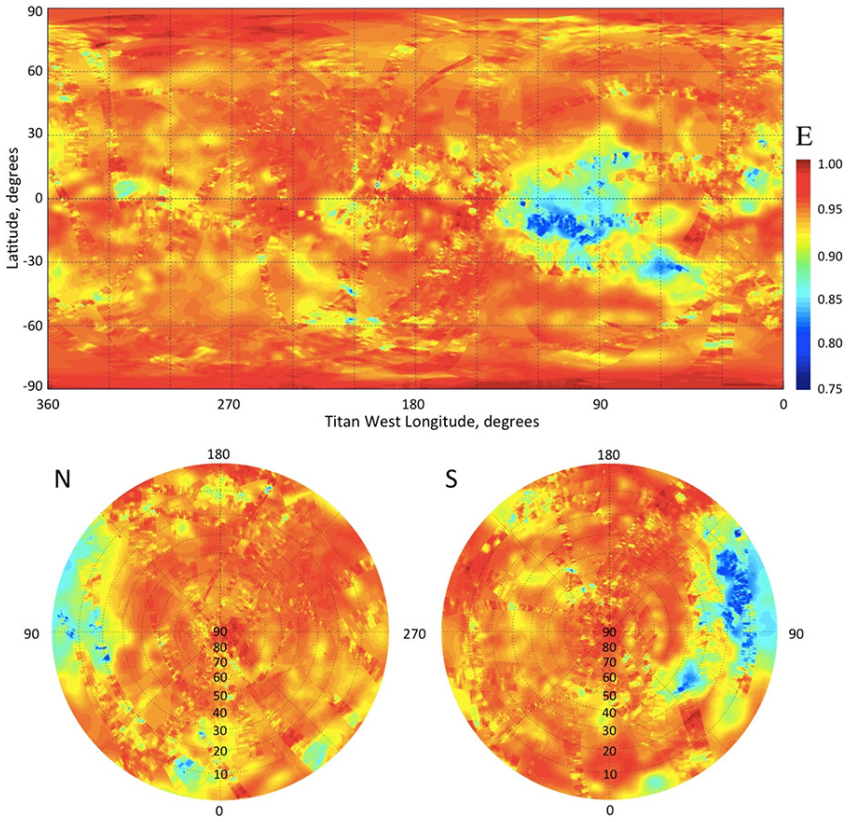

Figure RADAR-2. Global mosaic of emissivity of Titan at the 2 cm wavelength of the Cassini RADAR. This is the final result of the brightness temperature mapping of Titan incorporating all radiometric data obtained from Titan passes, a nearly 10-year span. The brightness temperature was measured as a function of position, polarization and time over a wide range of geometries and ranges, and calibrated to about 1% absolute accuracy using Huygens probe and Composite Infrared Spectrometer (CIRS) temperature measurements as described in Janssen et al. [2016]. The polarization data were used to construct a global mosaic of effective dielectric constant, enabling the conversion of all measured brightness temperatures to their equivalent values at normal incidence. The data were then folded into a massive least-squares solution for the seasonally varying brightness temperature distribution of Titan over the time scale of the observations. Comparison with surface temperature measurements obtained in the infrared (IR) using Kirchhoff's law then enabled the construction of the emissivity map shown. Note that Xanadu, the equatorial region centered on 100 W longitude, is extremely cold and non-emissive, characteristic of a high content of highly fractured water ice bedrock.

KEY OBJECTIVES FOR RADAR INSTRUMENT

The key RADAR science objectives are listed below, and discussed in further detail in the section entitled RADAR Science Results.

Titan Science

Surface units

TN1a: Determine the types, composition, distribution, and ages of surface units and materials, most notably lakes (i.e., filled vs. dry & depth; liquid versus solid & composition; polar versus other latitudes and lake basin origin).

CSM: T_AO4: Titan surface characteristics and internal structure—determine the physical state, topography, and composition of the surface; infer the internal structure of the satellite.

TC1a: Determine seasonal changes in the methane-hydrocarbon hydrological cycle—of lakes, clouds, aerosols, and their seasonal transport.

Internal structure

TN1b: Determine internal and crustal structure—liquid mantle, crustal mass distribution, rotational state of the surface with time, intrinsic and/or internal induced magnetic field.

TN2b: Determine icy shell topography and viscosity.

TN2c: Determine the surface temperature distribution, cloud distribution, and tropospheric winds.

Saturn Science

SN1b: Observe the aftermath of the 2010–2011 storm. Study the life cycles of Saturn's newly discovered atmospheric waves, south polar hurricane, and rediscovered north polar hexagon.

Ring Science

RN1c (R_AO2): Determine structural and compositional variations at high resolution across selected ring features of greatest interest, using remote and in situ observations.

Icy Satellite Science

IN1a: Determine the presence of an ocean at Enceladus as inferred from induced magnetic field and plume composition, search for possible anomalies in the internal structure of Enceladus as

associated with plume sources, and constrain the mechanisms driving the endogenic activity by in situ observations and remote sensing.

IN1c: Determine whether Dione exhibits evidence for low-level activity, now or in recent geological time.

I_AO1: Icy satellite geology and history—determine the general characteristics and geological histories of the satellites.

RADAR Science Assessment

Table RADAR-1 contains an assessment of RADAR science based on the objectives in the original Announcement of Opportunity (AO) and the Cassini Traceability Matrix (TM) developed for the Equinox and Solstice missions.

Table RADAR-1. Matrix of RADAR science objectives. Green color indicates that RADAR data with sufficient quality were obtained during the Cassini mission to contribute to a given science objective.

RADAR Science Objectives	AO and TM Science Objectives	RADAR Science Assessment	Comments
Titan Science			
Surface units	TN1a, CSM:T_AO4, TC1a		
Internal structure	TN1b, TN2b, TN2c		
Saturn Science	SN1b

Ring Science	RN1c (R_AO2)		

RADAR Science Results

Titan Science

In its 13-year presence at Saturn, Cassini made a total of 127 passes by Titan, some as close as 950 km. Forty-eight of these were used by RADAR, with one lost in downlink—for a detailed description of results from individual flybys, see Lorenz et al. [2018]. SAR coverage was limited by both Cassini's orbital path, which used Titan for gravity assists, and by intense competition among instruments for observation time—resulting in a seemingly random set of strips 100–200 km wide (Figure RADAR-3). However, the swaths were well distributed in latitude and longitude, allowing for an emerging global picture of the surface. Aerial SAR coverage at the end of the mission was

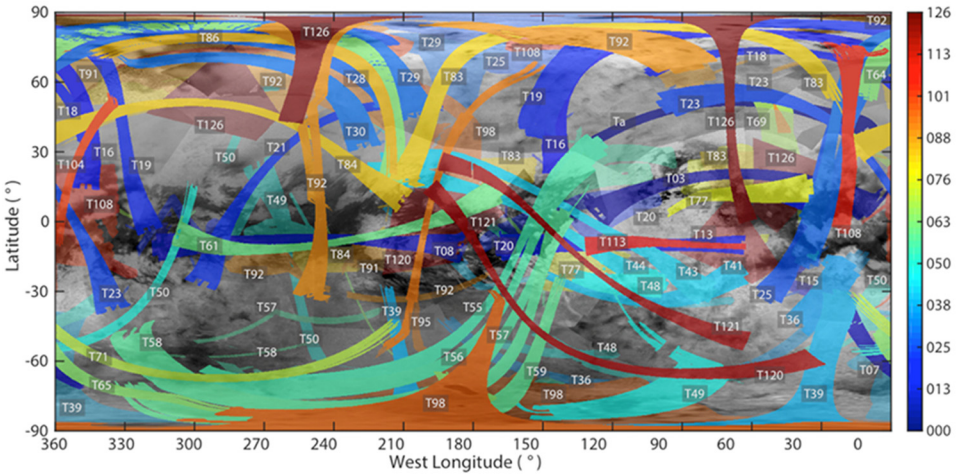

Figure RADAR-3. Combined Titan SAR coverage from the entire Cassini mission. Swaths are shown over an ISS basemap.

46% using nominal SAR mode and 74% including coarser-resolution (>1.5 km) HiSAR. Repeat images were obtained over 14% of the surface, and 1.5% was covered four or more times [Lorenz et al. 2018]. Real-aperture scatterometry and passive radiometry data exist over the entire surface, at varying resolutions.

Together with near-infrared and mid-infrared images taken by other Cassini instruments—Visual and Infrared Mapping Spectrometer (VIMS) [Brown et al. 2004] and the Imaging Science Subsystem (ISS) [Porco et al. 2004]—RADAR has given us an opportunity to discover a new world that is both Earth-like and unearthly. We find familiar geomorphology in its mountains, dunes, rivers, and seas, but note that these features are composed of unfamiliar materials. In this section, we review RADAR's contributions to geology, hydrology, and surface-atmospheric interaction in an attempt to summarize our knowledge of Titan at the end of the Cassini mission.

Interior

Static and time-varying gravity field measurements [Iess et al. 2010, 2012], rotational dynamics measurements [Stiles et al. 2008, 2010; Lorenz et al. 2008a; Meriggiola et al. 2016], and shape models [Zebker et al. 2009a; Mitri et al. 2014; Corlies et al. 2017] have been used to infer the interior structure of Titan. Magnetic field measurements have shown that an intrinsic magnetic field is not present on Titan [Wei et al. 2010]. The determination of the rotational dynamics from Cassini RADAR SAR images has been key to constraining the interior structure of Titan. As described in the previous section, Cassini RADAR SAR coverage of Titan is dependent on orbit dynamics and competition for observation time. As a result, SAR swaths appear somewhat randomly distributed with coincidental overlaps (with only a few exceptions). Where overlap occurs, and assuming that the same surface features appear in both images, it is possible to determine how quickly Titan has rotated between observations and thus estimate Titan's pole location and spin rate [Stiles et al. 2008, 2010], analogous to previous work using Magellan SAR imagery to estimate the spin model of Venus [Davies et al. 1992]. First, a set of recognizable landmarks observed in two different SAR

images are obtained at different times located in a Titan centered inertial, non-rotating (J2000) reference frame. Pixels chosen in each SAR image corresponding as closely as possible to the same point on the landmark are aligned, using several techniques to minimize landmark mismatches. The spin state parameters are estimated by minimizing the misregistration error—that is, the apparent movement in Titan body-fixed coordinates of the landmarks between observation times. Feature mapping is much more robust for radar than for passive optimal imagery, because radar geolocation is independent of spacecraft pointing knowledge except that the general direction (within 10 degrees or so) must be known to exclude mirror ambiguities. Accurate radar pixel locations in inertial space depend only on the accuracy of the measurement of delay, Doppler shift, spacecraft velocity and position, and presumed target body topography. Nearby SARTopo [Stiles et al. 2009] measurements of topography help determine more precisely variations in feature locations in inertial space. Using similar methodology and a more extensive set of observations, Meriggiola et al. [2016] also provided a rotational model of Titan estimating the spin pole location, the spin rate, the precession, and the nutation. Further, these authors show that the pole location is compatible with the Cassini State 1 (a dynamical equilibrium wherein the spin axis, the orbit norma,l and the normal to the invariable plane are coplanar).

Stiles et al. [2008] and Meriggiola et al. [2016] have provided an estimate of Titan's obliquity (0.31°). The obliquity together with the quadrupole moment of the gravity field (J2 and C22) measurements [Iess et al. 2010, 2012] constrain the moment of inertia of Titan. These results were used by Bills and Nimmo [2011] to estimate the radial mass distribution of Titan and, when combined with the low-degree gravity field derived from Cassini spacecraft Doppler tracking data [Iess et al. 2010], suggest that Titan's outer shell is mechanically decoupled from the deeper interior. Bills and Nimmo [2011] and Meriggiola et al. [2016] find that the estimated obliquity is compatible with a deep interior decoupled from the outer ice shell by a global subsurface ocean. Note that Lorenz et al. [2008a] interpreted the initial indication in Stiles et al. [2008] of nonsynchronous rotation as indicating a subsurface ocean, drawing on predictions of atmospheric angular momentum exchange with a decoupled shell by Tokano and Neubauer [2005]. However, the spin state determination has significant degeneracy between nonsynchronous rotation and precession of the spin pole, and subsequent observations seem to favor synchronous rotation. Thus, the conclusion of Lorenz et al. [2008a] of an internal global ocean indicated by RADAR spin measurements remains correct, but for perhaps the wrong reasons. The presence of a subsurface ocean inferred from the rotational dynamics of Titan is consistent with the large tidal response of Titan (tidal Love number $k_2 = 0.589 \pm 0.150$) [Iess et al. 2012; Mitri et al. 2014]. In agreement with this scenario, the Permittivity, Wave and Altimetry (PWA) instrument on board Huygens' probe measured a Schumann-like resonance, also suggesting the presence of a subsurface ocean [Bèghin et al. 2012]. In summary, the gravity, topography and rotational dynamics measurements in combination with thermal-evolution models indicate that Titan is internally differentiated (Figure RADAR-4), and has an outer ice shell, a subsurface ocean, a high pressure layer at the base of the ocean, and a deep rocky or rock-ice mix interior [Hemingway et al. 2013; Mitri et al. 2014; Tobie et al. 2014].

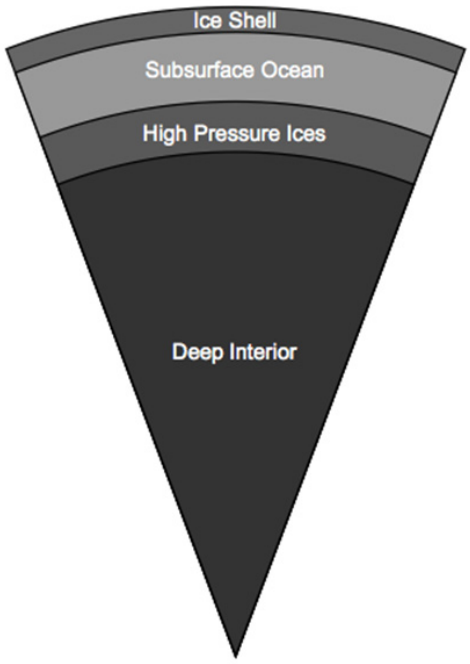

Figure RADAR-4. Possible present-day structure of Titan's interior showing that Titan is internally differentiated with a deep rocky or rock-ice mix core.

Global shape

RADAR observations using both the altimetry and SARTopo modes reveal Titan's global shape and yield insights to its interior structure. The roughly 60 satellite-derived elevation surface traces—Figure RADAR-5 [Zebker et al. 2009a]—show that Titan's polar radius is less than, and the equatorial radii are greater than, predicted by its gravity field. Best-fitting solutions are shown in Table RADAR-2.

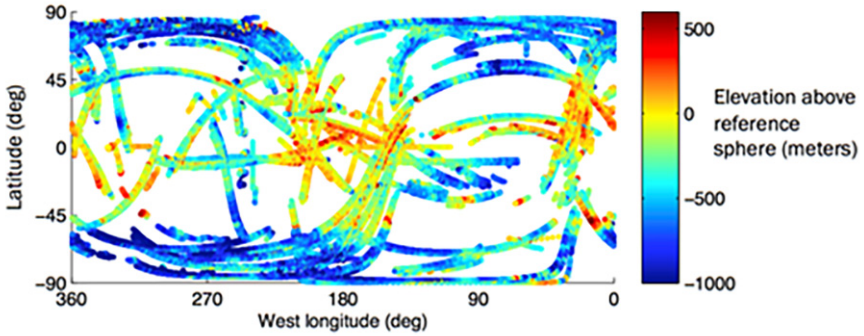

Figure RADAR-5. Cassini measurements of Titan surface height above a reference sphere of 2575 km radius. As expected, the shape is dominantly triaxial ellipsoidal, with topographic lows near the poles and topographic highs at the prime-meridians and anti-meridians. However, the polar flattening is greater than expected for a hydrostatic body, meaning the equatorial topography stands higher than expected and the polar depressions are lower than expected, suggesting that the depth to the subsurface ocean is smaller at the poles than at the equator.

Table RADAR-2. Titan gravity and shape triaxial ellipsoids (m).

	Gravity	Elevations	Difference
a axis	2574875 ± 7.3	2575124 ± 26	−249
b axis	2574716 ± 7.4	2574746 ± 45	−30
c axis	2574660 ± 4.5	2574414 ± 28	246
a translation	0.8 ± 5.6	69.8 ± 6.2	
b translation	0.1 ± 5.6	68.3 ± 8.0	
c translation	1.7 ± 3.9	45.8 ± 6.4	
Mean eq. rad.	2574795	2574761	−34
Hydrostatic ratio (a-c)/(b-c)	3.83	2.14	

The hydrostatic ratio (a-c)/(b-c), which is exactly 4 for a spin-locked satellite in hydrostatic equilibrium, for Titan's figure is observed to be only 2.14 [Zebker et al. 2009a; Corlies et al. 2017]. The hydrostatic ratio obtained from the third-degree gravity observations is 3.83—that is, the gravity field reflects approximate hydrostatic equilibrium. While the gravity field is consistent with a hydrostatically relaxed body, Titan's figure is not. If both of these data constraints pertain, Titan's interior does not conform to a set of spherically symmetric shells, as these data imply that the average satellite density at the equator is less than at the poles. If Titan has a vast interior ocean of liquid water, then some ice layers (less dense than liquid water) are thinner at the poles than the equator. A simple model satisfying both sets of data and assuming isostatic compensation (Figure RADAR-6) could be the result of uneven heat dissipation in Titan's interior, such as may result from tidal interaction with Saturn or its other moons.

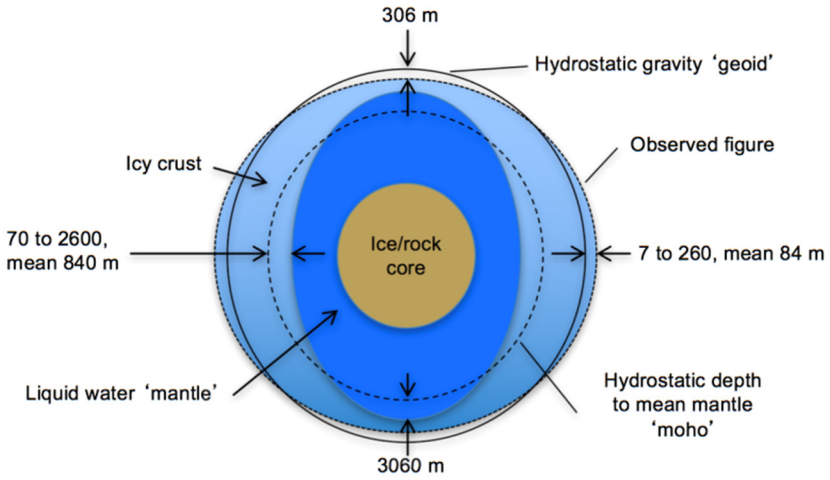

Figure RADAR-6. Model consistent with Cassini gravity and figure measurements, assuming isostatic compensation. The thinner ice shell (exaggerated for visibility in the figure) at the poles could result from uneven heat dissipation within Titan from tidal interactions, and the relatively shallower geoid at the poles is one explanation for the preponderance of lakes at the most northern and southern latitudes. The shallower geoid allows mobile liquids to lie closer to the surface.

Another simple model explaining the overly oblate topographic figure assumes that there is greater precipitation of hydrocarbon snow or loosely packed hydrocarbon particulates at the equator than at the poles, perhaps with a net equatorward transport from the poles, which would also be consistent with the data. This could account for increased distance from the surface to the planet center at the equator if sufficient material were so transported. We note that this is consistent with the observation of 100 m tall dune structures near Titan's equator (see the section entitled Dunes), so that poorly consolidated material may indeed collect there to a greater extent. Several hundred meters of deposition at the equator would match the mean equatorial radii of both models, but precipitation would have to preferentially occur in the sub- and anti-Saturnian directions, which seems unlikely.

Further comparisons of the gravity and shape observations constrain the depth of any outer ice shell enclosing a global subsurface ocean [Zebker and Wong 2016]. While the exact value varies depending on how the spherical expansion is constrained, the observed gravity to topography ratio is 0.070 for the third order terms and 0.042 for fourth order [Zebker and Wong 2016]. These imply ice shell thicknesses of 327 and 187 km, respectively, a factor of ≥2 more than the 100 km expected from thermal models [Sohl et al. 2003; Nimmo and Bills 2010]. The Zebker and Wong solution yields a tidal Love number h_{2t} of about 0.5, and a basal heat flow of 2.5 mW/m^2. This would suggest that heat from Titan's core is lower than often assumed, hence the amount of radiogenic material in the core is likely less as well. These data also constrain the depth of Titan's mantle and density of its core, placing added restrictions on its composition and evolution. Supposing that Titan has an undifferentiated ice/rock core beneath the ocean, and that the moment of inertia is most likely in the range 0.33–0.34 [Iess et al. 2010], then a 200 km crust estimate from above and Titan's well-known mean density of 1.88 g cm^{-3} implies an ocean depth and core density ranging from 308 km and 2.74 g cm^{-3} (MOI = 0.33), to 226 km and 2.55 g cm^{-3} (MOI = 0.34).

The Cassini-Huygens mission has revealed the surface of Titan in unprecedented detail, enabling us to discern different geomorphological units on the surface … .

Composition and surface and subsurface properties

The Cassini-Huygens mission has revealed the surface of Titan in unprecedented detail, enabling us to discern different geomorphological units on the surface (see the section entitled RADAR Science Results), constrain the relative times of emplacement of these units, and place constraints on composition. Titan has an ice shell (Figure RADAR-4), but water ice signatures are not easily detected due to atmospheric scattering and absorption that hamper the observations and the presence of complex organic molecules on the surface. The extended, dense, and hazy N_2-CH_4 dominated atmosphere shields the surface from direct optical observations, except at certain wavelengths where the methane absorption is weak. These methane atmospheric windows [McCord et al. 2006] are exploited by the Cassini VIMS to obtain compositional information of the top few microns of the surface, as discussed in the section entitled Surface. Composition from

VIMS and RADAR, while RADAR can probe the surface and subsurface scattering properties, and hence place additional constraints on composition.

SURFACE AND SUBSURFACE SCATTERING PROPERTIES

Compared to the surface of the Moon or Earth, the off-nadir radar response from most of Titan's surface is quite strong at Ku-band. This indicates that more complex processes than simple surface scattering, such as a significant volume scattering component, have to be considered [Elachi et al. 2005; Wye et al. 2007; Paganelli et al. 2007; Janssen et al. 2016]. Indeed, given the low Titan surface temperatures and the low loss tangent of analogs of materials relevant to Titan's surface, signals from Cassini RADARs Ku-band instrument should penetrate the surface down to a depth ranging from a few decimeters for an organic and compacted near-surface, to several meters for a pure water ice near-surface [Paillou et al. 2008a], and thus have multiple opportunities to be scattered. The RADAR observations of Titan are consistent with subsurface volume scattering processes, in addition to pure surface scattering. Analysis of Cassini scatterometer and radiometer measurements obtained simultaneously (see Figure RADAR-7) are best fit using models where volume scattering, enabled by the low material losses, is enhanced by coherent backscatter processes [Zebker et al. 2008; Janssen et al. 2011].

Janssen et al. [2016] further advance that a regionally enhanced degree of volume scattering is indicative of a higher abundance of water ice in the near-surface. This is because water ice is more transparent to microwaves than common organic materials, allowing for more opportunities for scattering. This would be consistent with about 10% of Titan's near-surface being water ice-rich while the composition of the remaining terrains is dominated by more absorbing organic materials, likely byproducts of the intense atmospheric photochemistry [Lorenz et al. 2008b; Hörst 2017]. The regions that contain a high degree of volume scattering include mountainous terrains, impact craters, fluvial and fan-like features, all of which possibly correspond to highly fractured or unconsolidated sedimentary materials derived from erosion. Many of these materials could also have originated from cryovolcanism, in which the radar signature could be explained by a strong volume scattering effect in a thick water-ammonia ice layer using a two-layer scattering model [Paillou et al. 2006]. Radar-bright sinuous channels in the southwest of Xanadu (see section entitled Xanadu), showing very large radar cross-sections, are also consistent with the presence of icy, low-loss, rounded scatterers, acting as efficient natural retro-reflectors [Le Gall et al. 2010].

Weaker radar reflectors such as Titan's dunes are most likely organic in nature (as also supported by VIMS—for example, Barnes et al. [2008], Soderblom et al. [2009], and Clark et al. [2010]). However, we note that these features exhibit somewhat high backscatter at large incidence angles compared to Earth analogs, which suggests even aeolian sediments may contain centimeter-scale gravels producing a significant volume scattering component [Paillou et al. 2014]. Features interpreted as mega-yardangs were observed on Titan, and they also exhibit a much brighter radar signature than their terrestrial analogs, indicating that additional scattering processes, such as volume scattering, occur in those materials as well [Paillou et al. 2016].

Lastly, and of particular interest, is the case of Titan's methane-dominated lakes, where radar waves can penetrate down to several thousand wavelengths (at least 150 m) and be subsequently backscattered by the bottoms of a lake or seabed [Mastrogiuseppe et al. 2014]. These results are consistent with recent laboratory investigations of the electrical properties of liquid hydrocarbons [Mitchell et al. 2015].

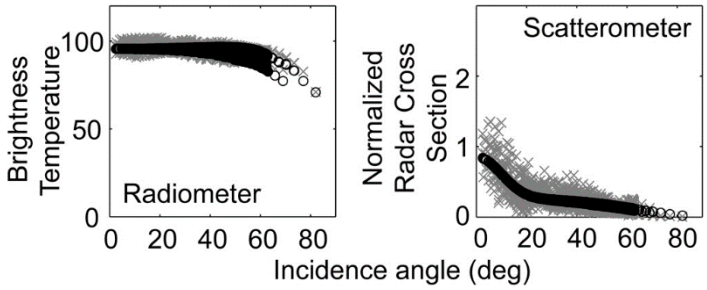

Figure RADAR-7. Angular dependence of radiometer (left) and scatterometer (right) measurements of a portion of Titan's surface. Grey X's are observations, while black circles are modeled values assuming both surface and volume scattering terms. Both sets of curves fall off slowly with incidence angle, indicative of significant volume scattering.

Surface composition from VIMS and RADAR

A combination of RADAR and near-infrared multispectral imaging data—VIMS—is a powerful way to distinguish and categorize geomorphological features into units with distinct chemical compositions (that remain to be identified). Spectroscopic observations of Titan's surface are severely hindered by the presence of an optically thick, scattering and absorbing atmosphere, allowing direct investigation of the surface within only a few spectral windows in the near-infrared. Based on the 1.29/1.08 μm, 2.03/1.27μm, and 1.59/1.27 μm band ratios measured by VIMS at low to moderate latitudes, three main spectral units were initially distinguished on the surface of Titan: 1) bright material mainly distributed in the topographically high and mid-latitude areas; 2) blue material adjacent to the bright-to-dark boundaries; and 3) brown material that correlates with radar-dark dune fields [Barnes et al. 2007; Soderblom et al. 2007; Jaumann et al. 2008].

Even though these spectral units are distinct, their actual compositions remain elusive. A number of chemical species was proposed to exist on the surface of Titan, but only a few absorptions were unambiguously detected from remote-sensing observations carried out by VIMS during Cassini flybys. A methane-ethane dominated composition seems to be present in the polar lakes and seas of Titan—for example, Brown et al. [2008], and Lunine and Lorenz [2009]. IR spectroscopy, microwave radiometry and scatterometry are sensitive to the physical structure of the surface to a different extent and at different scales. IR spectroscopy measurements are used to determine surface composition, but they are also affected, down to depths of micrometers, by the physical properties of the surface material like roughness, photometric geometry, and porosity.

Correlations between near-infrared and microwave data of Titan's surface are useful to gather a broader understanding of surface properties. These were quantified at coarse spatial resolution

by Tosi et al. [2010a], who applied a multivariate statistical analysis to an aggregated dataset made up of infrared spectra acquired by VIMS at spatial resolution of tens of km together with scatterometry and radiometry data measured by RADAR. This technique allowed for the identification of regional surface units at equatorial to mid-latitudes. Some of these units matched both the major dark and bright features seen in the ISS mosaic of Titan [Porco et al. 2005; Turtle et al. 2009], whereas other units showed boundaries not apparent from the visible and near-infrared remote-sensing data set. In particular, while dark equatorial basins are very similar to each other in terms of infrared and microwave reflectance at this spatial scale, the major bright features do not share the same characteristics.

A comprehensive investigation of Titan's surface features using the VIMS and RADAR-SAR datasets at the best available spatial resolution is still the best approach to characterize geomorphologic units using both spectral and morphologic characteristics. For example, the correlation between the 5 μm bright materials and RADAR empty lakes suggests the presence of sedimentary or organic-rich evaporitic deposits in dry polar lakebeds [Barnes et al. 2011a; MacKenzie et al. 2014]. Langhans et al. [2012] extensively studied the morphology, distribution, and spectral properties of Titan’s fluvial valleys showing that these are mostly associated with the bright surface unit.

In recent years, several investigators have applied radiative transfer models in addition to comparison between datasets—for example, Hirtzig et al. [2013]; Solomonidou et al. [2014]; Lopes et al. [2016]. These studies allow definition of both the surface and the atmospheric contributions from VIMS spectral imaging data after performing the appropriate pixel selection of areas of interest with the help of SAR data.

The application of radiative transfer analyses to the VIMS Titan data yields extracted weighted surface albedos in the seven methane windows, which have been tested against a variety of Titan candidate ice and organic constituents to provide constraints on the possible material present in various geomorphological units [Solomonidou et al. 2018]. An updated material library is used based on Bernard et al. [2006], Brassé et al. [2015], and the Grenoble Astrophysics and Planetology Solid Spectroscopy and Thermodynamics (GhoSST) database (https://ghosst.osug.fr). This library includes several materials at different grain sizes, such as ices of acetylene (C_2H_2), ethylene (C_2H_4), ethane (C_2H_6), propane (C_3H_8), cyanoacetylene (HC_3N), water (H_2O), ammonia (NH_3), methane (CH_4), and carbon dioxide (CO_2), in addition to spectra of laboratory tholins [Bernard et al. 2006; Brassé et al. 2015], and spectra of dark materials such as asphalite, kerite, different types of anthraxolite and amorphous carbon, which have been proposed to lower the total surface albedo of Titan’s surface—[Lellouch et al. 2006; GhoSST database].

Considering the different grain sizes, the library consists of 148 different constituent possibilities that can also be mixed. By using this constituent library, spectral simulations are made and an iterative process is used to obtain the best fit to the observations, bearing in mind that there is no unique solution for the whole mixtures. With these and other caveats, Solomonidou et al. [2018] have derived constraints on the possible major constituent for each geological unit and reported a latitudinal dependence of Titan’s surface composition with water ice being the major

constituent at latitudes poleward of 30° N and 30° S, while Titan's equatorial region appears to be dominated by a very dark organic material, possibly aromatic in character [Clark et al. 2010]. The surface albedo differences and similarities among the various geomorphological units also have implications for the geological processes that govern Titan's surface and interior (e.g., aeolian, cryovolcanic, tectonic).

Surface geology

MAJOR GEOLOGIC UNITS AND MAPPING

SAR data have been used since the early days of the mission to interpret different types of terrains (Figure RADAR-8) [Stofan et al. 2006; Paganelli et al. 2007, 2008; Lopes et al. 2010]. More recent work used not only SAR data but added correlations with data from other RADAR modes (altimetry, SARTopo, scatterometry, and radiometry), and also from VIMS and ISS to provide sufficient information on Titan's surface to distinguish the major types of terrain units [Malaska et al. 2016a; Lopes et al. 2016]. Also see Lopes et al. [2019] for the recently produced global geologic map. These data were also used to establish the major geomorphologic unit classes on Titan and their ages using contacts between units. In order of total surface area, the classes of units are: plains, dunes, mountainous/hummocky terrains, labyrinth terrains, lakes, and impact craters. The oldest units are the mountainous/hummocky and the labyrinth terrains; it is not possible with currently available data to differentiate the relative ages of these two oldest types of terrain. The mountainous/hummocky terrains consist of mountain chains and isolated radar-bright terrains. The labyrinth terrains consist of highly incised and dissected plateaus with medium radar backscatter. The plains are younger than both mountainous/hummocky and labyrinthic unit classes. Dunes and lakes of liquid hydrocarbons are the youngest unit classes on Titan. Additionally, we have identified individual features such as crater rims, channels, and candidate cryovolcanic features. Crater rims and candidate cryovolcanic features are locations more likely to expose materials from the icy crust, while the hummocky/mountainous materials are thought to be exposed remnants of the icy crust.

Characterization and comparison of the properties of the unit classes and individual features with data from radar radiometry, ISS, and VIMS provide information on their composition and possible provenance and shed light on the interconnection between the interior, the surface, and the atmosphere. Both microwave emissivity and VIMS are helpful in characterizing the units, although both have different penetration depths with microwave emissivity penetrating 10s of cm into the surface, while infrared-based responses such as VIMS and ISS, penetrate only the top surface coating, on the order of microns. Microwave emissivity data infer that the hummocky/mountainous terrains and impact crater rim features have relatively low emissivity (and greater radar scattering) in radiometric data, consistent with more water ice near the surface (Figure RADAR-2). The undifferentiated plains, dunes, labyrinth terrains, and lakes all have high emissivity (lower radar scattering) in radiometric data, which is consistent with low-dielectric organic materials.

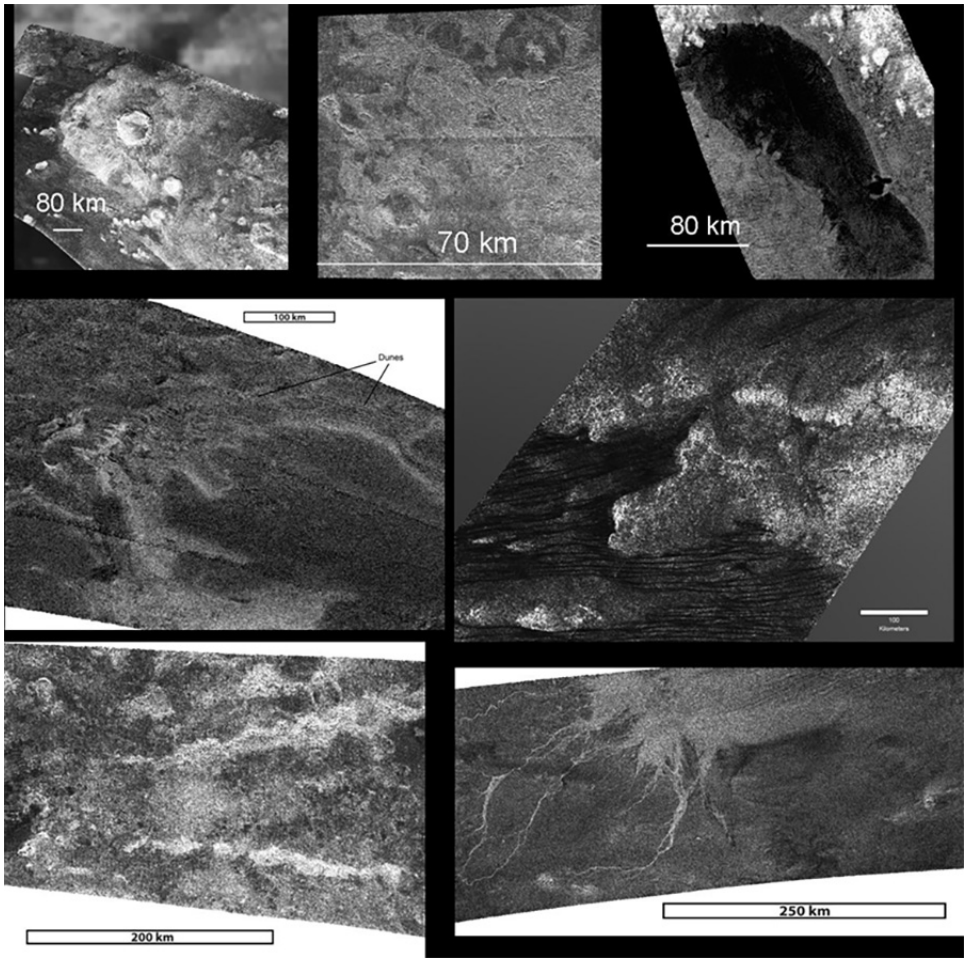

Figure RADAR-8. Examples of geologic features on Titan. Top row from left: Sinlap crater with its well defined ejecta blanket. Middle: Crateriform structure (suspected impact crater) on Xanadu. Right: Ontario Lacus near Titan's South Pole. Middle row, left: Bright (high radar backscatter) deposit Winia Fluctus abutting darker undifferentiated plains, the dunes indicated by arrows overlie part of deposit. Middle row, right: Dunes abutting against hummocky and mountainous terrain. Bottom left: Mountains (radar bright) in the equatorial region. Right: Elivagar Flumina, interpreted as a large fluvial deposit, showing braided radar-bright channels that overlie radar-dark undifferentiated plains.

Spectral coatings of the terrain units were described in Solomonidou et al. [2018] and discussed in the section entitled Surface Composition from VIMS and RADAR. From this analysis, three groups of compositional mixtures are reported, which include the major geomorphological units mentioned there: water ice, tholin, and a dark component. The units with spectral responses most similar to water ice are the labyrinth terrains and a number of different types of plains such as the streak-like, the scalloped, and the undifferentiated plains that are concentrated at the higher parts of the mid-latitudes. The impact crater ejecta and the alluvial fans are part of a different compositional group in which a tholin-like material is dominant. The units covered with an unknown dark constituent are the hummocky/mountainous terrains, the variable plains, the dunes, and the undifferentiated plains that are close to the equator and possibly contaminated by dune material

[Lopes et al. 2016; Solomonidou et al. 2018]. Since microwave radiometry and VIMS are global datasets (at lesser spatial resolution than SAR), we can also use these correlations to infer global distributions of regions not covered by SAR. This is particularly important as SAR data did not provide complete coverage of Titan at the end of the Cassini mission.

PLAINS

Plains are the most widespread type of terrain on Titan [Lopes et al. 2016]. Although there are several different types of plains, by far the most extensive are the Undifferentiated Plains, first mapped by Lopes et al. [2010]. These are vast expanses of radar-dark terrains that appear fairly uniform in SAR images, with no major topographic units, and are for this reason often referred to as blandlands. Lopes et al. [2016] mapped the distribution of the Undifferentiated Plains using SAR swaths up to flyby T92 (July 2013) and found that these terrains are located mainly at mid-latitudes. Their gradational boundaries and paucity of recognizable features in SAR data make geologic interpretation challenging, so Lopes et al. [2016] used all the RADAR datasets available, plus VIMS and ISS, to examine and evaluate different formation mechanisms including: (i) cryovolcanic origin, consisting of overlapping flows of low relief; or (ii) sedimentary origins, resulting from fluvial/lacustrine or aeolian deposition, or accumulation of photolysis products created in the atmosphere. Their analysis showed that exposure of Undifferentiated Plains in the lower mid-latitudes are consistent with a composition predominantly containing organic rather than icy materials and formed by depositional and/or sedimentary processes, unlike the undifferentiated plains in the higher mid-latitudes, which are consistent with water ice [Solomonidou et al. 2018]. The study concluded that aeolian processes played a major part in the formation of the Undifferentiated Plains, though other processes (fluvial, deposition of photolysis products) are likely to have contributed, possibly in differing proportions depending on location. However, the distribution of Undifferentiated Plains, both at local and global scales, is consistent with aeolian deposition being the major process contributing to their formation.

Spectral differences between the Plains and Dunes seen in VIMS data imply that the materials, at least on the top layers of the surface, are not exactly the same. Spectral differences in terms of surface albedo values between locations of Undifferentiated Plains [Lopes et al. 2016; Solomonidou et al. 2018] show that Plains at lower latitudes (closer to the dune seas) are more spectrally similar to dune materials, suggesting that they are related and supporting the idea that dune materials are transported by wind to mid-latitudes [Malaska et al. 2016a]. The Undifferentiated Plains located at lower mid-latitudes (and therefore closer to the equatorial dunes) appear to be composed predominantly of organic materials, which may have been cemented by an organic substance and/or wetted by methane, causing them to become spectrally different from dune materials, at least at a surficial level. Work by Malaska et al. [2016a] and Lopes et al. [2016] suggests that the plains deposits may be derived from modified dune materials—thus tying two of the major geomorphologic units together. If the Undifferentiated Plains materials are mainly the result of aeolian deposition but contain liquids due to methane rain or fluids transported by channels, this could explain why they show relatively high emissivity (lower global dielectric constant, less efficient volume scattering) as well as why they are free of observable dunes (reduced sediment mobility). It would also be consistent with the high level of degradation of craters

found at mid-latitudes, potentially due to efficient erosion by fluvial, pluvial, or subsurface flow activity [Neish et al. 2016].

DUNES

One of the youngest and most areally extensive geomorphologic units on Titan consists of sand dunes [Lorenz et al. 2006]. These appear as long, narrow, and SAR-dark features against a SAR-brighter substrate or interdune (Figure RADAR-9), presumably because dune sands are smooth to RADAR at the 2.17 cm Cassini SAR wavelength. The dunes are generally 1–2 km wide, spaced by 1–4 km and can be over 100 km long [Lorenz et al. 2006; Radebaugh et al. 2008]. Limited measurements of heights from radarclinometry suggest they are 80–130 m [Neish et al. 2010]. They are grouped together in large dune fields, or sand seas, equatorward of ± 30° latitude. The Titan's dunes interact with topographic obstacles, seen as SAR-bright and generally isolated mountains, in a way that indicates general W-E transport of sand; they pile up on the west side of obstacles, divert in their azimuth around the obstacles, and are sparser on the east side [Radebaugh et al. 2010]. Their size, general morphology and relationship with underlying terrain and obstacles, and their style of collection are nearly identical to large, linear dunes in Earth's sand seas of the Sahara, Arabia and Namibia [Lorenz et al. 2006; Radebaugh et al. 2008; Le Gall et al. 2011; Le Gall et al. 2012]. Such dunes on Earth typically form under bimodal winds [Fryberger and Dean 1979; Tsoar 1983]. A more recent model calls on a dominant, slightly off-axis wind and a secondary wind causing sand flux down the dune long axis [Courrech du Pont et al. 2014; Lucas et al. 2014].

Figure RADAR-9. Sand dunes on Titan appear as long, narrow, and SAR-dark features against a SAR-brighter substrate or interdune. Dunes on Titan as seen by the Cassini SAR, wavelength 2.17 cm, with spatial resolution of 350 m in the Belet Sand Sea, from the T61 (August 2009) swath on the equatorial leading hemisphere, at 11° S, 255° W. Dune surfaces are generally smooth and absorbing to SAR and thus typically, as here, appear as SAR-dark lines against a rougher and/or fractured, and thus radar- bright substrate, unless the RADAR is pointed directly at a dune face, in which case it appears as a thin, SAR-bright line. Occasionally the radar incidence is such as to give bright glints from dune slopes. The open arrows indicate the direction of SAR illumination and incidence angle. Figure from Radebaugh et al. [2013].

Regardless of whether the classical (bimodal) or fingering-mode dune growth mechanisms applies, a fundamental challenge raised by the RADAR observations of the dunes is the eastward direction of growth and sand transport [Lorenz et al. 2006; Radebaugh et al. 2010]. This contrasts with expectations that low-latitude near-surface winds should generally blow to the west. The solution appears to be that the dunes reflect strong but infrequent eastward winds, either associated with vertical mixing in the atmosphere at equinox leading to strong westerly gusts [Tokano 2010] or methane rainstorms having a similar effect [Charnay et al. 2015]. Additionally, convergence of the meridional transport predicted in models—for example, Lucas et al. [2014] can further explain why Titan's dunes are confined within ±30° latitudes, where sediment fluxes converge—see also Malaska et al. [2016a].

Titan's dune sands are not only dark to SAR but they are also some of the darkest materials seen by ISS [Porco et al. 2005; Karkoschka et al. 2017] and have a low albedo and "red" slope as seen by VIMS, thus comprising the VIMS dark brown spectral unit [Soderblom et al. 2007; Barnes et al. 2008; Clark et al. 2010; Rodriguez et al. 2014]. Volume scattering within the dunes is very low, consistent with smooth, homogeneous surfaces in general, and lacking large voids or clasts [Janssen et al. 2009; Le Gall et al. 2011], although modeling by Paillou et al. [2014] suggests shallow surface ripples and some volume scattering. The observations indicate the dunes cannot be composed of water ice, but rather must be made of organics, ultimately derived from photolytic processing of methane in the upper atmosphere, and precipitation to the surface [Lorenz et al. 2006, 2008a; Soderblom et al. 2007]. Sand sources could include river channels, as on Earth [Radebaugh 2013], low-latitude evaporite deposits, which can show similar VIMS properties [Barnes et al. 2011a]; or the mid-latitude blandlands, though it is more likely that sands are being transported there from the equatorial regions [Lopes et al. 2016; Malaska et al. 2016a]. The extent of the dunes indicates that sand has been generated on Titan in great volumes and transported by wind, and that processes have acted on the surface long enough to produce extensive and morphologically consistent landforms [Radebaugh 2013].

Gathering all exploitable SAR and HiSAR images since the start of the Cassini mission, Rodriguez et al. [2014] built a global map of the dune coverage available at that time, accounting for observations from TA to T92 flybys (from October 2004 to July 2013) and more than 30 individual RADAR SAR and HiSAR swaths. They evaluated that dunes cover 13 ± 2% of the 58.1% of Titan's surface observed with SAR and HiSAR, considering only those images having sufficient spatial resolution to identify individual dunes—that is, excluding HiSAR swaths with a resolution coarser than 2 km/pixel. In terms of latitudinal distribution, 99.6% of the imaged dunes are found within the equatorial belt (within ±30° latitudes—61.3% of which has been imaged after flyby T92. The overlapping of a VIMS global mosaic and the global distribution of dunes as seen by the RADAR highlights the strong correlation between the dunes and a specific infrared unit spectrally compatible with complex solid organics (the dark brown unit). This allowed an extrapolation of the dune geographic distribution to the entire spatial extent of the VIMS dark brown unit, even in locations where dunes are not seen because of lack of RADAR coverage, and extending the previously estimated total surface area of Titan covered by dunes up to ≈17% (≈14×10^6 km^2, 1.5 times the surface area of the Sahara desert on Earth), the same as early estimates from Lopes et al. [2010]. A simple calculation of the volume—for example, Lorenz et al.

[2008b]—indicates that dunes are a major surface reservoir of organics, probably originating from the atmosphere.

In addition to dunes, there are other aeolian features and landforms on Titan's surface. These are wind streaks and yardangs, or wind-carved ridges. The wind streaks are visible in ISS images as bright features that extend in the downwind direction from obstacles—for example, Porco et al. [2005]; Lorenz et al. [2006]; Malaska et al. [2016a]. They can be several tens of kilometers wide and long, can have flow-like, teardrop shapes, and appear as though wind has shaped the bright landscapes and deposited dark materials, likely sand, in the low regions downwind of the obstacles. These features help indicate the direction of the winds, which also broadly parallels the linear dunes seen in Cassini SAR images [Malaska et al, 2016a].

Deposits that are SAR-bright, circular in planform and likely elevated into small mounds or domes are found in some regions in the northern mid-latitudes [Lopes et al. 2016]. These domes are easily eroded as revealed by deep, badlands-like river channels that flow outwards from their centers. Cutting across the channels and the domes are a series of parallel, long lineation ~1 km wide, spaced by a few km, and tens of kilometers long [Paillou et al. 2016; Northrup et al. 2018]. They are similar in appearance and SAR brightness, radiometry and scatterometry to yardangs, or wind-carved ridges [Paillou et al. 2015]. These appear to have formed in easily eroded materials, similar to yardangs on Earth and Mars, and further indicate the action of wind at moderate to high latitudes now or in the past [Northrup et al. 2018].

IMPACT CRATERS

Before Cassini arrived at Saturn, the impact cratering history on Titan was unknown from direct observations. Estimates of the cratering rate were made by extrapolating the crater distributions observed on other Saturnian satellites, or by predicting impact rates by comet populations. Such estimates suggested that at least several hundred craters larger than 20 km in diameter should be present on Titan [Zahnle et al. 2003]. Impactors that would create craters smaller than 20 km in diameter are expected to be disrupted by Titan's atmosphere [Artemieva and Lunine 2005; Korycansky and Zahnle 2005]. Cassini RADAR observations show an extreme paucity of craters. Only 23 certain or nearly certain craters and ~10 probable craters >20 km in diameter have been observed on Titan, with a handful of smaller crater candidates [Wood et al. 2010; Neish and Lorenz 2012; Buratti et al. 2012; Neish et al. 2016]. This suggests that Titan has a crater retention age of several hundred million years [Wood et al. 2010; Neish and Lorenz 2012], with the oldest surfaces located near the equator and the youngest surfaces located near the poles [Neish et al. 2016].

The craters that are observed on Titan all show evidence for extensive modification by erosional processes (Figure RADAR-10). Channels are observed to cut through the ejecta blankets and floors of several impact craters [Wood et al. 2010; Soderblom et al. 2010; Neish et al. 2015]. Many of Titan's impact craters are located in its equatorial sand seas, and also show evidence for extensive infilling by sand [Wood et al. 2010; Le Mouelic et al. 2008; Neish et al. 2013]. In addition to the morphologic evidence for erosion and burial, Titan's craters are consistently shallower than similarly sized fresh craters on Ganymede (often by many hundreds of meters), suggestive of infill

[Neish et al. 2013]. Given the distribution of depths, aeolian infilling appears to be the dominant modification process on Titan [Neish et al. 2013], but fluvial erosion seems to play an important secondary role [Neish et al. 2016]. Modification by viscous relaxation is expected to be minimal given the cold lithospheric temperatures on Titan, although insulation by sand could enable some relaxation in Titan's larger craters [Schurmeier and Dombard 2018].

In addition to being highly modified, Titan's impact craters are not uniformly distributed across the moon. There is an almost complete absence of impact craters near Titan's poles, with the majority of the craters found in the topographically high, equatorial sand seas [Neish and Lorenz 2014]. There have been several hypotheses advanced to explain this observation. Neish and Lorenz [2014] proposed the lack of craters near Titan's poles might be indicative of marine impacts into a former ocean in this region. Moore et al. [2014] suggested that extreme climate change occurred in Titan's recent past, causing global methane rainfall that produced sediment that settled in Titan's topographically low polar regions, burying any craters there. Finally, Neish et al. [2016] suggested that an increased rate of fluvial erosion near the poles could degrade Titan's craters to the point where they would be unrecognizable from orbit. In any case, Titan's cratering record demonstrates that it is an extremely dynamic world, and studying its impact structures can reveal much about the processes that have shaped it.

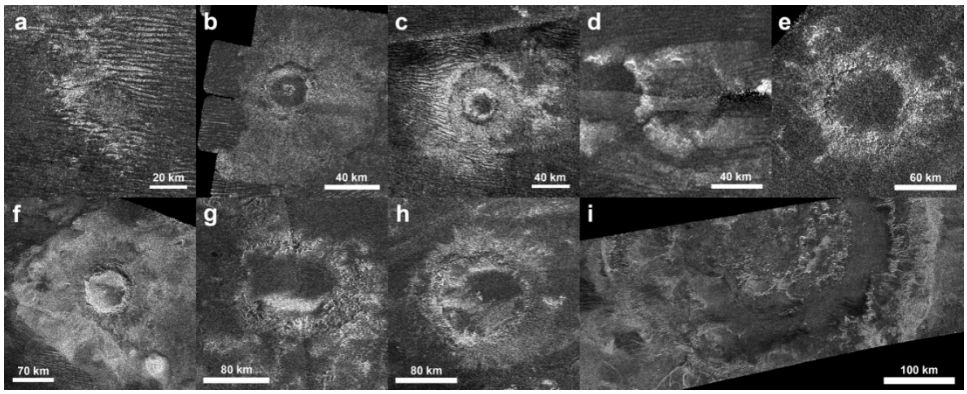

Figure RADAR-10. Nine probable impact craters observed on Titan by Cassini RADAR. From smallest (a) to largest (i) the impact craters on Titan show modification by exogenic processes such as fluvial erosion and infilling by sand [Neish et al. 2013].

MOUNTAINS AND TECTONICS

Features of relatively high topography, termed mountains, have been observed across Titan (Figure RADAR-11). Topography on icy satellites is rare, taking the form of, for example, impact crater rims, grooved terrain on Ganymede, or the towering scarps of Miranda. This is in part because water ice generally loses strength with increasing depth, making high topographies difficult to support. However, the exceptional amount of erosion on Titan may also be responsible for terrain height reduction. Overall, topography on Titan is rather subdued, having a range of just a few kilometers [Lorenz et al. 2013; Corlies et al. 2017]; nevertheless, there are features on the surface aside from impact crater rims that are elevated. These take the form of isolated blocks, chains, ridges, and elevated plateaus [Radebaugh et al. 2007]. Mountains of all types are SAR-bright due

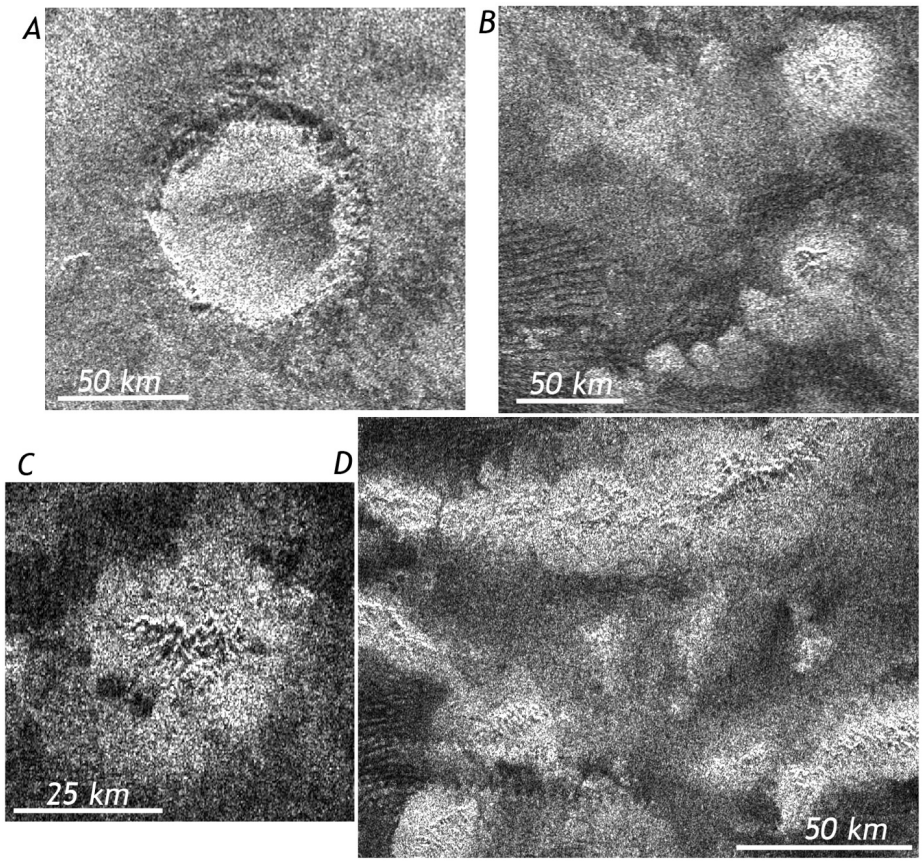

Figure RADAR-11. Some examples of mountains on Titan. Radar illumination is from the top in all cases, and north is up. Bright, possibly erosional, blankets surround the central, high elevation features visible as bright/dark pairs. A) Sinlap crater, shown to demonstrate the effects of radar illumination on a rimmed depression; B) Individual mountain blocks in the T3 swath south of Sinlap crater; C) Rugged mountain from the T3 swath; D) A portion of mountain ranges west of the Huygens landing site from the T8 swath. Figure from Radebaugh et al. [2007].

to the roughness and fractured nature of the materials, as well as the slope geometry with respect to the SAR antenna look direction and incidence angle. Mountains also exhibit high scattering and have a high emissivity as seen by RADAR [Janssen et al. 2009, 2016], and are part of the VIMS bright blue unit [Barnes et al. 2007], indicating a higher water-ice component, which is dominant in Titan's lithosphere.

Isolated mountain blocks are found only in a few select regions and tend to be several km across and a few hundred meters high as calculated from radarclinometry [Radebaugh et al. 2007]. More frequently, mountains are found in small belts near the middle and high latitudes. They are only few to tens of kilometers in length and a few hundred meters high. Mountain chains are the most areally extensive rugged features (aside from Xanadu) and are the most dramatic on the surface, being found dominantly at the equatorial regions and generally aligned E-W. They are up to several hundred kilometers in length, are arcuate in planform, and can be up to several kilometers high [Radebaugh et al. 2007; Radebaugh et al. 2016]. In Xanadu, there are extensive, mountainous and rugged terrains. These appear crenulated to SAR and exhibit multiple

overlapping peaks concentrated in regions over tens to hundreds of square kilometers. They are interspersed with lineations that indicate a regional tectonic fabric, likely extensional, given the straight nature of the lineations [Radebaugh et al. 2011]. All mountains on Titan are highly rugged and exhibit signs of extensive erosion from methane rainfall and possibly mass wasting. All mountain ridges and chains exhibit a preferential orientation [Cook-Hallett et al. 2015; Liu et al. 2016a] indicating internal tectonic forces operating on their formation. The equatorial mountain chains differ in morphology from long, narrow tectonic features on other icy satellites: they sit on elevated topography [Radebaugh et al. 2016], they are arcuate in morphology, and they have low slopes [Liu et al. 2016b]. This indicates they are more likely to have been created by contractional tectonism, by N-S directed forces in the interior and at the equator. Such thrust faulting could have been enabled by liquid methane within the crust, which could act to lubricate fault zones, much as occurs on Earth with water [Liu et al. 2016b]. A similar conclusion is reached for the mountain ridges north of Xanadu, which contain the highest peak on Titan at just over 3,300 m [Radebaugh et al. 2016]: that they were formed by contractional tectonism [Mitri et al. 2010]. Some very large-scale tectonic rises, several hundred kilometers across, may be topographic rises related to laccolithic activity [Schurmeier et al. 2017].

CRYOVOLCANISM

The possibility of finding cryovolcanic features on Titan had been discussed prior to Cassini by Lorenz [1993, 1996]. The case for cryovolcanism was strengthened by results from the Gas Chromatograph Mass Spectrometer (GCMS) instrument on board the Huygens probe, which detected the radiogenic isotope of argon in Titan's atmosphere [Niemann et al. 2005] in concentrations suggesting that the atmosphere was in communication with a reservoir of the parent atom. Prior to the first Titan flyby using RADAR, VIMS imaged a bright feature (later named Tortola Facula) that Sotin et al. [2005] proposed to be cryovolcanic in origin. However, SAR images obtained later in the mission showed Tortola Facula to be a local topographic high similar to others elsewhere on Titan [Lopes et al. 2013] and not a candidate for a cryovolcanic feature. Sotin et al. [2005] further suggested that the upwelling of large cryovolcanic plumes might be releasing sufficient methane into the atmosphere to account for the known atmospheric composition.

Cassini RADAR and VIMS revealed several features interpreted as formed by cryovolcanism [Barnes et al. 2006; Sotin et al. 2005; Lopes et al. 2007; Soderblom et al. 2009; Wall et al. 2009; Lopes et al. 2013; Solomonidou et al. 2016]. However, the interpretation has been the subject of some debate—for example, Moore and Pappalardo [2011]—and has not been entirely resolved by Cassini data [Nixon et al. 2018], primarily due to limitations in spatial resolution and coverage. The cryovolcanic interpretations by RADAR (using several data sets including SAR, stereogrammetry [Kirk et. al. 2010], SARTopo, and radiometry) and VIMS (surface albedo retrievals, surface composition constraints, and temporal variations) are based on morphology, differences in surface albedo between the cryovolcanic areas, their surrounding terrains and several other geomorphological features, and temporal variations detected by VIMS [Barnes et al. 2005; Solomonidou et al. 2014, 2016, 2018]. However, the Cassini mission did not reveal any hot spots, i.e., thermal enhancements, that would have provided conclusive proof. The detection of thermal activity at Titan’s surface using radiometry data (which is sensitive to variations of ~1K) or VIMS,

would require Cassini's instruments to be observing the right locations at the right times and in multiple occasions, an unlikely scenario given the consensus that cryovolcanic candidate features are not ubiquitous on Titan [Lopes et al. 2010].

Landforms considered as possibly cryovolcanic include flow-like terrains seen on the western margin of Xanadu [Wall et al. 2010], spectrally different regions in Tui Regio [Barnes et al. 2005] and tangled flow regions in Hotei Regio [Soderblom et al. 2009; Wall et al. 2010]. These flow-like morphologies even exhibit elevated, lobate margins typical of flows. Other possible cryovolcanic features are the steep-sided, small lakes at the north polar region (see section entitled Lakes). These landforms have slightly elevated rims, steep sides, flat floors, and deposits diffuse to SAR surrounding them. All of these characteristics are typical of maar craters on Earth [Wood et al. 2007] though they are also generally consistent with dissolution and sublimation-related features [Hayes et al. 2017].

The strongest evidence for cryovolcanic features on Titan was put forward by Lopes et al. [2013] who combined SAR imaging (including stereogrammetry, Figure RADAR-12) and VIMS data (Figure RADAR-13) for a region that includes two mountains, Doom Mons (40.4° W, 14.7° S) and Erebor Mons (36.2° W, 5.0° S), as well as a depression, Sotra Patera (40.0° W, 14.5° S), and a region consisting of flow-like features, Mohini Fluctus (centered at 38.5° W, 11.8° S). Doom and Erebor Montes are tall mountains (Doom being ~70 km in diameter and 1.5 ± 0.2 km high,), Sotra Patera is

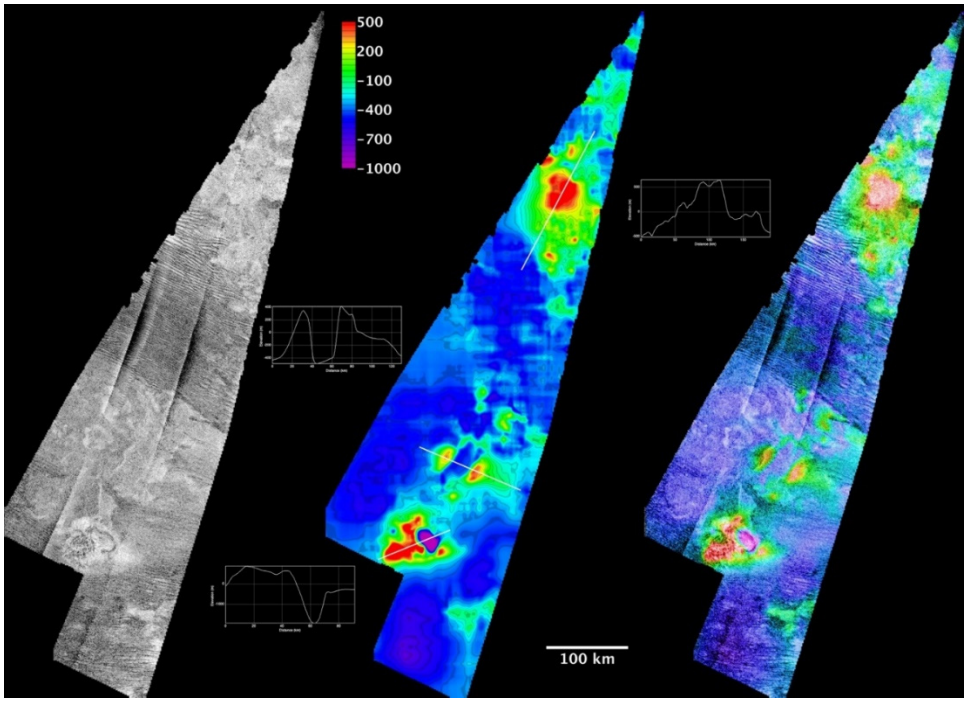

Figure RADAR-12. Topography of Doom Mons, Sotra Patera and (at the top) Erebor Mons region from SAR stereo. The image on the left is SAR over the region. The central image shows a color-coded DTM (scale shown), with the tops of Doom and Erebor Montes being the highest points, the white lines show the locations of the three profiles shown. The SAR and DTM are merged at the right. Figure from Lopes et al. [2013].

the deepest depression found on Titan (1.7 ± 0.2 km deep, relative to surrounding terrain). It is non-circular and interpreted as a collapse feature adjacent to Doom Mons (Figure RADAR-13). Mohini Fluctus appears to emerge from Doom Mons. Other non-circular, collapsed depressions are located between the two Montes, and flow-like features also surround Erebor Mons.

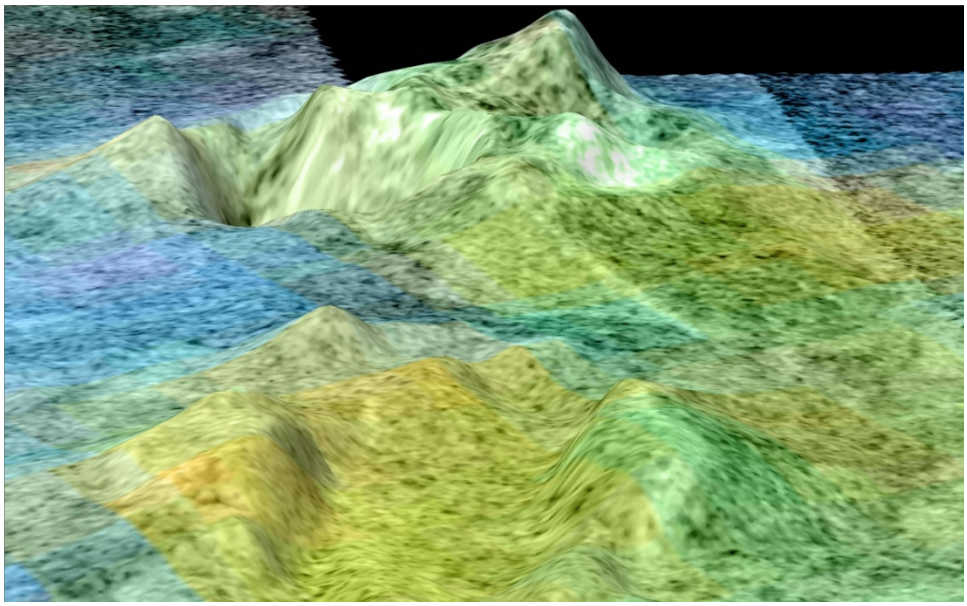

Figure RADAR-13. Perspective view of Doom Mons and Sotra Patera. This 3-D image was obtained by combining a digital topographic model (produced from two SAR swaths) and VIMS data showing compositional differences in representative color, which shows that the dune fields (in blue) are of a different composition from the candidate cryovolcanic materials in shades of green and yellow. The image shows one of the tallest peaks on Titan, Doom Mons, which is ~70 km in diameter and 1.5 ± 0.2 km high. Doom Mons is adjacent to the deepest depression so far found on Titan, Sotra Patera, an elongated pit ~30 km in diameter and 1.7 ± 0.2 km deep. The DTM data have a vertical exaggeration of 10:1. A movie showing the whole region can be seen at http://photojournal.jpl.nasa.gov/catalog/PIA13695.

A criticism by Moore and Pappalardo [2011] of initial interpretations by RADAR of cryovolcanic candidates reported by Lopes et al. [2007] is that flow-like features could have been produced by fluvial activity, since channels are seen in areas such as Hotei Regio and Ganesa Macula (which topography later obtained by RADAR showed it was not a shield or dome as initially interpreted). However, the Doom Mons-Sotra Patera-Erebor Mons region is totally devoid of visible fluvial channels, making a fluvial origin for Mohini Fluctus and other flows unlikely. A vast dune field is located between Doom and Erebor Montes, indicating a dry region. The depressions seen in the region, including Sotra Patera, are not circular, are very deep, and are therefore unlikely to have had an impact origin [Lopes et al. 2013]. VIMS data analysis has contributed to the cryovolcanic interpretation via two different types of investigation. First, analysis of VIMS data using a radiative transfer model [Solomonidou et al. 2014] showed that the surface albedo of the candidate cryovolcanic features is different from that of plains or dunes, indicating differences in composition [Solomonidou et al. 2014]. Following this and again using a radiative transfer model on a large selection of VIMS data, Solomonidou et al. [2016] revealed temporal changes for the Sotra Patera

and Mohini Fluctus areas, which became brighter up to a factor of two in terms of pure surface albedo and brightness during one year (2005–2006), while surrounding areas and the undifferentiated plains and dunes did not present any significant change for the same period of time. The surface albedo variations, together with the presence of volcanic-like morphological features consistent with volcanism, suggest that the regions might be active and possibly connected to the deep interior via cryovolcanic processes. Additional support for cryovolcanic origin of these features comes from interior structure models of Titan and corresponding calculations of the spatial pattern of maximum tidal stresses [Sohl et al. 2014], which indicate that the Doom Mons-Sotra Patera-Erebor Mons area is a likely region for cryovolcanic activity.

LABYRINTH

The enigmatic labyrinthic terrains of Titan are defined as elevated highly-dissected plateaus with intersecting valleys or remnant ridges of low to medium backscatter with a generally >5,000 km^2 extent [Malaska et al. 2010; Moore et al. 2014; Malaska et al. 2016b; Malaska et al. 2017a]. The Katain Labyrinth (Figure RADAR-14) is a typical example. SARTopo suggests that labyrinth terrains are among the locally highest units on Titan [Stiles et al. 2009]. Often the valley floors contain radar-dark floors or fill. The valley and upland widths are variable: in areas where the valleys are narrow and the intervening uplands (or valley spacing) are wide, the terrain appears in the form of a dissected plateau; when the widths of the valleys and the widths of the intervening plateaus are about equal, the terrain appears as a series of valleys and intervening plateaus; and when the valleys are wide and the widths of the intervening plateaus are small, the terrain can appear as a series of remnant ridges. Closed valleys may also be present, although this may be a misinterpretation due to the coarse resolution of the Cassini RADAR.

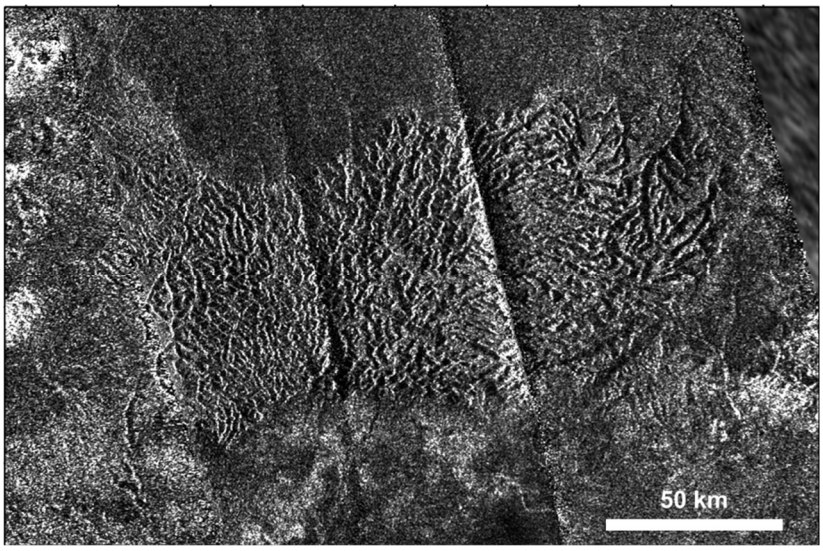

Figure RADAR-14. SAR image of Katain Labyrinth. The highly dissected feature at center is Katain Labyrinth. SAR illumination is from right (large straight lines through center are SAR artifacts due to beam overlap). Sinusoidal projection centered at 349 W. North is at top.

Wide valleys may appear suddenly in the plateaus, suggestive of amphitheater-headed valleys. The overall planforms of the labyrinth terrain units are circular, ovoid, or tabular. The valley density at a scale of 300 m/pixel is above 0.02, significantly higher than the density of valley networks described elsewhere on Titan such as the network in western Xanadu [Burr et al. 2009]. The valley networks inside the labyrinth units are rectangular to dendritic, suggesting varying amounts of structural and topographic control. Some of the more circular planform labyrinths have valley or ridge networks that are radial, extending away from the center of the region, suggesting that doming occurred prior to erosion, possibly as a result of a liquid water laccolith injection at depth [Shurmeier et al. 2017, 2018]. At the terminus of the valley networks and in contact with the labyrinths, undifferentiated plains units are found, suggesting a close connection between the two types of units, at least at the local scale.

The labyrinth terrains are composed almost wholly of a possibly uplifted thick plateau of organic materials, with very little water ice materials present.

The labyrinth terrains are composed almost wholly of a possibly uplifted thick plateau of organic materials, with very little water ice materials present. The emissivity data shows that labyrinth terrains have significantly higher emissivity than mountain and hummocky terrains and have similar emissivities to dunes or undifferentiated plains. The microwave data are consistent with the labyrinths being composed of low dielectric organic materials and are not consistent with materials containing significant amounts of water ice.

The labyrinths were likely formed from the uplifted plateaus through a combination of dissolution coupled with mechanical erosion, or other phase changes that could allow the development of closed valleys with transport of the remaining materials to the outlying plains. Karstic dissolution is a likely scenario, and many of the labyrinth terrains have morphologic analogs with terrestrial karst terrains [Malaska et al. 2010]. Theoretical predictions and laboratory work have shown that organic materials on Titan may dissolve when exposed to Titan hydrocarbon rainfall or liquids [Raulin 1987; Lorenz and Lunine 1996; Cordier et al. 2009; Malaska et al. 2011a; Glein and Shock 2013; Malaska and Hodyss 2014; Cornet et al. 2015; Cornet et al. 2017]. Dissolution geology on Titan may create a landscape that is similar to terrestrial karst terrain present in water-soluble materials such as limestone and gypsum on Earth [Malaska et al. 2011a; Malaska and Hodyss 2014; Cornet et al. 2015]. Preliminary modelling by Cornet et al. [2017] suggests that blocks of Titan soluble materials could dissolve under Titan conditions to form the features observed by SAR that are similar to polygonal karst. The evolution sequence begins with incised valleys in a plateau, then widening to form the end-stage wide-floored remnant ridges. Type examples of each stage are found in close proximity near Sikun Labyrinth in Titan's south polar terrain and are shown in Figure RADAR-15. However, other formation scenarios are possible, including differential hardening and deflation, aeolian deflation, or other phase change and removal processes such as sublimation. From superposition relations, the organic labyrinths represent an ancient terrain [Malaska et al. 2016b]. Thus, the labyrinth terrains unit represents a significant deposit of organic materials on Titan, and suggests that significant organic deposition, lithification, and uplift/exposure occurred early in Titan's history.

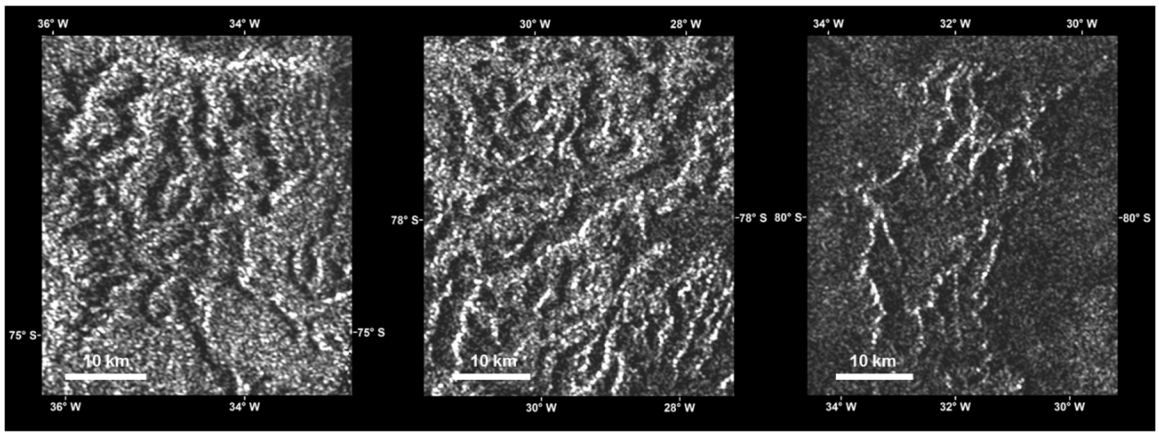

Figure RADAR-15. SAR images of different types of labyrinth terrains found in close proximity in Titan's south polar terrain. Left: Naraj Labyrinth, represents thin valleys incised in a plateau, Center: Sikun Labyrinth, represents valleys and plateaus of near equal width, Right: Tupile Labyrinth, a type example of remnant ridge. Sinusoidal projection. North is at top.

Xanadu

Much of Titan's geology has a regional organization; dunes and mountain belts are found near the equator, lakes and seas are found near the poles, and relatively bland regions are located in the mid-latitudes [Lopes et al. 2010]. Xanadu (Figure RADAR-16), however, is a continent-sized region that breaks with all predictions. It is 4,000 × 2,500 km wide, is located on Titan's leading hemisphere, and interrupts the equator-encircling sand seas. The feature was observed before Cassini arrived [Lemmon et al. 1993; Smith et al. 1996], and efforts were made to observe and understand Xanadu by Cassini SAR and other instruments. Xanadu is generally SAR-bright, which indicates it is composed of rough and fractured terrains [Radebaugh et al. 2011]. It has a high backscatter but low brightness temperature as indicated by scatterometry and radiometry measurements, which is consistent with a water-ice composition in the bedrock [Wye et al. 2007; Zebker et al. 2008; Janssen et al. 2009, 2016]. Furthermore, some portions of Xanadu are correlated with the VIMS dark blue unit, indicating there is a higher than average percentage of water-ice exposed at the surface [Barnes et al. 2007].

Xanadu is unique in several respects to other regions on Titan. While geologically diverse, many regions in Xanadu have extremely rugged terrains, manifest as many adjacent, deeply eroded, and incised mountain ranges [Radebaugh et al. 2011]. There are broad scale linear features characteristic of NE-SW and NW-SE extensional tectonism, and broadly arcuate mountain ranges indicative of N-S directed contractional tectonism [Radebaugh et al. 2011]. These features all indicate a long and complicated tectonic history for Xanadu. Extensive, dendritic networks of varying morphologies [Burr et al. 2009], large channels that distribute fans and cobbles to the south [Le Gall et al. 2010], and the extensive erosion of the mountains also reveal a long erosional history. Over twice as many impact craters or possible impact craters can be found in Xanadu as on the rest of Titan [Wood et al. 2010; Radebaugh et al. 2011], which is further evidence of the generally old nature of Xanadu compared with the rest of the surface of Titan [Radebaugh et al. 2011; Wood

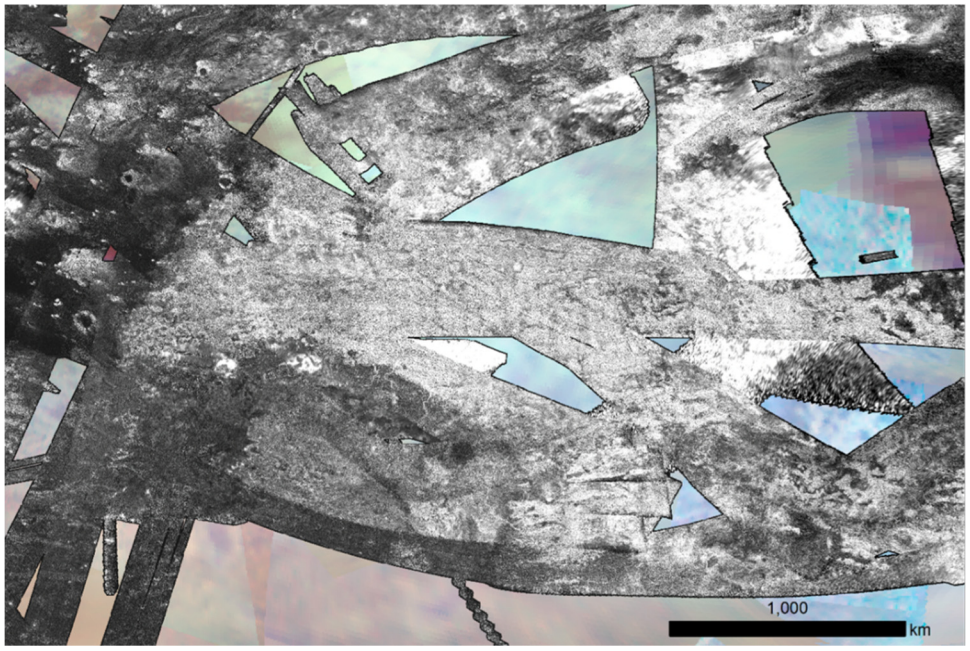

Figure RADAR-16. Xanadu region. All Cassini SAR and HiSAR image swaths covering the Xanadu region, overlain on a VIMS basemap. Xanadu is generally SAR-bright because of rough terrain and fractured ice, which is interspersed with valleys filled with SAR-darker sediment. Some regions of Xanadu are VIMS dark blue, consistent with the presence of exposed water ice. The southwest margin of Xanadu has large river channels emptying to the south.

et al. 2010]. A region of mottled terrain is found on the western margin, with arcuate depositional morphologies and lack of integrated drainage, postulated to be a possible cryovolcanic deposit [Wall et al. 2009]. These morphologies are consistent with other possible cryovolcanic zones in Hotei Regio, bordering Xanadu's southern margin [Soderblom et al. 2009]. These landforms may instead be related to swamp-like deposits entirely fluvial in origin, but they are unique and not widespread.

Xanadu's most puzzling characteristic is that despite the abundance of mountains and high local topographic differences, the region as a whole appears to be regionally lower in elevation than anywhere else near the equator [Zebker et al. 2009a; Stiles et al. 2009]. This is evidenced by radar altimetry measurements as well as SARTopo observations [Stiles et al. 2009]. It is possible that after a time period of mountain-building and contraction, there was gravitational collapse of the water ice crust [Mitri et al. 2010], resulting in broad extensional tectonism and down-dropping of Xanadu [Radebaugh et al. 2011]. This scenario might have led to Xanadu-bounding fault zones, along which the possible cryolavas of western Xanadu and Hotei in the south could have ascended [Radebaugh et al. 2011].

What could have driven this N-S directed contractional tectonism is unknown but might have resulted from global contraction related to interior cooling, tidal spin-up or spin-down, or internal convection [Radebaugh et al. 2011]. Another scenario hypothesized for the formation of Xanadu

involves a large impact event early in Titan's history, leaving behind a disrupted terrain [Brown et al. 2011].

Several outstanding questions about Xanadu remain, in addition to its origin: Why is it regionally depressed? Why do the dunes of the equatorial sand seas not cover and fill Xanadu? Why is water ice more exposed here than in most other places on Titan? Much remains to be learned about this unusual region.

Lakes

While ISS revealed ~50 dark features poleward of 70° S during one of Cassini's first observations of Titan, these features were not initially referred to as lakes as they could not be distinguished from dark equatorial dune fields at optical wavelengths [Porco et al. 2004]. The first high-resolution and definitive observations of Titan's hydrocarbon lakes were acquired by the RADAR in July 2016 (T16), when ~75 features with exceptionally low backscatter, high emissivity, and distinctly lacustrine morphology were identified in SAR images [Stofan et al. 2007]. Subsequent observations have revealed more than 650 such features, both dry and filled, scattered throughout Titan's polar terrain [Hayes et al. 2008; Birch et al. 2017]. These features have diameters that follow a log-normal distribution with a median of 77 ± 20 km [Hayes et al. 2016]. The morphology of both dry and filled lakes and seas on Titan provide a record of past and current climatic conditions and surface evolution processes. For example, while Titan's large seas have complex shorelines that are consistent with drowning of pre-existing topography, most of the smaller lakes are steep-sided depressions that are more consistent with dissolution-based erosion driven by karstic processes [Hayes et al. 2017; Cartwright et al. 2011; Langhans et al. 2012]. For a recent and more detailed review of Cassini's exploration of Titan's lakes and seas, see Hayes et al. [2016].

Lakes and seas encompass 1% of Titan's total surface area [Hayes et al. 2016]. The majority of surface liquids (97% by area) reside in the north polar region, with 80% of all liquid-filled surface area contained in three large seas; Kraken Mare, Ligeia Mare, and Punga Mare (Figure RADAR-17; note that the coloration in this figure is artificial). The largest modern liquid body in the south polar region is Ontario Lacus, although several large empty basins that encompass an area similar to the northern maria (7.6×10^5 km^2) have been identified and interpreted as paleoseas [Hayes et al. 2010, 2011; Birch et al. 2018b]. The observed dichotomy in lake distribution has been attributed to a net transport of ~5×10^{14} kg of methane per Titan year from the South Pole to the north, driven by a seasonal asymmetry in solar insolation that is the result of Saturn's eccentric orbit around the sun [Aharonson et al. 2009; Lora and Mitchell 2015]. Summer solstice in Titan's southern hemisphere occurs near perihelion while northern summer solstice occurs at aphelion, resulting in 25% higher peak insolation during southern summer as compared to northern summer. Long timescale (~100,000 year) orbital cycles can switch the direction and magnitude of the seasonal asymmetry driving this transport, moving liquid deposits between the poles similar to the way Croll-Milankovitch cycles drive ice ages and other long-term climate effects on Earth [Aharonson et al. 2009]. The presence of drowned river valleys at the terminus of channels flowing into the northern seas [Stofan et al. 2006], as well as the presence of exposed and abandoned river deltas adjacent

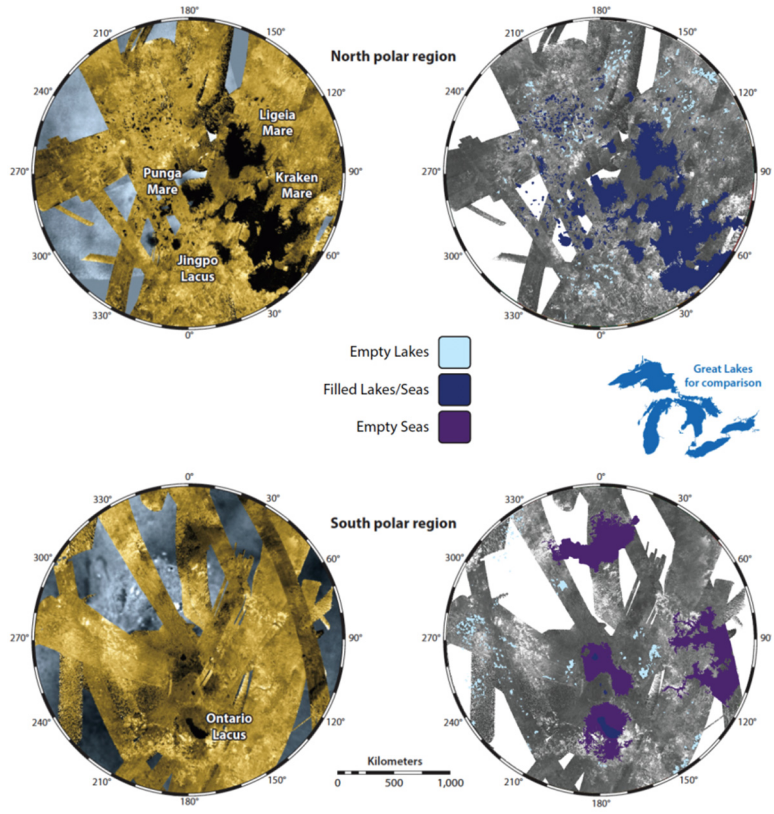

Figure RADAR-17. Map of lakes and seas on the northern (top) and southern (bottom) polar regions of Titan.

to the shores of southern Ontario Lacus [Wall et al. 2009], support the theory of rising and falling liquid levels as the magnitude and direction of net pole-to-pole methane transport varies with Titan's orbital cycles [Lora et al. 2014].

While a few small lakes have been observed to disappear or brighten in both the north and south over the 13 years of Cassini observations, no large-scale changes in the sea shorelines have been observed over the course of the mission. Given the resolution of the RADAR, however, this is not surprising. Although confirmed and stable liquid deposits are currently restricted to polar terrain, the equatorial features Hotei and Tui Regiones have been interpreted as possible low-latitude paleoseas [Moore and Howard 2010]. Both regions are surrounded by fluvial networks that appear to converge on a field of radar-bright, lobate, depressions that are morphologically similar to high-latitude lakes [Moore and Howard 2010]. Dark flow-like features identified adjacent to the radar-bright depressions have been interpreted as cryovolcanic deposits [Barnes et al. 2006; Wall et al. 2009], suggesting that both paleo-lakes and cryovolcanic flows may be present at Tui Regio and Hotei Regio [Lopes et al. 2013]. The existence of modern equatorial lakes has been proposed based on the longevity of low albedo localities observed by Cassini VIMS [Griffith et al. 2012; Vixie et al. 2015], although none of these features have been observed in higher-resolution SAR or altimetry datasets of the regions. Ample evidence exists (e.g., at the Huygens landing site) for at least transient liquids at low latitudes, and very flat areas exist that may be lake beds. Indeed, strong specular reflections

were observed at low latitude by the Arecibo radar on Earth (the longest-range radar astronomy experiment conducted to date) before Cassini's arrival, and the favored interpretation at the time was as extant bodies of smooth liquid hydrocarbons [Campbell et al. 2003]. A recent reinterpretation of the Arecibo returns is in progress at the time of this writing [Hofgartner et al. 2014b].

In May 2014, the RADAR acquired nadir-pointed altimetry over Ligeia Mare. The resulting altimetry echoes revealed waveforms that displayed two distinct returns, one from the surface of Ligeia Mare and one from its seabed [Mastrogiuseppe et al. 2014]. The difference in the received timing between these returns was a direct measure of Ligeia's depth (Figure RADAR-18), while the relative intensity difference between the surface and subsurface return was a measurement of the liquid's loss tangent (i.e., absorbance). While several studies—for example, Brown et al. [2008]; Lorenz et al. [2008a]; Lunine and Lorenz [2009]; Cordier et al. [2012]; Cornet et al. [2012]; Ventura et al. [2012]—have used indirect measurements to constrain the depth of Titan's lakes and seas, the altimetry observations over Ligeia represent the first direct measurement of extraterrestrial bathymetry profiles. Following the identification of Ligeia Mare's seabed, several passes of Titan were modified to repeat the experiment over Punga Mare and Kraken Mare [Mastrogiuseppe et al. 2016]. A reprocessing of altimetry data acquired over Ontario Lacus in December 2008 allowed the technique to be applied to Ontario Lacus as well [Mastrogiuseppe et al. 2018]. Ligeia Mare was determined to have a depth of 170 m at the deepest point along the observed track [Mastrogiuseppe et al. 2014] and, in combination with SAR images, the total volume of the basins was found to be around 14,000 km^3 of liquid [Hayes et al. 2016]. The estimated Ku-band loss tangent was $4.4 \pm 1 \times 10^{-5}$ [Mastrogiuseppe et al. 2016]. Assuming a methane-ethane-nitrogen composition and using the laboratory measurements of Mitchell et al. [2015] with the Lorentz-Lorenz formulation, the best-fit loss tangent is consistent with a methane-dominated composition of 71% CH_4: 12% C_2H_6: 17% N_2. As large quantities of liquid ethane should have been produced by photolysis of methane in the upper atmosphere, and as at least trace amounts of ethane have been detected in Ontario Lacus [Brown et al. 2008], the lack of significant ethane—and other higher order hydrocarbons such as propane—in Titan's lakes and seas requires that the ethane be sequestered in reservoirs (e.g., subsurface liquid deposits or sequestration in crustal clathrate hydrate).

To within error, the loss tangents of Punga Mare and the shallower parts of Kraken Mare (Figure RADAR-18) suggested a similar composition to Ligeia [Mastrogiuseppe et al. 2018]. Along most of Kraken Mare the seafloor was not detected, indication that the seas are either too deep or too absorptive in these areas. Within Punga Mare, a clear detection of the subsurface was observed up to 120 m along-track [Mastrogiuseppe et al. 2018]. At Ontario Lacus, however, the loss tangent was observed to be greater ($7 \pm 3 \times 10^{-5}$), consistent with a composition of ~47% CH_4, ~40% C_2H_6, and ~13% N_2,and suggesting an increased abundance of high-order hydrocarbons as compared to the northern seas. This higher loss tangent could be related to an increased abundance of more involatile hydrocarbons and/or nitriles or suspended particulates that represent a lag deposit generated as methane is transported from the south to the north over multiple seasonal cycles. The final RADAR observation of the bathymetry campaign was the T126 (April 22, 2017) final flyby of Titan, which observed several small-to-medium size (10–50 km) hydrocarbons lakes present at the northern polar terrain, revealing that such lakes can exceed one hundred meters of depth and have similar loss tangents, and therefore composition, to the northern seas. When the bathymetry

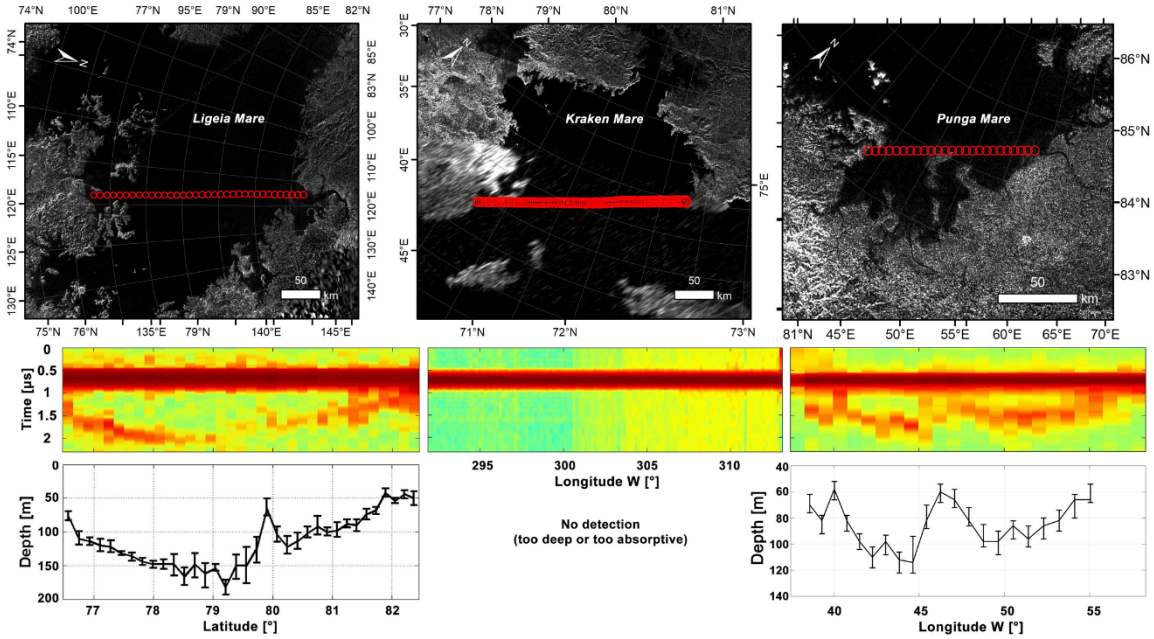

Figure RADAR-18. SAR mosaics, radargrams, and relative bathymetries (respectively in the upper, middle, and bottom panels) relative to the flyby T91 over Ligeia Mare (left), the flyby T104 over Kraken Mare (center), and the flyby T108 over Punga Mare (right) altimetry observations. Note that seafloor echoes have been detected for Ligeia and Punga Maria, while only surface returns are present over the open sea of Kraken Mare.

measurements are used to anchor models of sea and lake depth from SAR images, the estimated volume of all Titan's observed lakes and seas is ~70,000 km^3 [Hayes et al. 2016]. It is interesting to note that this represents only 1/7 the amount of methane that currently resides in Titan's atmosphere, suggesting that the lakes and seas do not drive global-scale heat transport or meteorology. It is also worthwhile mentioning that measuring the bathymetry and microwave absorptivity of Titan's seas was not planned initially and represents an exciting discovery made during the Cassini spacecraft lifetime.

T126 data (together with previous passes) revealed that some of the northern lakes have raised rims. Recent analysis of these features have produced different hypotheses for their origins [Birch et al. 2018a; Mitri et al. 2019].

RIVERS/CHANNELS

When water falls to the surface of the Earth, the most visible conduits on its journey downslope are networks of fluvial channels that slowly transport it toward the oceans. These networks take on many different forms that are the result of the mechanical and chemical properties of the surface [Burr et al. 2006], the climate and weather that generate fluid flow, and the mechanisms that produce topographic relief [Black et al. 2017]. The observation of channels on Titan by Cassini and Huygens [Collins 2005; Lorenz et al. 2008c; Lunine et al. 2008; Burr et al. 2009; Black et al. 2012; Burr et al. 2013] has thus provided similar constraints on the nature of Titan's surface and the

climatic conditions that proved favorable for the formation of these features, albeit in a far more limited fashion.

Cassini's RADAR imaged large portions of the moon and showed that valley networks are distributed at all latitudes [Lorenz et al. 2008c; Burr et al. 2009; Lopes et al. 2010] and have a wide variety of surface morphologies (Figure RADAR-19). Cassini has observed canyon networks at the poles with a diversity of valley networks analogous to Earth [Poggiali et al. 2016], including both dendritic and rectilinear networks globally [Burr et al. 2013], and even a meandering like feature in

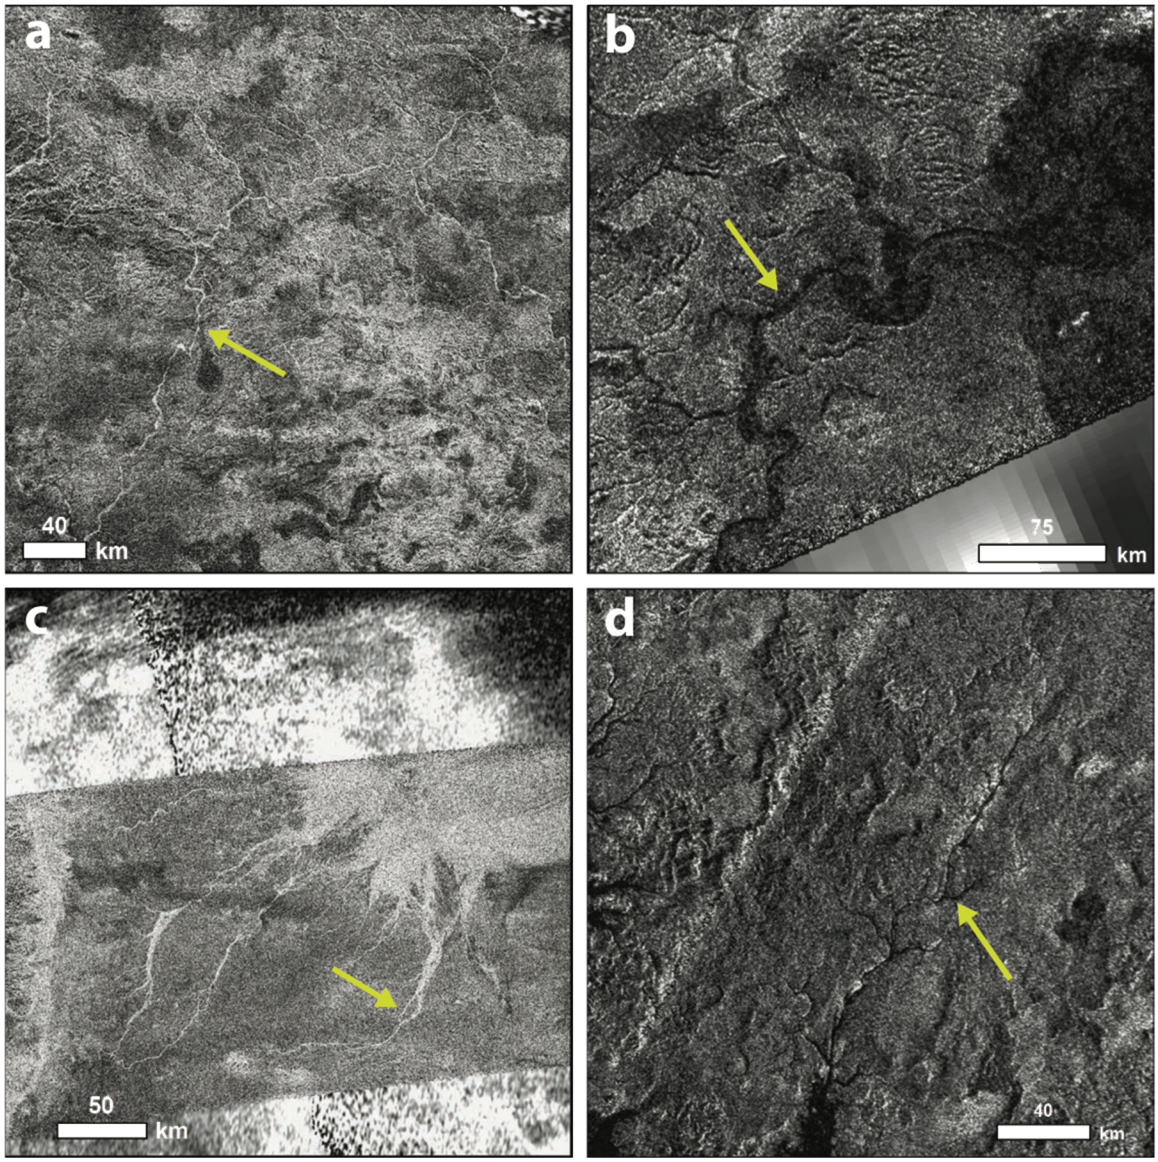

Figure RADAR-19. Erosions on Titan. (a) Rectilinear networks in eastern Xanadu; (b) Celadon Flumina, a meandering network near the South Pole; (c) Elvigar Flumina, a braided network that deposits into an alluvial fan; (d) Vid Flumina, a dendritic canyon network up to 500 m deep that drains into Ligeia Mare.

the south polar region [Malaska et al. 2011b; Birch et al. 2018b]. The presence of canyons implies a vertically weak bedrock, which may be influenced by fractures in the crust and/or a relatively highly erodible material. Similarly, rectilinear channels imply a fractured bedrock, where channels are forced to follow tectonically controlled paths of weakness. Meandering networks, meanwhile, imply the presence of a cohesive substrate [Howard et al. 2009]. A critical unknown following the Cassini mission, however, is whether there are any systematic variations in morphologic type that may be indicative of crustal heterogeneities [Burr et al. 2013] and/or variations in transport efficiencies/climate change [Moore et al. 2014].

Due to the coarse resolution of the Cassini RADAR, we have been limited to studying only the largest valley networks on Titan. We therefore have a limited idea about the extent to which Titan's landscapes are dissected by fluvial networks. The one exception to this was the region where the Huygens lander descended, where descent images, with an order-of-magnitude higher resolution [Tomasko et al. 2005], showed a highly dissected network of dendritic valleys [Perron et al. 2006]. It is likely that Titan is dissected everywhere at the scale observed by Huygens, however, a definitive answer to this question requires image data and topography with a resolution finer than the scale of fluvial dissection (10s of meters).

While it is not surprising that Titan has a global network of fluvial valleys, the mere presence of channelized flow conduits implies that the surface material can be eroded either physically or chemically, and that flows of sufficient magnitude, either from precipitation or groundwater, are able to erode Titan's surface. However, using estimates for the initial topography and erodibility of the substrate, channels may be very inefficient agents of erosion on Titan [Black et al. 2012] or there may be a gravel lag deposit that inhibits erosion under Titan's current climate [Howard et al. 2016]. Better estimates for the physical and chemical properties of both the bedrock and the fluid(s) [Burr et al. 2006; Cordier et al. 2017; Malaska et al. 2017a; Richardson et al. 2018] are needed to provide better understanding about the role that fluvial channels have played in sculpting Titan's surface.

In some locations, fluvial channels terminate in alluvial or fluvial fans—distributary landforms that indicate a transition from a high to a low elevation [Radebaugh et al. 2017; Birch et al. 2017]. These are fairly low in slope, and in some cases can run out to large distances, indicating the carrying power by methane fluid of organic sedimentary rock [Radebaugh et al. 2017]. These landforms are widely distributed across the surface, but they are not abundant [Birch et al. 2017]. This may indicate there is not frequent rainfall that can generate surface erosion, or that topographic gradients are gentle on a global scale such that these landforms are not readily generated.

Temporal change

Temporal changes were detected on Titan during the course of the Cassini mission, due to seasonal or other effects. Data from more than one instrument are key for determining the possible causes of change. For example, as mentioned in the section entitled Cryovolcanism, the radiative transfer code analysis of VIMS data from Tui Regio (2005–2009) and Sotra Patera (2005–2006) showed temporal surface albedo changes in two areas identified by SAR as cryovolcanic

candidates: Tui Regio darkened by 50% and Sotra Patera brightened by a factor of 2 [Solomonidou et al. 2016]. These changes could be due to endogenic and/or exogenic processes, possibly cryovolcanism or atmospheric deposition.

Magic Islands

For the majority of the Cassini mission, Titan's lakes and seas were observed to be quiescent, with no temporal changes and maximum vertical surface roughness on the order of millimeters [Barnes et al. 2011b; Stephan et al. 2010; Wye et al. 2009; Zebker et al. 2014; Grima et al. 2017]. This lack of observable surface roughness has been attributed to a seasonal effect in which polar winds were too weak to create waves or other dynamic features [Hayes et al. 2013]. As the northern hemisphere transitioned from spring equinox to summer solstice, temporal changes were observed in all three of Titan's seas. Specular reflections offset from the geometric specular point were observed by VIMS in Punga Mare [Barnes et al. 2014], transient bright features were observed by RADAR in Ligeia Mare [Hofgartner et al. 2014a, 2016], and both offset specular reflections and transient radar-bright features were observed in Kraken Mare [Hayes et al. 2016].

The transient bright features were nicknamed "Magic Islands" due to their appearing/disappearing act and similarity in appearance to islands in SAR images.

The transient radar-bright features were nicknamed "Magic Islands" due to their appearing/disappearing act and similarity in appearance to islands in SAR images. The features are not islands, however, and are most consistent with waves, or floating and/or suspended solids and bubbles. Based on the frequency of these phenomena in analogous terrestrial settings, wind-driven waves (intended to mean roughness of the liquid surface regardless of the process causing the roughness) are the most probable hypothesis. Tides, changes of sea level, and changes of the seafloor are unlikely to be the primary cause of the temporal changes. Magic Islands were observed in three regions; two in Ligeia Mare [Hofgartner et al. 2014a, 2016] and one in Kraken Mare [Hayes et al. 2016].

Figure RADAR-20 shows the time evolution of the first and most observed Magic Island region. This region was observed to have Magic Islands on two occasions; the transient bright features were in the same location on both occasions but differed in areal extent and morphology. HiSAR and VIMS observations acquired between the two SAR detections did not detect Magic Islands, however, the possibility that the Magic Islands were present but not detected in these observations could not be ruled out. Magic Islands were definitely not present in SAR observations before the first appearance and after the second appearance (Figure RADAR-20 includes a subset of the images of the region).

The Kraken Magic Island was also observed as a 5-micron sunglint by VIMS within two hours after the radar detection. The co-detection of the Kraken Magic Island by both RADAR and VIMS

suggests that it is likely caused by surface waves, as the reflecting facets must be smooth at both microwave and micron length scales [Hayes et al. 2016].

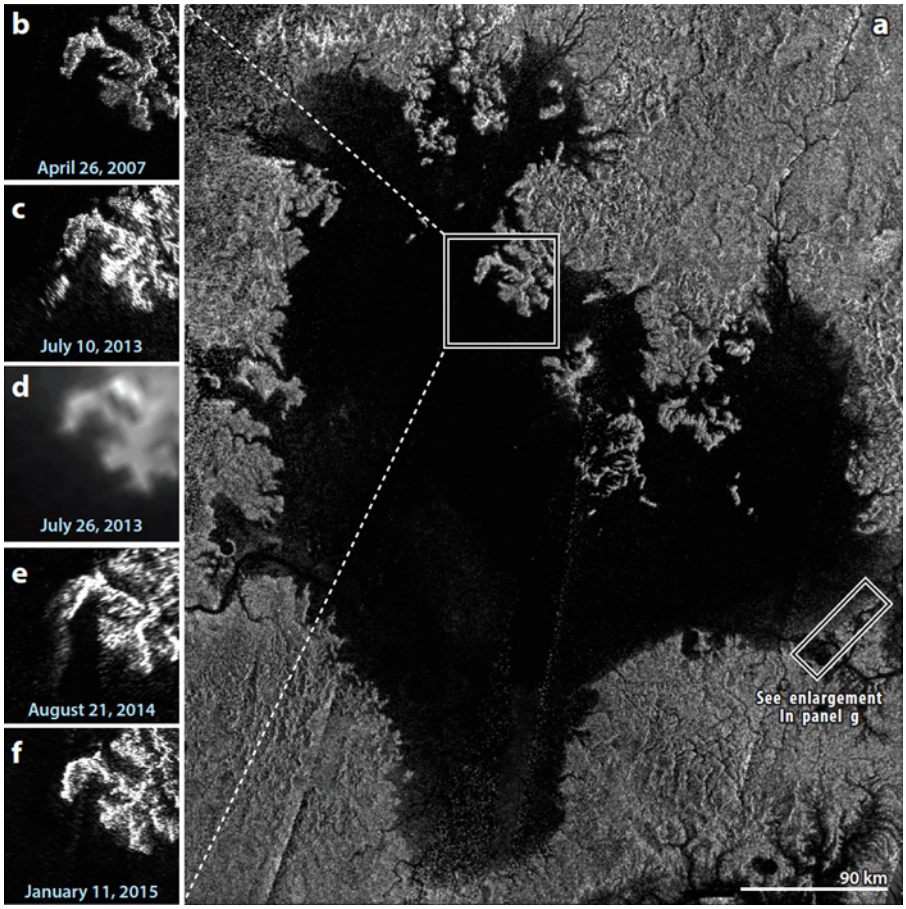

Figure RADAR-20. Time evolution of the first and most observed Magic Island region. The large panel on the right is a SAR mosaic of Titan's hydrocarbon sea, Ligeia Mare. The panels on the left show the temporal variation of a region observed to have Magic Islands. Transient bright features (Magic Islands) are observed in the images from July 10, 2013 and August 21, 2014 that are not present in any other images of this region [Hayes 2016]. The VIMS observation on July 26, 2013 (panel d) did not detect Magic Islands, however, the possibility that they were present but not detected in these observations could not be ruled out. Magic Islands were definitely not present in SAR observations before the first appearance and after the second appearance. The figure shows only a subset of Cassini observations of the region, see Hofgartner et al. [2016] for all observations with a resolution sufficient to observe the Magic Islands.

ARRAKIS PLANITIA PRECIPITATION AND OTHER TRANSIENT EVENTS

The first Cassini observations of surface change on Titan were obtained over Arrakis Planitia, near the South Pole, where ISS observed the appearance of dark splotches (interpreted as ponded hydrocarbon liquid) in June 2005 that were not present in the previous observation acquired in July 2004 [Turtle et al. 2009]. In October 2004, between those two observations, a large cloud outburst was observed near Titan's South Pole from Earth-based telescopes [Schaller et al. 2006].

SAR images and SARTopo later found that the ISS dark splotches occurred in topographic depressions that are morphologically similar to steep-sided depressions interpreted as empty lakes in the north [Soderblom et al. 2016]. VIMS observations of this area acquired between 2007 and 2009 show that the dark splotches had become brighter than the surrounding terrain [Soderblom et al. 2016]. SAR images of the area obtained in October 2007 and December 2008 showed the absence of dark splotches in the same topographic depressions, this time in the microwave, that were interpreted as either the evaporation or infiltration of ponded liquid [Hayes et al. 2011].

In addition to Arrakis Planitia, temporal changes have also been observed at other locations in the South Pole as well as within the northern lakes and seas and at equatorial latitudes. The largest observed surface change occurred in 2010 when an equatorial area of over 500,000 km in size was observed to darken, presumably by methane precipitation, after a chevron-shaped cloud passed over the region [Turtle et al. 2011]. SAR images of the area suggest that the darkened region represented local topographic lows. The area was later observed to return to its original albedo [Barnes et al. 2013]. Whereas there have been no definitive changes observed in the shorelines of the northern lakes and seas through April 2017 (flyby T126), there have been several surface changes reported for lacustrine features in the south polar region. Turtle et al. [2011] argued for shoreline recession at Ontario Lacus between ISS images acquired June 2005 and March 2009, although the poor resolution of T51 makes quantitative measures difficult. Hayes et al. [2011] found that, while inter-instrument comparisons can be dangerous, SAR images acquired in 2009 (T57/T58) and 2010 (T65) were consistent with a receded shoreline when compared to the June 2005 images obtained by ISS. However, Cornet et al. [2012b] argued that, to within measurement error, the data are consistent with no changes at all. Hayes et al. [2011] also discussed repeat RADAR passes of the south acquired in 2007 and 2008/2009 that contain lacustrine features that seem to disappear between subsequent SAR observations. The observed ten-fold increase in SAR backscatter cannot easily be explained by geometric effects and suggests that, between the observations, liquid either infiltrated into the ground, evaporated, or did both [Hayes et al. 2011]. Other temporal changes, including roughening events interpreted as wave or fluvial activity as well as Titan's mysterious magic islands have been observed within the northern seas. These changes are discussed in the section entitled Magic Islands.

Although the Cassini mission's exploration of Titan's methane cycles has ended, ground-based observations can continue to monitor Titan's weather until future missions can map fluvial features at a higher resolution and characterize the composition of surface material (including the lakes and seas) through in situ exploration.

Observation of a Summer Lag in the North Pole (by Radiometry)

One of the main scientific objectives of the Cassini Extended Mission (2008–2017) was to monitor the changing seasons on Titan. If any change were to occur, it should be primarily in Titan's arctic regions where the most important temperature variations are expected (though limited to 2-4 K over the course of a year).

Onboard Cassini, both the Composite Infrared Spectrometer (CIRS) and the microwave radiometer had the ability to measure the variations of surface/near-surface temperature with time [Jennings et al. 2009; Cottini et al. 2012; Janssen et al. 2016] and both instruments observed a lag in the summer warming of the northern polar terrains [Jennings et al. 2016; Le Gall et al. 2016]. They reported a much slower rise of temperature in late spring (2014–2015) than predicted by a global circulation model (GCM), even assuming a very high thermal inertia for lakes and seas [Tokano 2005]. Further, there seems to be no significant temperature difference between the land and the seas, which suggests that the solid surface surrounding the lakes and seas of Titan are saturated with liquid and behave thermally like the liquids. They may as well experience evaporative cooling which would explain the low measured temperatures in the north polar region and have important implication for the hydrocarbon cycle on Titan.

Surface and atmosphere interaction

Winds and temperature

In contrast to the contemporary instantaneous winds revealed by sea surface roughness (see section entitled Major Geologic Units and Mapping), the widespread observations of dunes on Titan attest to winds that have acted over significant periods in the past, and indeed the possibility that aeolian landforms might shed light on Titan's climate history was recognized before Cassini's launch—for example, Lorenz et al. [1995]. Since so few trackable cloud features have been observed on Titan, the aeolian features in Titan's landscape have emerged as one of the principal constraints on Titan's meteorology. Specifically, it has been estimated that the saltation threshold for the movement of dry sediment on Titan requires surface winds of the order of 1 m/s—for example, Greeley and Iversen [1987], Lorenz et al. [1995], and Lorenz [2014]. This estimate is based on an assumption of interparticle cohesion not too different from terrestrial sands: some laboratory measurements suggest they could be slightly larger [Burr et al. 2015] and it is possible or even likely that (methane/ethane) moisture [Yu et al. 2017] and/or electrostatic charging [Lorenz 2014; Mendez-Harper et al. 2017] could be responsible for stronger cohesion. In any case, the presence of dunes requires winds sometimes exceeding this threshold in the past.

The construction or reorientation time for dunes of the size (~100 m tall) observed by Cassini is substantial, of the order of 50,000 years [Ewing et al. 2015; Lorenz et al. 1995; Lorenz 2014]. Thus, not only does the presence of dunes require that the winds have been above the saltation threshold for a substantial integrated period, but also that the dune pattern observed today retains some memory of winds extending into the past by a substantial part or multiple of an astronomical (Croll-Milankovich) climate cycle—see, for example, Aharonson et al. [2009]; Lora et al. [2014]. In particular, Ewing et al. [2015] noted that some of Titan's dunes are somewhat crescentic, implying a recent dominance of a northward meridional component to the winds—see McDonald et al. [2016].

The generally-eastwards direction of sand transport implied by the dune morphology was noted early [Lorenz et al. 2006; Radebaugh et al. 2008; Lorenz and Radebaugh 2009] and was a

challenge to meteorological expectations, since low-latitude near-surface winds should have on average an easterly (westwards) flow, much like the trade winds on Earth. Tokano [2008] made some of the first systematic experiments with a GCM to attempt to reproduce the observed pattern by positing the influence of Xanadu as a highland or bright region. The vexing paradox—see for example Lorenz and Zimbelman [2014]—was resolved by invoking occasional westward gusts [Tokano 2010; Charnay et al. 2015] such that even though the average wind direction is eastwards, these typical winds are below the threshold speed and so are not reflected in the sand transport. Thus, the landscape is shaped only by the stronger (westward) gusts—with the saltation threshold acting like a diode in an electrical analogy of alternating winds. Tokano [2010] found that a threshold of order 1 m/s was consistent with obtaining a dune pattern similar to that observed, and suggested that stronger vertical mixing in the low-latitude troposphere during the equinox period might cause the required westward flows. This idea has been developed somewhat further by Charnay et al. [2015], who suggested that methane rainstorms in particular may be responsible. Significant developments in the mapping of dune morphology and orientation to wind diversity and sand supply/mobility have taken place in the last decade and a half, stimulated in no small part by the Cassini discovery of large linear dunes as well as other wind-borne features [Lorenz and Radebaugh 2009; Malaska et al. 2016a]. Detailed observations suggest that there is a divergence of material transport in the equatorial regions, and a convergence in the mid-latitude regions around latitude 35°. This suggests that a relationship exists between two major land units on Titan: the longitudinal dunes and the undifferentiated plains, as discussed in the section entitled Plains. It has been suggested [Rubin and Hesp 2009] that sticky sand may yield longitudinal features, and laboratory results with organic material have shown that electrostatic charging may be significant for Titan organics under cryogenic, dry conditions [Mendez-Harper et al. 2017]. Nonetheless, the interaction of multiple modes of dune growth may be important in decoding Titan's winds from dunes—for example, Lucas et al. [2014].

In contrast to the complex wind story, the overall distribution of dunes on Titan is somewhat straightforward from the standpoint of wetness. Early Titan GCM studies—for example, Rannou et al. [2006]; Mitchell [2008]—indicated that Titan's low latitudes should be dried out by the general circulation, as a result of the meridional (Hadley) cells on this slowly rotating world. Thus, the dunes form a broad equatorial belt on Titan, whereas they form belts at about 20 degrees north or south on the faster-rotating Earth. The size and spacing of dunes, assuming that they have been allowed to grow to their full extent without being limited by growth time or sand supply, has been determined—for example, Andreotti et al. [2009]—to correlate to the thickness of the atmospheric boundary layer. Essentially, the layer caps the dune growth once the spacing is roughly equal to the layer thickness. Lorenz et al. [2010] showed that the Huygens descent data were consistent with a boundary layer thickness of the order of 3 km, matching the typical dune spacing on Titan. Extensive dune spacing measurements—for example, Le Gall et al. [2011], and Savage et al. [2014]—show only small minimal variations with latitude. Charnay et al. [2012] found that a GCM with an improved boundary layer scheme reproduced the 3 km thickness, interpreting this as a seasonal boundary layer.

The full meteorological interpretation of the dune pattern revealed by Cassini's RADAR will require a finer scale of modeling than has been performed so far, including regional topography

and albedo effects. It may be that the dune fields, by virtue of having a low thermal inertia and albedo, cause their own sea breeze effect, modifying the local winds. The role of evolving ground moisture remains to be elucidated, although some hints of moisture effects on ground thermal inertia have been suggested in the RADAR radiometry data [Janssen et al. 2016].

Although the radiometer in principle is an indicator of surface temperature and could be used to independently constrain gradients with latitude etc. [Lorenz et al. [2003], in practice, the surface temperature estimates from the Cassini CIRS and the Huygens probe have been adopted as ground truth and the interpretation of the microwave radiometry has been principally in terms of the surface dielectric properties. However, future studies might profitably examine small-scale radiometer variations and their correlation with surface elevation—in principle, the ~1 K/km lapse rate may have a signature in surface brightness temperature.

METHANALOGIC CYCLE

Titan is the only place in the solar system, other than Earth, that is known to have an active hydrologic cycle.

Titan is the only place in the solar system, other than Earth, that is known to have an active hydrologic cycle. Titan's methane-based hydrologic cycle is an extreme analog to Earth's water cycle. Exchange processes between atmospheric, surface, and subsurface reservoirs produce methane and ethane cloud systems, as well as erosional and depositional landscapes that have strikingly similar forms to their terrestrial counterparts. Over its 13-year exploration of the Saturn system, Cassini has revealed that Titan's hydrocarbon-based hydrology is driven by nested methane cycles that operate over a range of timescales including geologic, orbital, seasonal, and that of a single convective storm. A fast physical (phase change) cycle drives active weather and fluvial processes over seasonal to orbital timescales. A medium-paced chemical cycle siphons off methane for photochemical synthesis in the upper atmosphere, depositing the products on the surface over timescales of millions of years. A long-term geologic cycle may sporadically inject methane into the system from Titan's interior over the age of the solar system. For a recent review of Titan's hydrologic cycle, see Hayes et al. [2018].

Titan as a system

Titan is the only moon in the solar system with an atmosphere so massive that it dominates the total volatile inventory in the surface-atmosphere system and provides strong radiative forcing and an active meteorology [Lorenz et al. 2005]. It also obscures the surface from view in both the optical and infrared, which is why the Cassini RADAR has been such a crucial tool. However, by the irreversible deposition of heavy hydrocarbons, nitriles, and other photochemical products from methane and nitrogen, the atmosphere also obscures the underlying surface geology to some extent. Were the current inventory of methane to condense onto the surface, it would form a layer 5 m thick [Mitchell and Lora 2016], but a variety of evidence suggests that many times that number is present in various solid and liquid deposits of organics on and within the crust [Hayes et al. 2018].

Therefore, Titan's geologic history is poorly constrained and in particular there is a significant uncertainty as to what fraction of the body's 4.5 billion years of existence is recorded on the surface. Observations relevant to its history include:

1. The low observed numbers of impact craters [Porco et al. 2005] yield an age of hundreds of millions of years, not billions [Lorenz et al. 2007; Wood et al. 2010; Neish and Lorenz 2012].

2. The rate of photodissociation of methane in Titan's atmosphere implies that the current gaseous inventory will be depleted in some tens of millions of years [Yung et al. 1984].

3. Titan's interior has at least partially differentiated, resulting in a rock-metal core, a high-pressure ice mantle of uncertain thickness, a liquid water ocean [Iess et al. 2010] perhaps with salts and ammonia [Mitri et al. 2014], and an ice crust 50 to 150 km thick. The core is either significantly hydrated [Castillo-Rogez and Lunine 2010], or there is a mixed rock-ice layer somewhere in the interior [Tobie et al. 2014].

4. A range of chemical and physical data from the atmosphere to the interior suggest that a significant event, or change in the way Titan evolves, occurred sometime between a few hundred million and a billion years ago [Horst 2017].

The relatively youthful age of the surface, which may be the result of geologic activity, older impacts occurring on surfaces covered by liquids [Neish and Lorenz 2014], extensive erosion, or substantial burial in organic matter, means that there is little if any geologic evidence of the first 3/4 of Titan's history. Two unanswered questions are: 1) what was the process/processes that eroded or covered older impact craters and other landforms; and 2) did the obscuration of features older than a few hundred million years occur continuously over time, or in some singular event?

There is no evidence of the answer to the second question, but a theoretical model of the evolution of Titan's interior by Tobie et al. [2006] provides an intriguing scenario that implies Titan had a significant change in the working of its interior, crust, and atmosphere about 500 million years ago [Wood 2018]. In the Tobie et al. [2006] model, Titan had a thin and rigid clathrate crust—with methane as the dominant guest species—up until 500 million to one billion years ago. During that earlier epoch, several major heating events resulted in the release of large (compared to the present atmospheric inventory) amounts of methane from the clathrate hydrate into the surface-atmosphere system. Within the last 500–1000 million years the interior has cooled sufficiently to allow an ice I crust to form underneath the buoyant clathrate hydrate crust, with diapirism in the thickening ice I crust providing one or several episodes of further release of methane into the surface-atmosphere system.

Wood [2018] called the onset of the ice I subcrust the Great Crustal Thickening Event and noted that the mode of geologic processes would change dramatically as Titan transitioned from a

body with a thin rigid conductive crust over the ocean to one with a thicker and rheologically heterogeneous crust.

Models of Titan's interior look broadly similar but with substantial disagreements on the thickness of the high pressure ice layer and the extent of silicate core hydration [Tobie et al. 2014]. How much this affects the surface evolution is unclear. While the idea is commonly held that the source of the methane to resupply the atmosphere is in crustal clathrate hydrate—such as that predicted in pre-Voyager days [Lewis 1971]—how the resupply works is unclear. Simple forcing out of the methane from the clathrate by the photochemically produced ethane eventually fails because of the stoichiometry (two methane molecules making one ethane), although this replacement could eventually weigh down the crust and cause an overturn because clathrate with predominantly ethane is heavier than ice I [Choukroun and Sotin 2012]. This could cause interesting geologic consequences in the present era when the clathrate is nominally underlain by warm ice I. Whether the methane hydrological cycle that we see today shaping so many aspects of Titan's surface is ancient or recent, episodic [Lunine et al. 1998] or continuous, remains a mystery that may be directly coupled to the poorly understood interior evolution. Or it may reflect a series of external events whose record in the Saturn system has yet to be properly read.

Birch et al. [2017] have pointed to geologic evidence (notably the presence of large sedimentary deposits) suggesting that the present epoch of lakes and seas of methane, ethane, and nitrogen might have been preceded by one with a widespread ocean of methane and other hydrocarbons. The longevity of such an ocean, in particular its decline, may be constrained by the limits on tidal dissipation of the orbital eccentricity during ocean shrinkage [Sagan and Dermott 1982; Sears 1992], since we now have measured global Titan topography. Finally, it is possible that Titan has run out of atmospheric and surface methane multiple times in its history, leading to dramatic atmospheric changes [Lorenz et al. 1997] and possibly epochs in the which the surface is worked by liquid nitrogen seas and rivers [Charnay et al. 2014].

If Titan's geologic and atmospheric nature have changed in a secular way over its history, it would join the other terrestrial planets—Venus, Earth, and Mars, in this regard. In each case, interior and surface-atmosphere changes over time have led to present-day characteristics that are likely to have been dramatically different from those in the past.

Open questions

Now that we have a global view of Titan contributed by several Cassini instruments, the questions that remain become more detailed and in general require more than one data type to address. Some also require a different type of sensing platform as well. NASA plans to send a rotorcraft to Titan called Dragonfly, scheduled to launch in 2026 and land in 2034 [Lorenz et al, 2018; http://dragonfly.jhuapl.edu/]. Dragonfly's primary objective is to look for prebiotic chemical processes, and it will also address open questions atmospheric, surface and subsurface properties. Other open questions are addressed in Lunine's Interdisciplinary Scientist (IDS) report on Titan elsewhere in this report.

Below we list a subset of those questions that might be addressed by future spaceborne radar instruments, keeping in mind that they have proven to be a challenge from several standpoints. In fact, because of Cassini's success, the minimum orbiter science payload considered worthwhile for such purposes is now fairly large [Reh 2007].

Direct benefit from higher resolution (<100m) SAR

- To what extent is the surface fluvial dissected?
- How do the organic compounds produced in the atmosphere evolve on the surface?
- Does cryovolcanism occur on Titan?
- What is the composition of the dune particles and how are they produced?
- What is the nature of the asymmetry in seasonal effects?

Indirect benefit from higher resolution SAR/HiSAR/scatterometry/ altimeter

- How did the lakes and sea basins form?
- What is the organic and inorganic composition of the surface?
- What is the circulation in the lakes and seas and how is it affected by the atmosphere?
- What is the salinity and composition of the deep ocean and is it in contact with rock beneath?

Direct benefit from a radar sounder

- What is the nature and extent of the exchange between the surface/atmosphere and deep subsurface and ocean?
- What is the depth and thickness of the subsurface ocean?

Saturn Science

Introduction

The thermal emission from the gas-giant planets was first observed by single-antenna telescopes in the 1950s [Mayer 1958], and quantitatively related to fundamental atmospheric properties in the following decade [Thornton and Welch 1963; Gulkis et al. 1969; Wrixon and Welch 1970]. Subsequent observations through the 1980s filled in the disk-temperature spectra of Jupiter and Saturn through the millimeter- and centimeter-wavelength range. This combined with advances in understanding the high-pressure microwave absorption of ammonia, which possesses a strong inversion band just longward of 1 cm wavelength, led to a consistent story of deeply convective

atmospheres with ammonia as the dominant absorber [Gulkis and Poynter 1972; Berge and Gulkis 1976; Klein and Gulkis 1978]. The advent around the same time of radio interferometers capable of using aperture synthesis to image the planets led to the first microwave image of Saturn, reported by Schloerb et al. [1979] using the interferometric Owens Valley Radio Observatory at 3.7 cm wavelength. The completion of the National Radio Astronomical Observatory's Very Large Array (VLA) in New Mexico was followed by a series of images of Saturn and its rings made with this instrument reported by a number of authors at wavelengths ranging from 2–21 cm wavelength (de Pater and Dickel [1982, 1991]; Grossman et al. [1989]; Grossman [1990]). These studies have resulted in a better understanding of Saturn's rings and atmospheric microwave spectrum, and have provided evidence of large-scale structure in Saturn's ammonia distribution including variable broad bands in the mid-latitudes. However, they have been limited by the capabilities of the VLA in spatial resolution and dynamic range for imaging extended objects; in addition, the process of Earth-rotational aperture synthesis used for imaging averages out longitudinal structure.

The microwave radiometer contained in the Cassini RADAR provides a unique opportunity to image Saturn with the advantage of close range and without the limitations of a ground-based approach other than the restriction to a single wavelength. This has resulted in nearly an order-of-magnitude improvement in both spatial resolution and sensitivity over Saturn microwave observations published up to the Cassini era, although improvements made to the VLA since then promise to close this gap. In this report we summarize the mapping campaign of Saturn carried out by the RADAR radiometer during the Cassini mission and its main results, leaving the details to papers already in the literature.

Observations

The thermal emission from Saturn's atmosphere was mapped globally on six occasions by the RADAR radiometer at its single wavelength (2.2 cm) and half-power beamwidth of 0.36°. Imaging was achieved by controlling the spacecraft orientation to scan the source using the spacecraft momentum wheels to scan back and forth from pole to pole. We obtained six global maps of the 2 cm thermal emission from Saturn distributed over a period from 2005–2015, each obtained using a period of approximately 14 hours centered on an equatorial periapsis pass. The motion of the spacecraft and Saturn's rotation combined to provide nearly complete global maps of Saturn in each pass. Janssen et al. [2013] presented the first five of these maps and described in detail the techniques used, calibrations, and general interpretations. A companion paper by Laraia et al. [2013] focused on the interpretation in terms of the ammonia vapor distribution in the ammonia cloud and sub-cloud region. A sixth map was obtained in May 2015 and a paper presenting its results is in preparation at the time of this report.

The five published maps are shown in Figure RADAR-21 as cylindrical maps of brightness temperature relative to a model Saturn atmosphere with nominal composition and fully saturated ammonia—for example, 0 K in the map indicates an absolute brightness as given by the fully

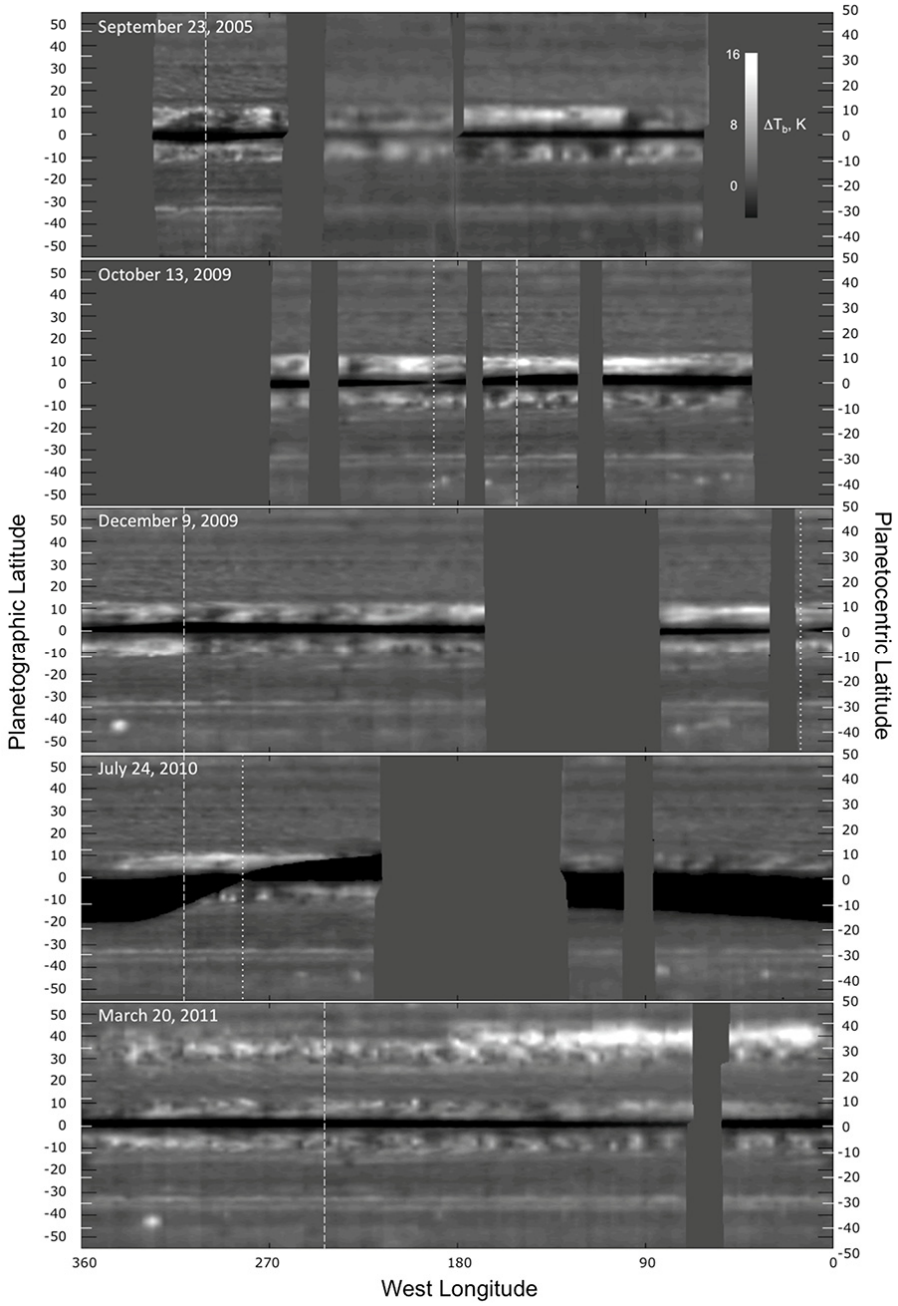

Figure RADAR-21. Global cylindrical maps of Saturn's thermal emission obtained at 2.2 cm wavelength during the Cassini prime and equinox missions. This was obtained by accumulating north-south scans from pole to pole during an approximately 14-hour period surrounding Saturn periapsis.

saturated model (see section entitled Key Objectives for RADAR Instrument). The Saturn brightness measurements themselves were calibrated to an absolute accuracy approaching 1% by transferring absolute calibrations obtained from Titan observations [Janssen et al. 2009, 2016] to Saturn. All observations were made during periods in the mission when the spacecraft was in Saturn's equatorial

plane. The inclination of the rings as seen by the spacecraft was less than 1° for all observations except for that of July 24, 2010 where it approached 4°. The dark band with variable width seen in the equatorial region is due to blockage by the rings. Gaps indicated by the uniform grey shading (corresponding to 0 K relative brightness) are lapses in data-taking where time had to be taken to unload the spacecraft momentum wheels. The dashed and dotted lines indicate periapsis and ring plane crossings respectively (there were no observations made exactly at ring plane crossing for the 2005 and 2011 maps). Planetographic latitudes are indicated by black ticks on the vertical scales, planetocentric by white. Mapping of the regions outside approximately ±50° latitude is of lower quality because of high emission angle and the results obtained there are not shown. The resolution in latitude is as good as 0.86° at the equator, and the sensitivity of each observation is ~0.1 K. The longitude resolution is limited by the scan rate of the spacecraft but averages about 2° at the equator.

Interpretation

The maps are interpreted in terms of a reference model for Saturn's atmospheric structure and composition based on Atreya [2010] and shown in Figure RADAR-22, using current values for the known constituents of the atmosphere [Hanley et al. 2009; Deveraj 2011]. The weighting function in

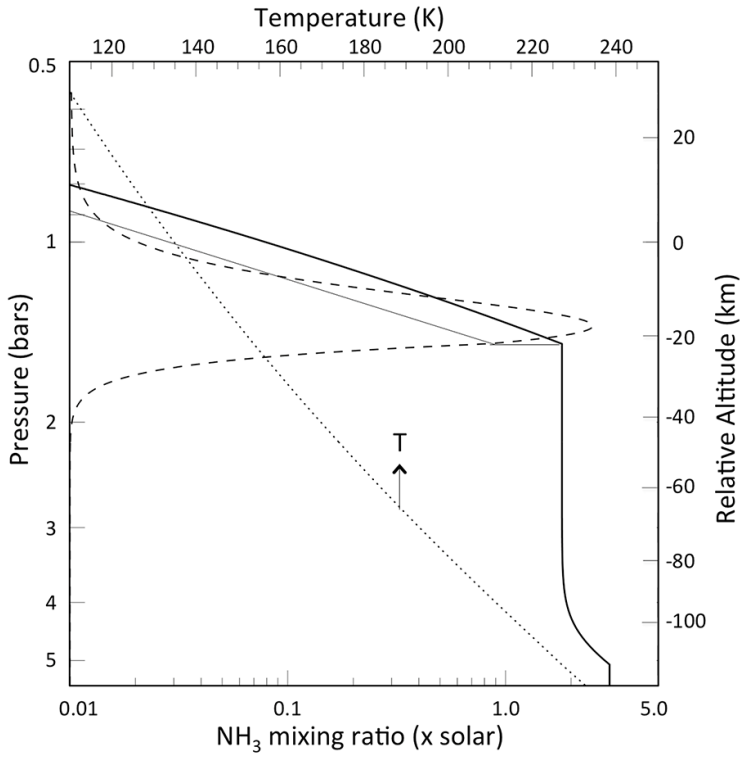

Figure RADAR-22. Atmospheric model used to compute reference brightness temperatures. The temperature (dotted line) and NH_3 mixing ratio in units of solar abundance (thick solid line) are shown as a function of pressure and altitude in the vicinity of the ammonia cloud region in the atmosphere. The reference model assumes 100% relative humidity for ammonia above its saturation level, while the light solid line shows a case for 50% relative humidity. The decrease in NH_3 mixing ratio above the 5-bar level is due to reaction with H_2S to form NH_4SH ice. The dashed line shows the 2.2 cm wavelength weighting function in arbitrary linear units at normal incidence for the reference model.

Figure RADAR-22 shows the region responsible for the thermal emission assuming that the ammonia is fully saturated in the cloud region. In this model, the microwave absorption, and hence thermal emission, is seen to be due almost entirely to gaseous ammonia and is located primarily within the ammonia cloud region. Any depletion of ammonia relative to the fully saturated model leads to excess brightness. The maps indicate that the ammonia cloud region is everywhere unsaturated (at least away from the equator where the atmosphere is blocked by the rings), and variations in the ammonia can be expected to trace atmospheric circulations in and below the clouds.

The maps in Figure RADAR-21 reveal features either never before seen or known features viewed from a perspective never before available. The region of the atmosphere responsible for the microwave brightness variations, roughly 0.5 to 2 bars, has been extensively observed with high-resolution instruments at infrared wavelengths. Nevertheless, the unique value of observations at 2.2 cm wavelength is the simple origin of the observed structure—it is just ammonia vapor and variations in its distribution. Low residual brightness indicate the presence of gas phase ammonia in the cloud region at concentrations approaching but not exceeding its saturation level, whereas higher brightness indicates a relative depletion. The variability of the brightness distribution across Saturn suggests the existence of circulations that cause the depletion or enhancement of the ammonia by means of gas flow into and out of the ammonia condensation region, while the morphologies of these variations give clues as to the nature of the dynamical forcing causing these flows. Obvious features include the bright bands that are symmetric about the equator from approximately 3° to 10° latitude north and south respectively, where regions of high brightness alternate with low brightness regions resulting in longitudinal variability not seen at higher latitudes (until the Great Northern Storm in the 2011 map). These regions are similar to Jupiter's equatorial belts as seen recently by the Juno microwave instrument on the Juno spacecraft [Bolton et al. 2017]. The regions of high brightness in these bands are dry in the sense of low ammonia abundance, and therefore resemble the dry sub-tropics of Earth.

In between the north and south equatorial bands, at the equator, is a central band of relative calm with the lowest brightness seen on Saturn, similar to that seen by Juno in Jupiter's equatorial zone. The low brightness seen here indicates ammonia concentration to be near saturation, consistent with the greatly enhanced NH_3 abundances found by VIMS in this region [Fletcher et al. 2011]. Although difficult to discern because of the ring blockage, this band is apparent at or near the ring crossings, most notably in the central segment of the 2005 map. Although at relatively low resolution, the ring inclination in this segment is near 0.01° as seen from the spacecraft, with the blockage causing less than a 1 K influence on the brightness. Laraia et al. [2013] present a more thorough examination of the ring blockage, using a ring model to retrieve the equatorial brightness at the ring plane crossings for all maps to confirm the presence of generally uniform near-saturated ammonia in the equatorial belt.

We investigated the significance of these maps more quantitatively by assuming a simple model for the ammonia distribution. In particular, we allowed the ammonia concentration to vary only in the cloud region only, assuming that it could be described there by a constant relative humidity (RH) in the range 0% < RH < 100%. Figure RADAR-23 shows an analysis using this model carried out by Laraia et al. [2013] of the March 2011 map, which fortuitously captured the Great

Northern Storm of 2010–2011 in progress. The map in panel (a) shows the relative humidity derived from the relative brightness and illustrates that, in general, most of the variation in brightness can be interpreted as variation of ammonia within the cloud region. Significantly, some regions cannot be described this way since the brightness temperature exceeds the model brightness with all cloud ammonia removed. Hence, in these regions, some of the sub-cloud ammonia must be removed as well. The Great Northern Storm (seen in panel (b) around the same time by the Imaging Subsystem) had progressed about halfway around the globe at the time of this map, and shows a dramatic decrease in ammonia extending well beneath the clouds. This supports a model describing the cause and consequences of this storm that predicts such an ammonia depletion [Li and Ingersoll 2015]. The north and south equatorial belts, and isolated storms in a region near 40°S latitude, show evidence of such strong depletion in this map, and all others as well.

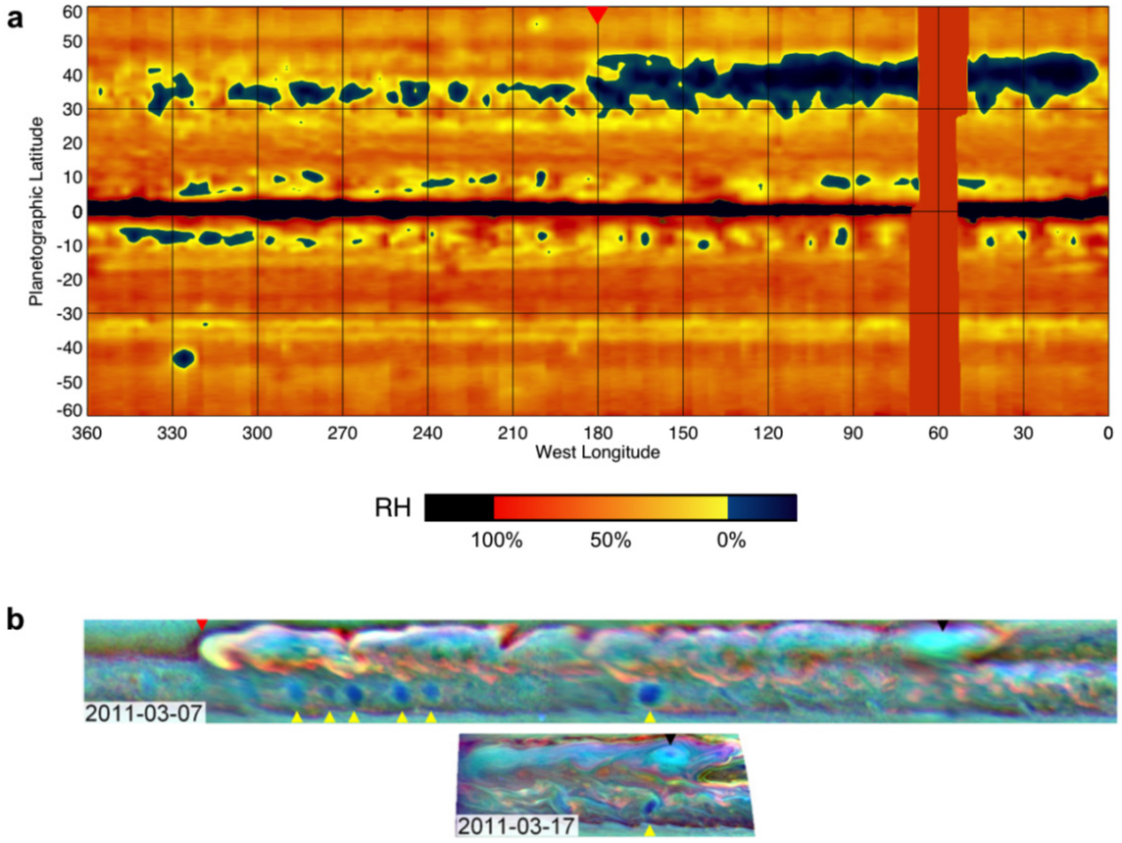

Figure RADAR-23. A simple model used for the ammonia distribution. (a) Map of ammonia cloud humidity from March 20, 2011. Black regions would indicate super saturation of ammonia in the cloud layer (we do not see any). Here, the black regions are due to the cold rings blocking the emission from the atmosphere. Blue regions are regions that require ammonia depletion below the ammonia cloud layer (i.e., RH < 0 in the cloud layer). The northern storm is blue, indicating low ammonia concentrations in the storm that extend to layers beneath the clouds. There are many local regions in the subtropical bands, as well as a storm in the southern hemisphere near 325°W, −43°, that require ammonia depletion below the clouds. (b) Two Cassini ISS images of the northern storm from Sayanagi et al. [2013] Figure 4. These are the closest dates we have to the 2.2 cm map date. Cloud heights are distinguished by the three color filters—red (CB2−750 nm), green (MT2–727 nm), and blue (MT3–889 nm).

A final global map was obtained in 2015, more than four years after the onset of the storm. This map is shown in Figure RADAR-24 in context with maps from 2010 and 2011, all together showing Saturn's atmosphere prior to, in the midst of, and after the storm onset. Figure RADAR-25 shows the relative humidity as described in Figure RADAR-23. This map shows the long-lived ammonia depletion in the latitudes affected by the storm as it has evolved, and contains valuable information on the nature of convection, meridional and zonal circulations in Saturn's sub-cloud atmosphere. A paper discussing the implications for the dynamics of Saturn's atmosphere is in preparation as of this writing.

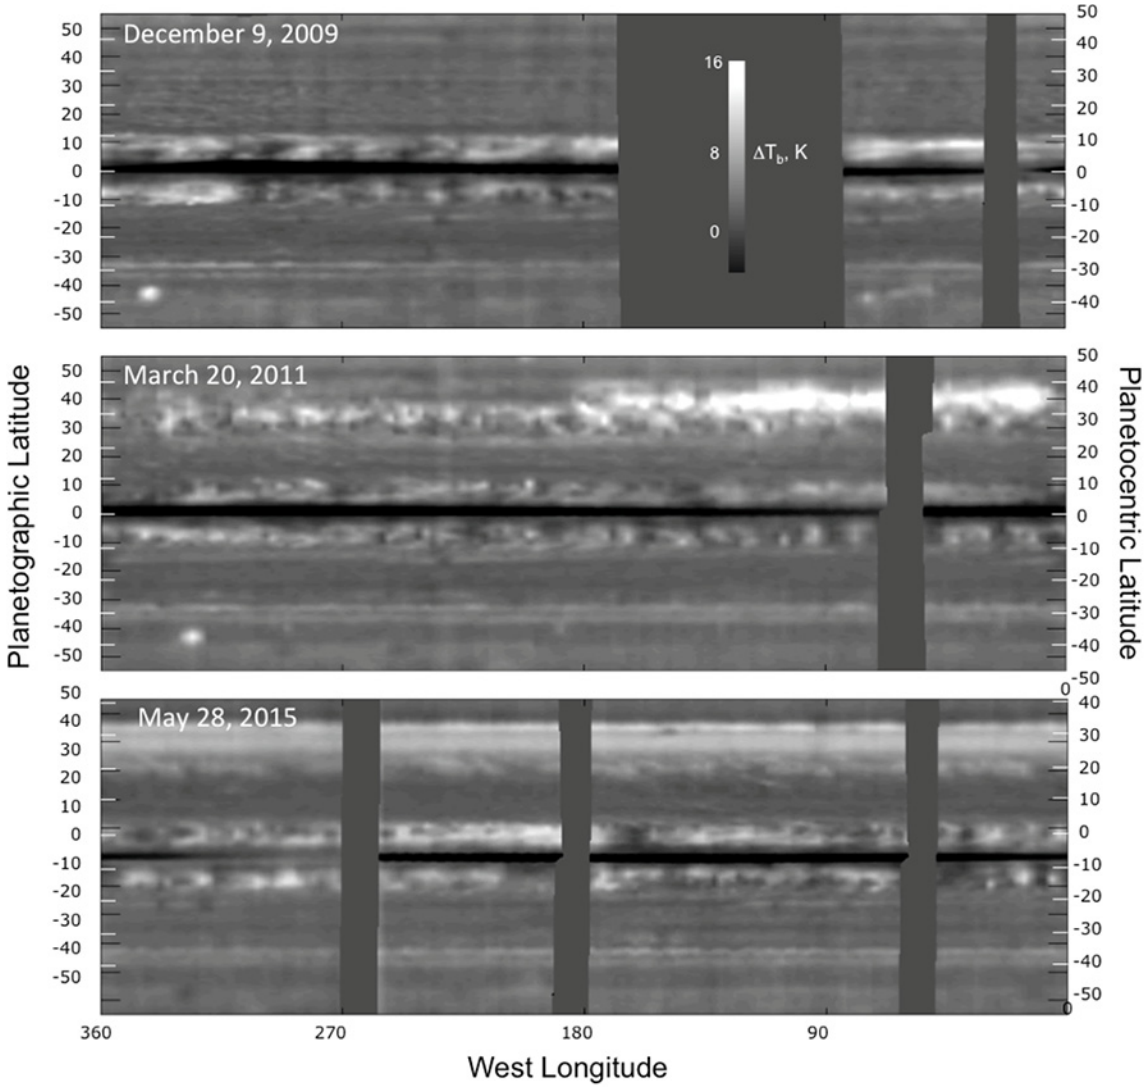

Figure RADAR-24. The global map of 2015 shown in context with earlier maps to show the development of the Great Northern Storm of 2010–2011. The relative brightness for each is shown as in Figure RADAR-21.

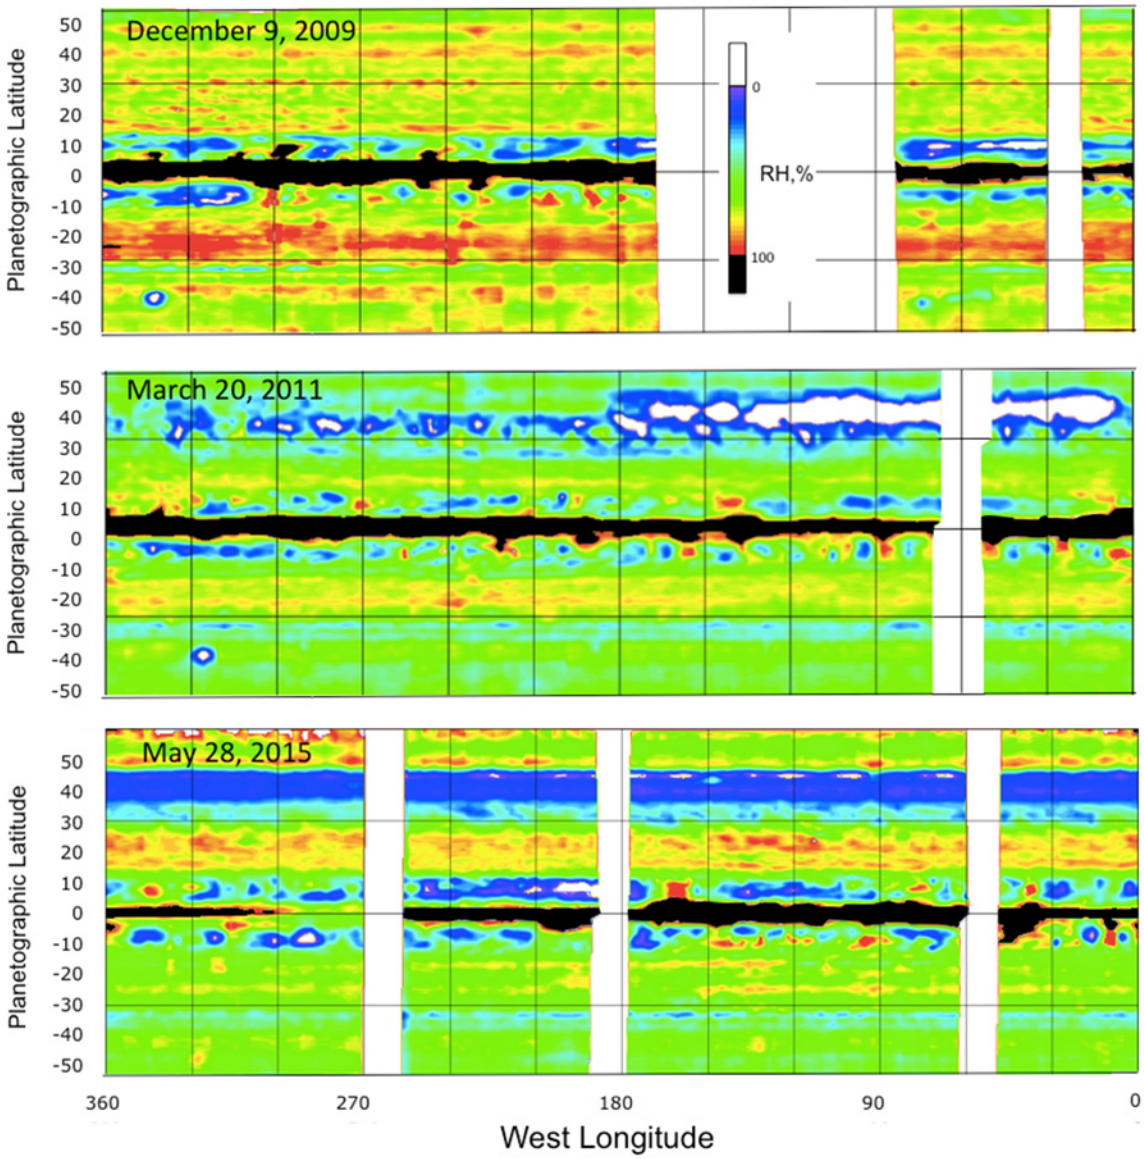

Figure RADAR-25. Ammonia cloud relative humidity for the brightness maps in Figure RADAR-24. Here regions of black are due to ring blockage, while white indicates regions where ammonia additional depletion below the cloud base is required to fit the observations.

Open Questions

The Cassini RADAR radiometer has provided unprecedented images of Saturn's equatorial and mid-latitude atmosphere at 2 cm wavelength. It has uniquely measured the cloud and sub-cloud humidity through the period of the Great Northern Storm of 2010–2011. This provides a basis for ground-based observations of Saturn over multiple frequencies using the VLA and Atacama Large Millimeter/Submillimeter Array (ALMA) radio interferometers to extend the atmospheric depths sounded and follow the slow decay of the 2010–2011 storm, which remains a puzzle. A follow-on

radiometric experiment based on the Juno orbiter's Microwave Radiometer [Janssen et al. 2017; Bolton 2017] would be an excellent complement to an atmospheric sounder assuming that difficulties in obtaining a close orbit and achieving deep sounding in Saturn's more absorbing atmosphere can be overcome. This would enable a comparative examination of the deep atmospheres of both gas giants, which appear to have strikingly different dynamical properties based on present results from Cassini and Juno.

Saturn Ring Science

Introduction

Saturn's rings are the most massive, extensive and diverse ring system in the solar system, …, their origin and age continue to be a subject of debate.

Saturn's rings are the most massive, extensive and diverse ring system in the solar system, yet despite decades of ground and spacecraft-based observations [Dougherty et al. 2009; Grossman 1990; de Pater and Dickel 1991; van der Tak et al. 1999; Dunn et al. 2002, 2005; Poulet et al. 2003; Nicholson et al. 2008], their origin and age continue to be a subject of debate. Although water ice has long been accepted as the most prominent component of ring composition [Cuzzi et al. 1984; Esposito et al. 1984], it is the small fraction of non-icy material that is crucial in understanding their origin and age through source composition and exposure time to extrinsic micrometeoroid bombardment [Cuzzi and Estrada 1998]. However, the abundance and character of this non-icy material remained poorly understood until the extensive observations of Saturn's rings by RADAR, in both its active and passive modes.

Microwave observations at mm- to cm- wavelengths provide an ideal window through which to study the non-icy material fraction in Saturn's main rings, as these are wavelengths where the absorptivity of water ice is negligible compared to that of most non-icy material, and thus the intrinsic thermal radiation from the ring layer is dominated by the non-icy components. Moreover, whereas visible and near-IR spectra are only sensitive to the top millimeter or less of ring particle surfaces, microwave observations are able to sample the bulk of the ring mass. Furthermore, microwave measurements at mm- to cm- wavelengths are most sensitive to mm- and cm- scale particles, which are known to be the most dominant sizes of the ring particles.

Passive radiometry observations at 2.2 cm

During the Cassini Prime Mission, the radiometer scanned Saturn and its rings at 2.2 cm wavelength on 12 occasions between December 2004 and October 2008. There are two categories of radiometric observations of Saturn's rings: low-resolution map scans from a distance of ~20 RS (where RS = 60,330 km is Saturn's radius) and high-resolution spoke scans (not related to the

fuzzy features seen in the B-ring) from a distance of ~5–8 RS. The map scan footprints cover all of the main rings at all azimuthal angles. The projection of the line connecting Saturn's center and the spacecraft onto the ring plane lies at zero degree azimuth, and the azimuthal angle increases anti-clockwise in the ring plane. At small azimuthal angles, the observed ring regions occult Saturn. These observations are comparable to stellar and radio occultations except that the light source is due to the planet's radiation. On the other hand, high-resolution spoke scan footprints only cover the main rings at five distinct intermediate azimuthal angles where the rings are not occulting Saturn. While map scans reveal the complete angular scattering profile, spoke scans show finer radial structures. RADAR has a main beam size of 0.36° in angular diameter (full width at half maximum (FWHM) power), which results in radial resolution of ~2,000 km in high resolution scans and ~6,000 km in low resolution maps.

While this dataset presents several advantages, it is also very challenging to process. Each measurement of antenna temperature is the convolution of the radiometer's broad gain pattern and the brightness temperature of all targets in the field of view [Janssen et al. 2009]. In order to remove the contribution to the signal from the sidelobes and obtain values of the brightness temperature, we developed an iterative adaptation of the successful calibration and sidelobe removal algorithms [Zhang et al. 2017a] developed for Titan and Saturn [Janssen et al. 2009, 2013, 2016]. Figure RADAR-26 shows the output of our calibration and processing applied to a low-resolution map scan of Saturn's rings. Figure RADAR-27 shows the brightness temperature T_b profile versus distance from Saturn center after one high-resolution spoke-scan; all such scans were collected when the rings were not occulting Saturn, at azimuthal angles larger than 20 degrees. Going from the C-ring to B-ring and then to A-ring, the distance from Saturn increases, and hence the planet's angular size decreases as seen from Cassini's vantage point. The dashed curves in Figure RADAR-27 illustrate the decreasing trend of incoming radiation from Saturn as the observation point moves further away from Saturn center. While T_b follows the trend of incoming Saturn radiation in most parts of the rings, the distinct bump (with a peak at ~83,000 km) in the C-ring's brightness is too large to be attributed simply to optical depth variation, which suggests some unusual properties. We will show that this effect may result from a radially variable increase in non-icy material fraction that produces an extra amount of intrinsic thermal emission.

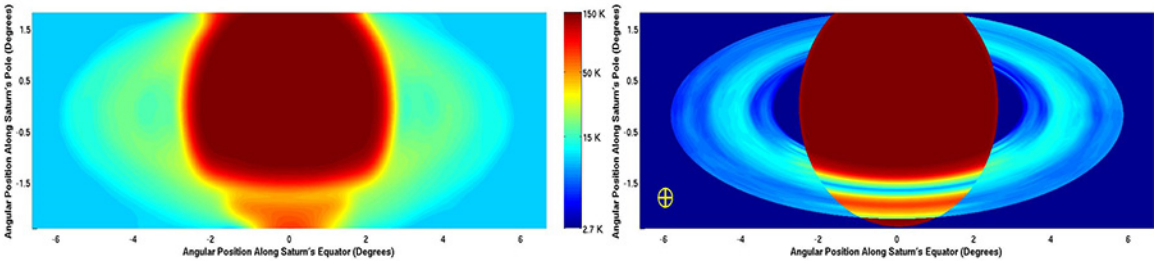

Figure RADAR-26. Calibration of low-resolution Cassini RADAR map scans as projected onto the sky in degrees. Left panel: The collected antenna temperature map. Due to the wide antenna pattern and extensive sidelobe contribution from Saturn, the antenna temperature shows very little clear structure of the main rings. Right panel: The output brightness temperature map obtained through our calibration. The yellow circle in the lower left corner shows the main beam size.

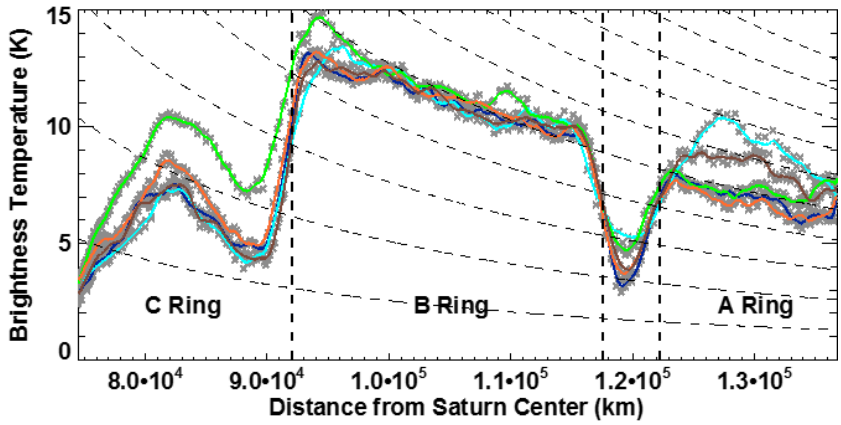

Figure RADAR-27. Brightness temperature T_b versus ring radius obtained from one high-resolution spoke scan. Solid lines of different color indicate spoke scans at different azimuthal angles. The black dashed lines show the trend of incident Saturn radiation, which decreases as one moves further away from Saturn's center.

Brightness temperature model

The observed brightness temperature has four components: 1) directly transmitted Saturn radiation (which exists in occultation data only); 2) scattered Saturn radiation; 3) intrinsic thermal emission; and 4) cosmic microwave background (CMB) contributions. To simulate the observed brightness we use the Monte-Carlo-based photon counting code SimRings [Dunn et al. 2002]. SimRings is able to deal with multiple scattering within the ring layer (where the light source is from extended Saturn emission) and derive the amount of directly transmitted Saturn radiation, scattered Saturn radiation and the intrinsic thermal emission from the ring particles that arrives at the observer. The rings' intrinsic thermal emission mainly depends on the non-icy material fraction since the emissivity of water ice at 2.2 cm is negligible. SimRings requires knowledge of the ring particles' composition and size distribution, which determines the scattering phase function, absorption rate, and the local optical depth.

The ring particle composition is used to determine the material's effective dielectric constant based on the Maxwell-Garnett mixing rule of Effective Medium Theory (EMT)—see Bohren and Huffman [1983]. We assume that the ring particles are made of porous water ice with non-icy material embedded in the form of small inclusions. We primarily use silicates as the candidate for the intermixed non-icy material which has dielectric constant $\varepsilon_{silicate} = 5.38 - i \cdot 0.134$ [Cuzzi et al. 1980].

The ring particles sizes are assumed to have a power law distribution, $n(a) = n_0 a^{-q}$, with minimum size a_{min}, maximum size a_{max}, power law index q and a constant n_0, which depends on the particle areal number density in the rings. Table RADAR-3 summarizes the nominal size distribution parameters we employed for each ring region. The size distribution parameters are determined from previous stellar and solar occultation observations [Zebker et al. 1985; Harbison et al. 2013; Cuzzi et al. 2009; Marouf et al. 2008; French and Nicholson 2000; Dones et al. 1993].

An important result derived from density wave measurements that relate the particle sizes and their mean densities is the opacity, which can be approximated as:

$$\kappa \sim \frac{3(4-q)}{4(3-q)} \cdot \frac{a_{max}^{3-q} - a_{min}^{3-q}}{a_{max}^{4-q} - a_{min}^{4-q}} \cdot \frac{1}{\bar{\rho}}.$$

Table RADAR-3. Particle size distribution parameters in the main rings.

Ring Radius (km)	a_{min}(cm)	a_{max}(m)	q
C-ring: 74,510–92,000	0.4	4.5	3.15
B-ring: 92,000–117,580	30.0	6.3	2.75
Cassini Division: 117,580–122,170	0.1	7.5	2.79
A-ring			
– A0: 122,170–127,900	30.0	5.4	2.75
– A1: 127,900–130,860	30.0	6.3	2.75
– A2: 130,860–133,423	30.0	11.2	2.75

In Saturn's C-ring and Cassini Division, millimeter-centimeter scale particles are dominant in the scattering process and a Mie phase function is a good approximation in these regions. However, in Saturn's B-ring and A-ring, particles are much larger than the wavelength and the particle non-sphericity effect becomes important. The phase function deviates from being simply Mie scattering and become more isotropic. In addition, due to the larger number density found in the middle B-ring and A-ring wakes, close packing of ring particles can also cause the phase function to be more isotropic. To that end, where Mie scattering alone is inadequate, we introduce a phase function that is a linear combination of Mie and isotropic scattering phase functions [Dunn et al. 2002].

$$p(\theta) = (1 - f_{iso}) \cdot p_{mie}(\theta) + f_{iso} \cdot \frac{1}{4\pi}$$

Here f_{iso} is the fraction of isotropic scattering, which is determined by matching the observed data.

The C-ring

Non-Icy Material Fraction Determined by Cassini Radiometry

In the low-resolution maps, the C-ring regions at near-zero azimuthal angles that occult Saturn reveal the forward scattering profile for the C-ring particles. We found that the modeled brightness temperature is much smaller than observed when assuming non-porous ring particles (see Figure RADAR-28). However, we are able to match the observation by either making the whole particle uniformly 75% porous or by assuming a core-mantle ring particle structure with a solid core and porous mantle, both of which result in a more forward-directed scattering phase [Zhang et al. 2017a]. Due to the complication of the core-mantle ring particle structure in our simulation, we defer treatment of the core-mantle particles to the section entitled Ring opacity favors large rocky chunks.

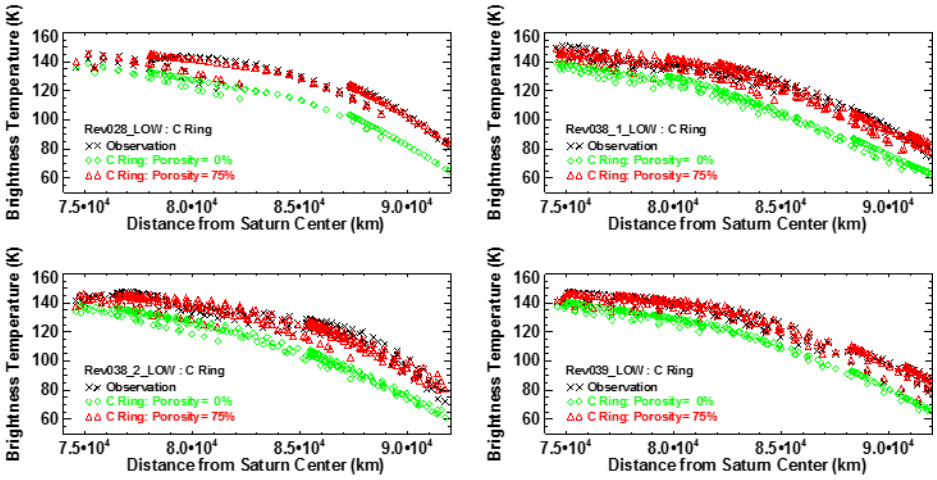

Figure RADAR-28. Brightness temperature model as compared to actual observations for C-ring particles with 75% porosity. Plotted is the brightness temperature versus ring radius for occultation observations of the C-ring low resolution maps during Rev028_LOW (upper left), Rev038_1_LOW (upper right), Rev038_2_LOW (lower left), and Rev039_LOW (lower right). Black crosses: Observed brightness temperature. Green diamonds: Simulated brightness temperature assuming zero porosity. Red triangles: Simulated brightness when assuming C-ring particles are 75% porous.

By adding 75% porosity, the bending angle of intrinsic refraction tends to be smaller and more light gets scattered into the forward direction.

Given that some of the smaller satellites in the Saturn system have bulk porosities in excess of 60% [Thomas et al. 2007; Johnson et al. 2005], and the recent works by the Rosetta team that reported a bulk porosity of 70–80% for comet 67P/Churyumov-Gerasimenko [Sierks et al. 2015; Kofman et al. 2015], it may not be surprising that individual ring particles can be so porous. One possible explanation might be that impact gardening due to micrometeoroid bombardment, which creates a regolith of increasing depth over time—Elliott and Esposito [2011]—may play a role in increasing particle porosity. Collisions among ring particles occur frequently within the C-ring, but at relatively low (mm/s) velocities, when compared to impacts by extrinsic micron-sized meteoroids (~10 times more frequent for the nominal choice of flux, see the section entitled Exposure time due to micrometeoroid bombardment). However, secondary impacts that arise as a result of the ejected material from the primary micrometeoroid impact should occur much more frequently than inter-particle collisions and at velocities of up to tens of meters per second—ballistic transport process as discussed in Cuzzi and Estrada [1998]. These secondary impacts might kick up loosely bound regolith particles such that a considerable exchange of material may happen locally between neighboring ring particles, keeping their regoliths fluffy. Thus, even though inter-particle collisions may have a tendency to compact a ring particle surface, it might be possible that the ring particles can achieve a quasi-equilibrium porous regolith that results from a balance of these combined impact and collisional processes.

While occultation observations mainly reveal the strength of the forward directed part of the scattering phase function, non-occultation observations in high-resolution spoke scans depend more on the scattering phase function at intermediate scattering angles. Figure RADAR-29 shows

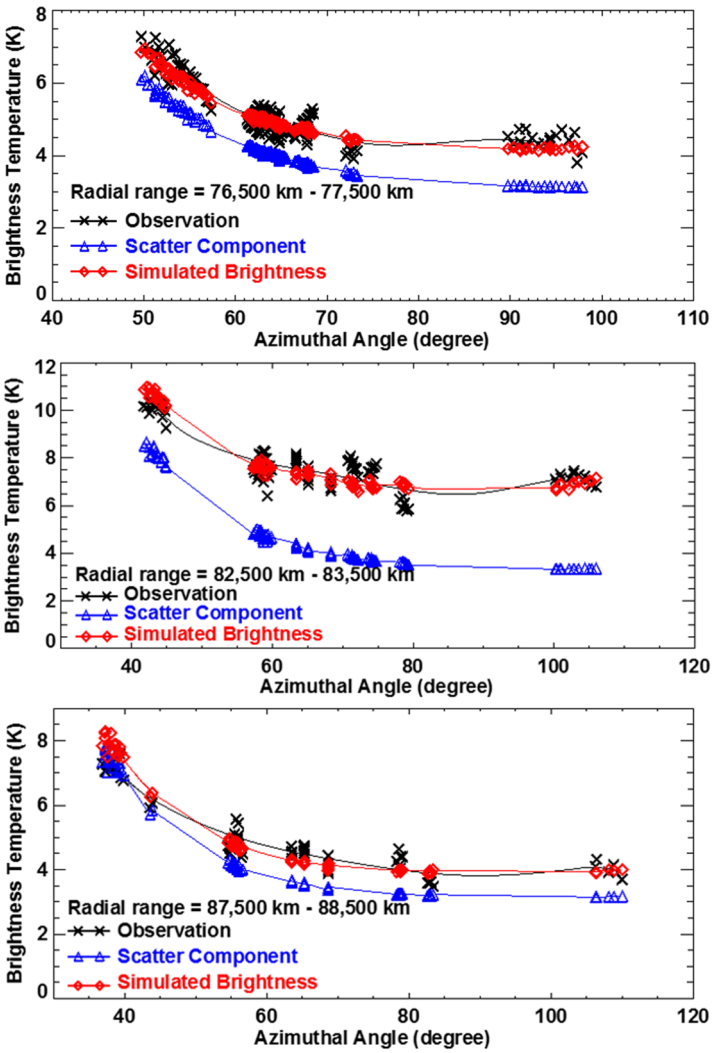

Figure RADAR-29. High-resolution spokes observations and simulations for three ring annuli. Brightness temperature versus azimuthal angle curves at three different ring radii for the: inner (76,500 km–77,500 km); middle (82,500 km–83,500 km); and outer C-ring (87,500 km–88,500 km). All observation data come from high-resolution scan Rev028_HIGH. We plot the observed brightness temperature (black crosses), scattering component with CMB contribution (blue triangles), and simulated brightness temperature (red diamonds—addition of scatter component, CMB contribution and intrinsic thermal emission). We have added ~2%, ~6% and ~1.5% non-icy material in the ring annulus for panels 1, 2 and 3, respectively. The simulated brightness temperature matches the observations well.

high resolution spokes observations and simulations for three ring annuli in the inner, middle and outer C-ring at intermediate azimuthal angles. The simulated scattering profile (brightness temperature versus azimuthal angle) matches the data fairly well with a radially varying non-icy material fraction as shown in Figure RADAR-30. The results of this analysis justify the necessity for including intrinsic thermal emission in order to match the observed brightness temperature, especially around ~83,000 km in the middle C-ring, where the brightness is observed to increase significantly beyond what can be attributed to scattered radiation from Saturn [Zhang et al. 2017a].

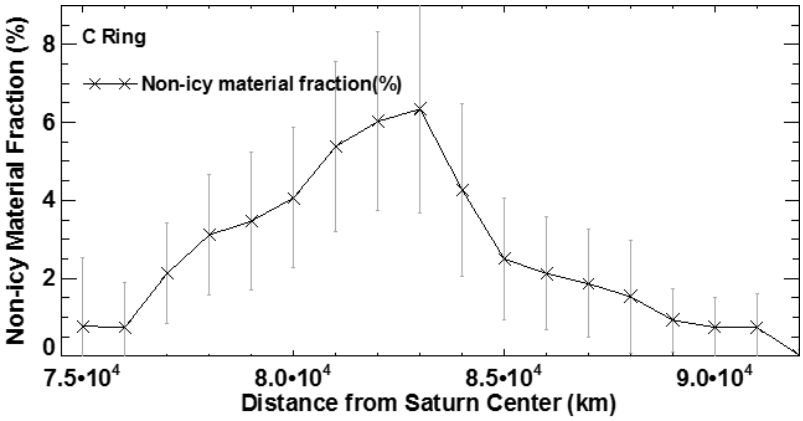

Figure RADAR-30. Simulated scattering profile. The derived radial variation of non-icy fraction reaches its maximum of ~6.3% silicate by volume in the middle of the C-ring and gradually decreases inward, and more sharply outward. The grey vertical lines show the range of one standard deviation.

In the previous paragraphs, we have treated C-ring particles as water ice with a fraction of voids and non-icy material as inclusions. The Maxwell-Garnett mixing rule of the EMT calculates the ring particle's averaged (effective) dielectric constant taking water ice as the host medium. This mixing rule treats one material as the matrix (host material) in which other materials (guest materials) are embedded in the form of small inclusions. However, this model is not symmetric as the host and guest materials do not contribute on an equal basis to the effective dielectric constant. Therefore, it makes a difference what one chooses as the host material. An alternative is to use vacuum as the host medium, which will result in 70% porous C-ring particles and 50% more non-icy material fraction in the C-ring (see Figure RADAR-31). These two cases, using either water ice or vacuum as the host medium, set the upper and lower limit of the non-icy material fraction in the ring particles. The non-icy material fraction will lie in between these two limits depending on which mixing rule is used.

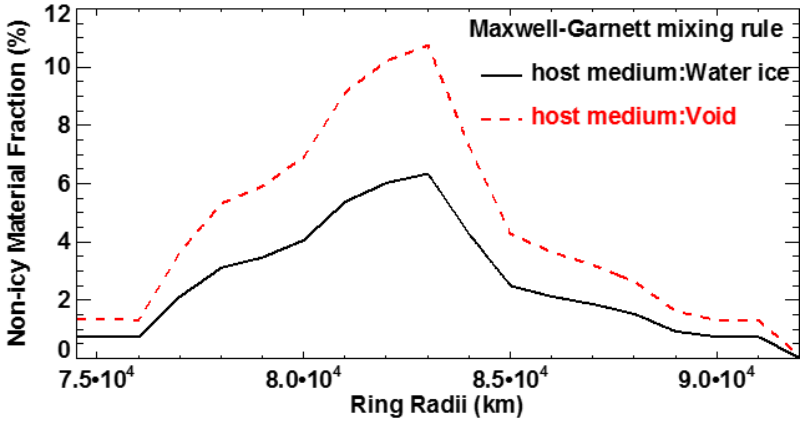

Figure RADAR-31. Using vacuum as an alternative model host medium. Black curve: Maxwell-Garnett mixing rule with water ice as the host material, and 75% porous C-ring particles. Red curve: Maxwell-Garnett mixing rule with vacuum as the host medium, and 70% porous C-ring particles.

EXPOSURE TIME DUE TO MICROMETEOROID BOMBARDMENT

After their formation, the rings have been continuously bombarded by extrinsic meteoroid impacts that have the effect of polluting them with non-icy material over time. The required exposure time to accumulate the observed fraction of non-icy material implies a lower limit on the rings' age. The exposure time scale due to micrometeoroid bombardment is inversely proportional to the local impact flux onto the ring plane.

The radial variability of the derived non-icy material fraction is surprising and warrants discussion. Considering that the local impacting flux depends approximately linearly on the local geometric optical depth in most regions of the C-ring, the final non-icy material fraction should be proportional to opacity, which equals geometric optical depth divided by surface density ($\kappa = \tau_{geometry}/\sigma$). The larger the opacity, the higher the non-icy material fraction should become, if meteoroid bombardment is the only pollution source. Though a complete opacity radial profile for the C-ring is still unknown, the current values at a few radial locations from density wave measurements suggest a higher opacity in the inner (and outer) C-ring of ~0.15 $cm^2\ g^{-1}$, and a significantly lower opacity in the middle C-ring of ~0.022 $cm^2\ g^{-1}$ [Baillie et al. 2011; Hedman and Nicholson 2013], which is the opposite trend to the shape of the non-icy material fraction we have found. In Figure RADAR-32, we demonstrate how the non-icy material fraction would evolve over 15 and 45 million years (upper panel) and 30 and 90 million years (lower panel) after the C-ring first formed assuming that the rings were initially pure water ice, that meteoroid bombardment is the only pollution source and that the C-ring optical depth and surface density have not changed significantly during that time. The opposite trend between the observed (black curve) and simulated (red dashed curve) non-icy material fraction profiles in Figure RADAR-32 implies that if the rings started as mainly pure ice ~15–90 million years ago, there must be some non-icy material source other than the nearly radially constant micrometeoroid flux in order to explain the enhanced non-icy fraction in the middle C-ring [Zhang et al. 2017a].

On the other hand, in order to accumulate the observed peak non-icy material fraction merely from meteoroid bombardment in the middle C-ring, it would require ~900 million years, which sets an upper bound on the age. However, if this is the case, it would imply that the non-icy material fraction in the inner and outer C-ring would be much higher than the observed values and a process that preferentially removes non-icy material from the inner and outer C-ring regions would be required in order to account for the observed distribution. Another alternative is that the C-ring did not start out as nearly pure ice. In such a case, if the non-icy material was intramixed within the initial ring composition, any radial variability that may have existed most likely would have already been smoothed out as a result of ballistic transport [Cuzzi and Estrada 1998; Estrada et al. 2015]. That is, ballistic transport, which behaves much like both a diffusive and advective process [Cuzzi and Estrada 1998] (see next section), generally works to smooth out any compositional differences that may have existed or that might arise in the rings. Indeed, how material is diffused/advected through ballistic transport in the rings is an effective means by which the age of ring features or the rings themselves can be determined. Therefore, the exceptionally high non-icy material fraction in the middle C-ring requires either the recent introduction of a high concentration of non-icy material, or a process that preferentially removes non-icy material from the inner and outer C-ring regions

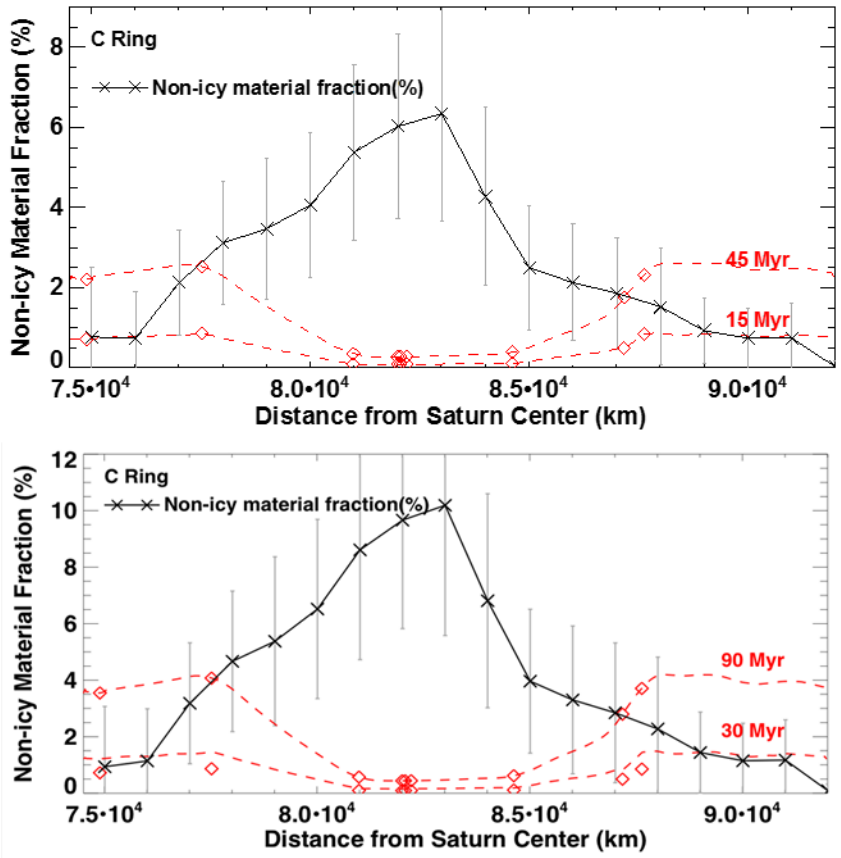

Figure RADAR-32. How the non-icy material fraction would evolve over millions of years. Black curve: Derived non-icy material fraction from the observations. Both cases using Maxwell-Garnett mixing rule with water ice (upper panel) and vacuum (lower panel) as the host material are shown. Red dashed curve: The non-icy material fraction evolution over 15 and 45 million years (upper panel) and 30 and 90 million years (lower panel), if meteoroid bombardment is the only source of contamination. Red diamonds demonstrate the positions where opacity measurements [Baillie et al. 2011; Hedman and Nicholson 2013] have been made through density waves.

[Zhang et al. 2017a]. We argue that the persistence of a non-uniform distribution of silicates within the middle C-ring strongly favors the former scenario. In the next sections, we describe the former scenario in more detail that attempt to address this observation.

A BAND OF NON-ICY MATERIAL FROM AN IMPACTING CENTAUR AT C-RING CENTER

In the first scenario, we assume that meteoroid bombardment has continuously contaminated the whole of the C-ring since it first formed, and that a higher concentration of non-icy material was injected into the middle C-ring at a more recent time. Barring any process that might dilute the non-icy fraction—for example, a by-product of ballistic transport is that icier material spills over from the B-ring to C-ring [Durisen et al. 1992; Estrada et al. 2015]—the implied age of the C-ring from this evolution is between 15 and 90 million years based only on the pollution of the inner and outer

C-ring for the nominal micrometeoroid flux (see Figure RADAR-32). Note that this estimate is inversely proportional to the time-averaged micrometeoroid flux.

Any additional contribution to the effective dielectric constant of material must be attributed to an alternative, more localized source. In order to further examine this source, we investigated a scenario in which the middle C-ring was contaminated by a debris cloud derived from a Centaur disrupted by previous encounters with Saturn [Hedman et al. 2011]. Centaurs captured into orbit around Saturn might break apart into debris through tidal disruption as they pass close to the planet, or even through direct collision with the rings. This debris will follow the same bound trajectory and crash into the rings potentially across a range of radii at later periapses [Hedman et al. 2011]. Assuming the non-icy material is all silicates, and that this material is now finely ground and intramixed within the ring particles, we find that the observed non-icy material distribution may be produced during the break-up of a Centaur with radius R ~7–20 km. The capture of the Centaur would likely involve it passing through the ring plane several times leaving little material behind initially, becoming weaker and rubblized until tides break up the object into smaller fragments which could then be captured and integrated into the rings [Hyodo and Ohtsuki 2014]. In such a scenario, it is not clear that the material would initially be concentrated into a narrow annulus of material. However, in the case that a narrow annulus is the initial condition, the spreading timescale of the high concentration of non-icy material through ballistic transport [Cuzzi and Estrada 1998] could help constrain the earliest possible time the initial contamination occurred. A conservative estimate of the time it would take for the intramixed pollutant that initially occupies an annulus at ~83,000 km to spread into the observed distribution is about 9.3 million years. Therefore the non-uniform radial peak in our intramixed, non-icy material fraction profile would be a relatively new structure, with an age on the order of ~10 million years, though the absolute time scale depends on the meteoroid flux rate at infinity and how gravitationally focused the micrometeoroids are by Saturn. Such Centaur crossing events are fairly likely to occur over this time period. On average, about 5 to 52 Centaurs larger than 7 km in radius may have hit the Saturn system within the last ~10 million years. Once the Centaur is disrupted into debris by Saturn's gravity, the debris is likely to be absorbed by the rings after several orbits. The observational evidence would suggest, however, that successful disruption and capture events of such large Centaurs have not happened so frequently otherwise we might expect to see relatively large peaks in non-icy material concentration in other C-ring regions rather than the single, well-defined peak we observe in the middle C-ring.

RING OPACITY FAVORS LARGE ROCKY CHUNKS

In the previous section, we have discussed the case where non-icy material brought in by the incoming Centaur is intramixed within the ring particles as envisioned in the EMT model. However, it seems unlikely that an incoming Centaur, basically a rocky object that may have substantial internal strength, torn apart gently by tides and ultimately broken into pieces that reside in the C-ring, could be ground to powder this way, especially if it were done fairly recently. It seems more likely that there would still be many chunks of solid silicates in the centimeter-decimeter-meter size range left, which have now been coated by the icy ring material. This would require more total non-icy material in the middle C-ring since non-icy material affects emission most efficiently when

finely divided as in the EMT intramixed assumption versus a salt and pepper, or intramixing type model—Cuzzi and Estrada [1998]; Poulet and Cuzzi [2002]; Cuzzi et al. [2014].

Moreover, 75% porous ring particles containing less than 11% intramixed non-icy material implies a ring layer opacity of ~0.07–0.08 $cm^2\ g^{-1}$ using our nominal particle size distribution, which is inconsistent with the opacity measured through density wave. Recall that the derived radial opacity profile from density wave measurements is notably non-uniform. In order to have a radially varying opacity profile, the C-ring particles must have a radially-varying particle size distribution or a radially varying mean particle density $\bar{\rho}$. At the inner and outer C-ring, the measured opacity is higher than our calculated value, possibly suggesting fewer large particles in those regions. We are able to match the measured opacity by decreasing the maximum particle size from 4.5 m to 1.5 m −2.2 m in the inner C-ring and 1.3 m in the outer C-ring. However, by merely increasing the maximum particle size it is not possible to lower the opacity in the middle C-ring to the measured value ~0.022 $cm^2\ g^{-1}$. Therefore, the exceptionally low opacity in the middle C-ring suggests a potentially considerable amount of extra mass hidden in the ring particles, just where the finely distributed non-icy material also is. A particle in the middle C-ring is likely to contain large chunks of silicates, which originated from the disrupted Centaur.

We proposed a silicate-core and porous-dirty-icy-mantle model in which the mass of the Centaur is initially contained in a narrow annulus located at the peak of the current non-icy material fraction bump in the C-ring center (83,000 km) [Zhang et al. 2017a]. This annulus can viscously spread to the feature's current width (78,000 km–87,000 km) and surface density in as little as ~20–30 million years. It is possible that a combination of viscous spreading and ballistic transport acting together could shorten this time further. We find this variant more compelling because it successfully fulfills the requirements for a strong forward-directed scattering phase function, while explaining both our derived radially-variable thermal emission and the low opacity in the middle C-ring, without requiring the Centaur to be ground to powder.

Other main rings

Though the ring particles in the Cassini Division are very similar to the C-ring particles, and thus a pure Mie scattering phase function matches the observation well, B-ring and A-ring are much optically thicker and comprise particles much larger as compared to the wavelength. We found that a hybrid phase function that varies between Mie half-isotropic to purely isotropic fits the observations best in A-ring and B-ring. By fitting the shape of the scattering profile in the Cassini Division, we found that Cassini Division particles are likely to have 90% porosity, which is consistent with the high opacity ~0.064–0.111 $cm^2\ g^{-1}$ derived from density waves [Colwell et al. 2009]. Though we are not able to determine the porosity values for B-ring and A-ring particles only based on our data, the high opacities measured through density waves [Hedman and Nicholson 2016] suggest that B-ring particles have porosities in excess of 85% while A-ring particles are likely to have porosity value in between 55% and 90%. The radial profile of the derived non-icy material fraction and the corresponding required exposure time to meteoroid flux is rather flat in the B-ring, Cassini Division and A-ring as compared to that in the C-ring, which indicates that the non-icy material observed in these regions has been

accumulated from meteoroid bombardment. In Table RADAR-4, we summarize the derived results (i.e., particle porosity, scattering phase function, silicate fraction, and exposure time) for all the main rings [Zhang et al. 2017b].

Table RADAR-4. Summary of the main finds in C-ring, B-ring, Cassini Division, and A-ring from Cassini passive radiometry observations.

Rings	Radial Range (km)	Porosity	Phase Function	Silicate Fraction	Exposure Time (million years)
C-ring	74,510–92,000	70%–75%	Mie	Baseline: 1–2% Maximum: 6–11%	15–90
B-ring	92,000–117,580	85%–90%	From 50% Mie / 50% Isotropic to Isotropic	Inner/Outer:0.3–0.5% Middle: 0.1–0.2%	30–100
Cassini Division	117,580–122,170	≳90%	Mie	1–2%	60–100
A-ring	122,170–133,423	55%	Isotropic	0.2–0.3%	80–150
Inside Encke Gap		90%	30% Mie / 70% Isotropic		

Conclusion

We conclude that ring particles in the C-ring, B-ring, Cassini Division, and A-ring are likely to be highly porous [Zhang et al. 2017b]. The result that ring particles are very porous across all the main rings may come as some surprise, especially in dense, high particle packing fraction regions like the A-ring and B-ring wakes, since it might be expected that collisions between particles would lead to compaction. Yet relative velocities, and thus impact velocities between ring particles even in these dense regions are small, and is especially true if they are very dissipative—for example, Porco et al. [2008]—making collisions more gentle, and perhaps causing particles to spend more time being stuck in larger clumps—see, for example, Robbins et al. [2010]. Collisions at such low velocities might lead to sticking of ring particles, or only bouncing with some compaction of the particle's surface layers—for example, Güttler et al. [2010]. Meanwhile, micrometeoroid bombardment is continuously acting to garden those same ring particle surfaces, perhaps producing fluffy regoliths, not just from direct bombardment, but even more so from the secondary impacts due to the ballistic transport of the large amounts of impact ejecta. It may be that these competing effects might account for and/or maintain particle porosity.

The C-ring non-icy material fraction shows the most significant and interesting radial variation, reaching a maximum of 6%–11% by volume in the center of the C-ring near 83,000 km, and decreasing gradually to 1%–2% inward and rapidly outward from this radial location [Zhang et al. 2017a]. A possible scenario that nicely explains this trend has a passing Centaur providing the necessary material for post-formation enhancement of the C-ring non-icy material in addition to the micrometeoroid in-fall component. That is to say, the non-icy material fraction in the inner and outer C-ring, which is about 1%–2%, is due to meteoroid bombardment and indicates an exposure time of 15–90 million years. On the contrary, the non-icy material fraction radial profile in the B-ring, A-ring and Cassini Division are relatively flat and can be explained by merely meteoroid bombardment pollution.

Our derived results for the radial distribution of the mass fraction of non-icy material due to direct micrometeoroid bombardment in general support the idea that Saturn's rings are geologically young, formed ≲150 million years ago. The high contamination rate in the middle C-ring, which we have explained as being due to the breakup and deposition of a Centaur, occurs within this time frame [Zhang et al. 2017a]. It further suggests a formation scenario in which the rings are derived from the relatively recent breakup of an icy moon, perhaps of Mimas' mass consistent with the post Voyager ring mass estimate [Esposito 1984], though recently Hedman and Nicholson [2016] suggest that the total mass of the rings may be as little as 0.4 times Mimas' mass. However, no model for the origin of the rings in which they form within the indicated timescale has thus far been proposed. It might be argued that such a ring progenitor may have had a rocky core that could still in one form or another remain hidden within the rings [Charnoz et al. 2009b] which might then account for the anomalous fraction in the C-ring. However, how that rocky material ends up solely in the C-ring but apparently not elsewhere, combined with the fact that the radial distribution of non-icy material and observed opacity in the middle C-ring can be simulated through viscous diffusion of an initially high density annulus of rocky chunks embedded within icy mantles (core-mantle model) suggests that the Centaur capture scenario can readily account for the observations.

Active radar observation during Cassini's Grand Finale

During the Grand Finale, RADAR scanned along the line connecting the ring plane crossing point with Saturn's center in the active mode. These observations looked at the rings' backscattering as a function of radial distance. Although similar observations have been done at optical wavelengths, RADAR saw a different population of ring particles because our measurements will be dominated by cm-scale and larger particles, while the optical observations are seeing a wider spectrum of particle sizes. Figure RADAR-33 shows calibrated normalized backscattering cross-section in F-ring orbit Rev 260 and Proximal orbit Rev 282. These data have not gone through the range compression process and the resolution is therefore equal to the aperture resolution with angular diameter of 0.36°, which is about hundreds of kilometer as projected onto the ring plane. After the

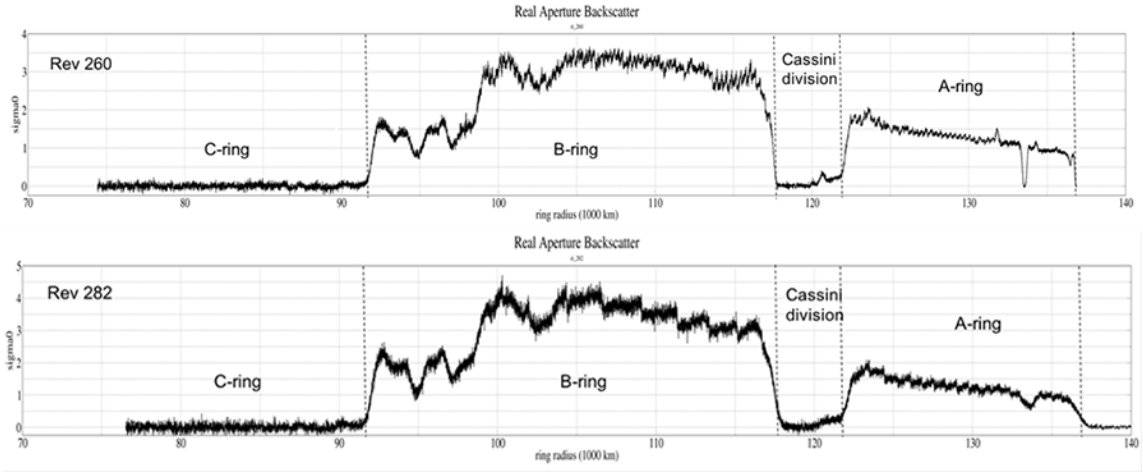

Figure RADAR-33. Normalized back scattering cross-section obtained in Rev 260 and Rev 282.

range compression we would expect the radial resolution to be as high as several kilometers. The Rev 260 observation was shortly after the ring plane crossing and thus has a shorter observation range and thus higher resolution.

In order to compare the observation with the known ring structure, we plot the rings optical depth with the red curve over the Rev 260 data (see Figure RADAR-34). We notice that the backscattering signal in the C-ring and inner Cassini Division is below the noise level, which is consistent with the previous Arecibo observation, which is due to the low optical depth, smaller particle size, and relatively larger absorption loss there. However, we do see backscattering from the outer Cassini Division, suggesting that the ring particles at the outer Cassini Division are more similar to those in the inner A-ring. These particles might have been spilled from the inner A-ring through ballistic transportation. We also notice that the backscattering in the A-ring interior Encke Gap (located at 133,590 km) is much higher than that exterior Encke Gap, suggesting that particles in the exterior Encke Gap tend to be smaller than those in the interior Encke Gap. The observed backscattering in B-ring and A-ring

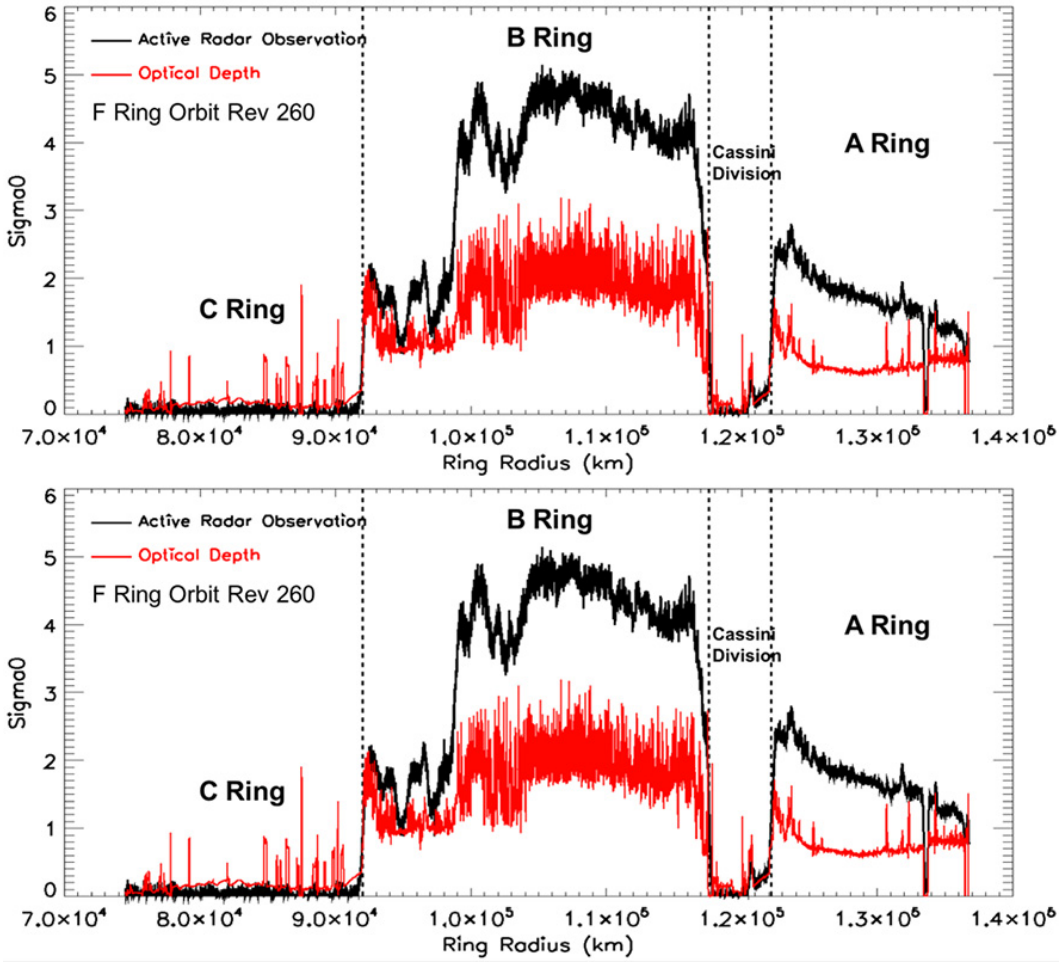

Figure RADAR-34. Comparison between the Rev 260 normalized backscattering cross-section (black curve) and rings optical depth (red curve). In the lower panel, we further zoom in and focus on the A-ring. For better comparison, we have rescaled the optical depth in the lower panel.

is lower than as predicted by a pure Mie scattering phase function. An accurate backscattering phase function is required in order to match the simulation with the observation, which will then help determining the non-spherical shape of the A-ring and B-ring particles. In the lower panel, we further zoom in and focus on the A-ring and Cassini Division. Despite the difficulty in calibrating these observations, we have successfully had the observation line up with the known fine structures. We are able to resolve the Encke Gap, which is about 300 km wide. Furthermore, we have captured all the density and bending waves structures, which are the dynamical structures we are interested in. There is still a great deal to be done, but we must acknowledge that these results of the Cassini era will stand firmly as the benchmark until that point in a possibly uncertain future that we may return to observe Saturn and its majestic rings up close once again.

Icy Satellite Science

Introduction

While it was initially designed to examine the surface of Titan through the veil of its optically opaque atmosphere, RADAR was occasionally used to observe Saturn's airless icy moons from long ranges (>50,000 km) and, less frequently, during targeted flybys. In this section, we give an overview of the Cassini radar/radiometry observations of Mimas, Enceladus, Tethys, Dione, Rhea, Hyperion, Iapetus, and Phoebe, many of which have not been published as of this writing. These observations have taught us much about the about the near-surface of the middle-sized satellites of Saturn, but many questions remain about their composition, structure and what it tells us about their geological history and interaction with Saturn and its rings.

Science objectives

Investigating the microwave properties … provides insights into the various physical and geological processes … and thus into what is common and what is specific to the history of each satellite.

After Titan, the six largest Saturnian satellites are, in order of distance from Saturn: Mimas, Enceladus, Tethys, Dione, Rhea, and Iapetus (Figure RADAR-35). Phoebe and Hyperion are smaller and exhibit irregular shapes. The collective formation of these moons and subsequent evolution remains an outstanding problem. All of them are composed largely of water ice [Clark et al. 1986]. However, their respective evolution history and near environment have led to different regolith composition and structure. In particular, they show evidence of varying degrees of geologic activity in the past and, in the case of Enceladus, the present [Porco et al. 2006]. Investigating the microwave properties of Saturn's airless satellites' near-surface provides insights into the various physical and geological processes that have affected them and thus into what is common and what is specific to the history of each satellite.

Figure RADAR-35. Saturnian icy airless satellites observed by the Cassini RADAR (with the exception of Hyperion). They are here presented at scale (in size, not in distance) and by order of distance from Saturn.

Microwave observations of Saturnian satellites are rare and recent. Until the 2004 through 2007 oppositions of the Saturn system, Earth-based radar measurements in the outer system were limited to Galilean satellites and Titan [Muhleman et al. 1990; Campbell et al. 2003; Roe et al. 2004]. Black et al. [2004, 2007] observed both hemispheres of Iapetus and the middle-sized Saturnian satellites Rhea, Dione, Tethys, and Enceladus with the Arecibo Observatory's 13 cm wavelength (2.38 GHz) radar system. The other Earth-based planetary radar system, Goldstone—equipped with a 3.5 cm transmitter (X-band)—has not been used to observe these objects or other Saturnian airless satellites yet. In addition, passive microwave observations of Saturnian moons from Earth are difficult to make due to confusion with emissions from the planet, the faintness of some targets and their small apparent size. That is the reason why, with the exception of Titan and Iapetus, they have never been conducted. In that regard, the Cassini RADAR and radiometry observations of Saturn's icy moons are pioneer.

RADAR operates at a wavelength (2.2 cm, f = 13.78 GHz), which is a factor of 6 times smaller than the 12.6 cm wavelength used by Arecibo, and 22 times longer than the millimeter wavelengths at the limit of Cassini's CIRS instrument. It has thus expanded the observation of the icy satellites of Saturn to a new and revealing length scale. The Cassini RADAR likely probes icy subsurfaces down to depths of several meters against few millimeters for CIRS. Its main scientific objective was to provide constraints on the thermal, physical and compositional properties of the first few meters below the surface of the investigated objects and, doing so, insights into the degree of purity and maturity of their water-ice regolith. The goal was also to further explore existing hemispheric dichotomies or regional anomalies such as the dramatic two-tone coloration of Iapetus. In addition, operations at closer ranges (i.e., spatially resolved) offered a unique opportunity to examine or detect features of interest at the surface and identify potential hot spots in the near-surface, in particular of Enceladus. Overall, RADAR observations of Saturn's icy moons were to enhance our understanding of the diversity of icy regoliths in the solar system by comparison with radio observations of other objects such as the Galilean satellites (e.g., de Pater et al. [1984], Muhleman and Berge [1991], and Black et al. [2001]), trans-Neptunian objects (e.g., Lellouch et al. 2017], or comets (e.g., Gulkis et al. [2015]).

Data acquisition, calibration, and reduction

Most of the Cassini icy satellite observations are distinguished by the relatively long range to the target. Notable exceptions are one close flyby of Iapetus that is partially analyzed in Le Gall et al.

[2014], two close flybys of Enceladus where one is partially analyzed in Ries and Janssen [2015] and Le Gall et al. [2017], one close flyby of Dione (not yet analyzed), and one close flyby of Rhea that is partially analyzed in Wye [2011] during which spatially resolved data were acquired in both the active (scatterometry) and passive (radiometry) modes of the instrument.

Background

RADAR data come in two flavors: active and passive. In its active mode, the instrument measures the radar albedo which describes the reflectivity of a target. The radar cross-section (RCS) of a target is the projected area of a perfectly reflective, isotropic target that would return an identical echo power to what is measured, if it was observed at the same distance from the radar and with the same transmitted and received polarizations. The radar albedo is derived by normalizing the radar cross-section by the projected geometric area of the target or equivalently by the RCS of a perfectly reflective target such as a smooth metallic sphere. It is thus a dimensionless quantity which is a measure of how reflective the target is in the backscatter direction. RADAR receives echoes in the same linear polarization as it transmits, so it provides same-linear radar albedos at 2.2 cm. For more details, see Ostro et al. [2006] and Wye [2011].

In its passive mode, RADAR records the microwave thermal emission from the near-surface through the measurements of its brightness temperature essentially at the same wavelength (2.2 cm) and with the same aperture as in active mode. By virtue of the Rayleigh-Jeans approximation, the 2.2 cm emissivity of the surface can be estimated from the measured brightness temperature dividing it by the effective physical temperature of the near-surface.

In best cases, active and passive distant observations follow each other so that the same (or almost the same) disk is observed in both modes and thus the derived disk-integrated radar albedo and brightness temperature can be compared, which is key for understanding the near-surface properties. When active and passive measurements are too separated in time, the sub-spacecraft point has changed between observations (both due to the motion of the spacecraft and the rotation of the satellite) and it is not relevant to compare active and passive measurements, especially for satellites that exhibit a hemispheric dichotomy.

Lastly, we note that there were two Hyperion observations, HY15 and HY39. However, these data are not included in this report because their reduction, which requires a shape model is still a work in progress.

Distant observations

Typical distant RADAR observations of Saturn's moons occur at ranges between 50,000 km and 500,000 km where the antenna beamwidth is comparable to or greater than the apparent angular extent of the target's disk. These experiments were designed largely for disk-integrated albedo and average temperature calculation. The derivation of these quantities is described in the next paragraph. Ostro et al. [2006, 2010] report on the distant observations of Saturn's major airless

satellites measured at the beginning of the mission. Since then, the observational database has significantly increased.

DISTANT ACTIVE STARES

During distant active observations, often referred to as stares, RADAR transmits 46 W through the 4 meter dish antenna with a half-power beamwidth of 0.37°. The receiver operates with a relatively high noise temperature around 900 K, and the received echo power is well below the noise floor. To overcome the low signal strength, the radar stares at the target body while accumulating echo measurements (see Figure RADAR-36 left). Spacecraft power constraints limit RADAR to a 7% transmit duty cycle, so the actual integration time is less than the total staring time, which usually runs 5 to 10 minutes for a single observation. In order to maximize the signal to noise ratio (SNR), the echo data is Fourier-transformed and then summed in the frequency domain. The transmit events consist of bursts of single frequency pulses at 13.78 GHz. The received echo power is spread out in the frequency domain by Doppler variation, which arises from the relative motion of the spacecraft and the rotation of the target body (see Figure RADAR-36 right). For the icy satellites, the Doppler variation ranges from a few hundred Hz up to about 4 kHz. The pulsed nature of the transmit events introduces grating lobes spaced at the pulse repetition frequency (PRF). The PRF is set to a frequency higher than the Doppler spread of the target, so the central spectral peak is separated from the grating lobes and shows the natural variation of the echo power over the target body.

The sum of the echo power in the power spectrum is then scaled by the radar equation to give a radar albedo for the target body. More especially, the radar equation is applied assuming azimuthal homogeneity and a diffuse surface scattering function given by $\sigma^0 = Acos^n\theta$ where θ is the incidence angle. The values of A and n are obtained from a least-squares fit to the observed power spectrum with a model consisting of the surface scattering function and the antenna gain pattern integrated over the illuminated area (see Figure RADAR-36). The resulting disk-integrated radar albedo is the uniform normalized backscattering value, which reproduces the observed integrated power assuming that the fit model is correct. Therefore, it is derived from the best-fit values of A and n as follows:

$$A_{\mathrm{SL}-2}^{\mathrm{disk}} = \frac{2\pi R_t^2 \int_0^{\frac{\pi}{2}} \sigma^0(\theta) \sin\theta d\theta}{\pi R_t^2} = 2\int_0^{\frac{\pi}{2}} Acos^n\theta \sin\theta \, d\theta. \qquad \text{Eq. 1}$$

It results:

$$A_{\mathrm{SL}-2}^{\mathrm{disk}} = \frac{2A}{n+1}. \qquad \text{Eq. 2}$$

For more details, see Ostro et al. [2006] and Wye [2011].

Table RADAR-5 presents the results of 79 active stares. These results are discussed in the next section (see also Figure RADAR-41). Note that it corrects a factor of 2 error in the originally published values in Ostro et al. [2006, 2010]. The original calculation was normalized by the total surface area of the visible hemisphere (i.e., $2\pi R_t^2$); but to be consistent with Earth-based

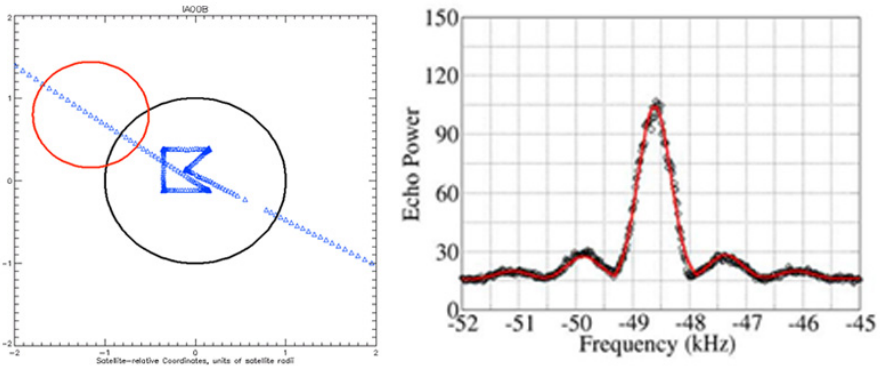

Figure RADAR-36. Distant active RADAR observations. Left: Boresight pointing directions (blue triangles) during the IA-B active stare observation. Iapetus' disk is in black. The beam size at the beginning of the observation is indicated in red. Right: Cassini 2.2-cm radar echo power spectrum (black circle symbols) acquired during the IA-B stare observation and model fit (red line). Figures extracted from Ostro et al. [2006].

observations and the usual convention for the definition of radar albedo, the correct normalization is the disk cross-sectional area (i.e., πR_t^2). This gives an albedo of 1 for a conducting sphere.

The last column of Table RADAR-5 shows the relative errors on the derived disk-integrated albedos. These describe the statistical uncertainties and were derived from the goodness of the fit. The absolute error is about 1.5 dB (1.4 in linear scale). It was estimated adding all known uncertainties on the transmitter power, receiver path losses, receiver gain, and beam solid angle.

We highlight that the choice of a surface scattering function as just a diffuse cosine law is supported by the shape of the measured spectra. As stated in Ostro et al. [2006], none of them, and none of the ground-based echo spectra from any of our targets or the icy Galilean satellites, show any hint of the specular (narrowband) scattering expected if the echoes were dominated by single backreflections from surface elements that are large and smooth at scales near the wavelength. Rather, the spectral shapes are broad, indicating diffuse scattering from structural complexity at some scale(s) comparable to the wavelength or larger.

We further note that radiometry data were also acquired during active stares. However, because the transmitter has just been turned ON at the beginning of the observation and/or because it is turned OFF and ON at least once during these observations, the receiver temperature is not stabilized and the calibration of the radiometry data is not straightforward.

[a] Observations for which there is a discrepancy in the best-fit n and derived radar albedo compared to what was published in Ostro et al. [2010] are marked by a * when the discrepancy is small and by ** when the discrepancy is significant.

DISTANT PASSIVE RASTER SCANS

Distant radiometry observations use the spacecraft reaction wheels to raster-scan a rectangular area centered on the target and extending off the disk for baseline calibration (see Figure RADAR-37). The rasters are approximately 2° in length with spacing less than half of the 0.37° beamwidth. First, the measured antenna temperatures are calibrated using the best current calibration of the instrument. This calibration is based on Titan and Saturn observations and described in Janssen et al. [2016], where it is argued that the resulting absolute uncertainty on non-Titan objects is better than 2%. The cold sky reference level (i.e., the Cosmic Microwave Background brightness temperature at 2.7 K) is determined by averaging the off-disk observations. Second, a limb-darkening brightness temperature model (see Figure RADAR-37 bottom) is used to derive the total emission from the moon, expressed as its disk-averaged brightness temperature $T_{\mathrm{b}}^{\mathrm{disk}}$. This model is convolved with the well-determined beam pattern of the radiometer along the raster-scan path in order to produce synthetic data with the same viewing geometry as the time-ordered measured data (see Figure RADAR-37). The model parameters, namely the pointing error,

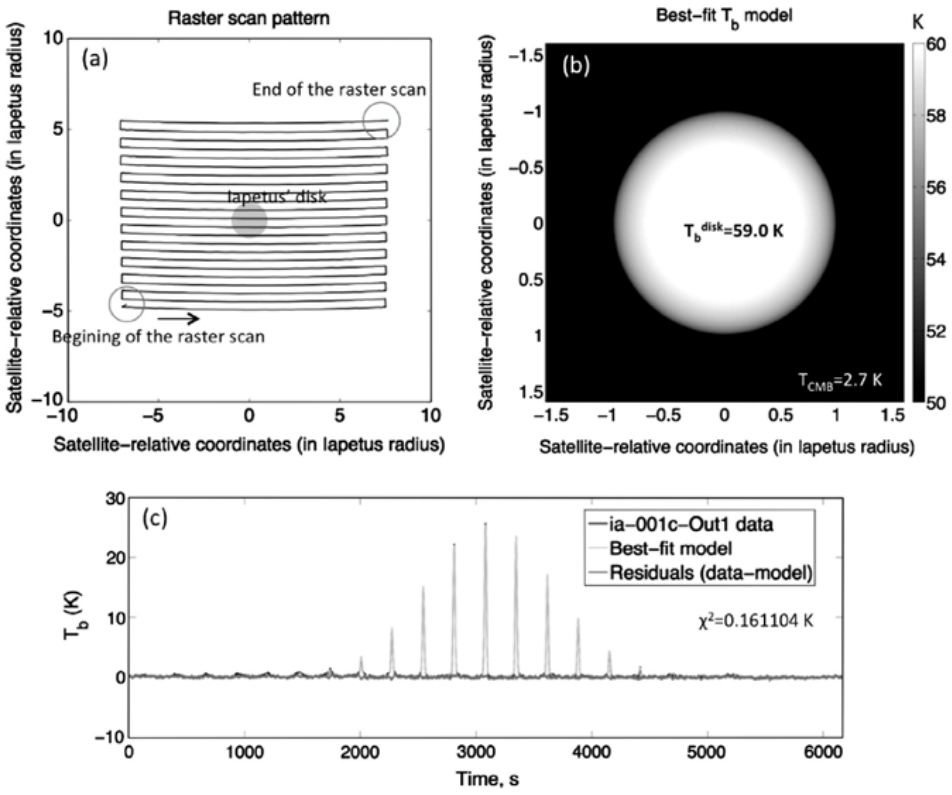

Figure RADAR-37. IA01c-1-Out1 distant radiometry observation of Iapetus. Top Left: Raster-scan pattern performed to collect radiometry data. The beam sizes at the beginning and the end of the raster scan are indicated; they are about the size of Iapetus' diameter (see also Table RADAR-6). Top Right: Measured calibrated antenna temperature compared to the best-fit model as a function of time. Radiometry distant raster-scan typically last one or two hours. Bottom: Best-fit model and corresponding disk-averaged temperature. The model assumes a circularly symmetric bright disk (730 km in diameter) with a $\cos^n\theta$ brightness taper to account for limb darkening (where θ is the emission angle and n = 0.04). Figure is extracted from Le Gall et al. [2014].

the timing offset and the brightness scale factor, are adjusted until the chi-squared sum of the residuals is minimized. T_b^{disk} is derived from the best-fit brightness temperature model as follows:

$$T_{\mathrm{b}}^{\mathrm{disk}} = \frac{1}{\Omega^{\mathrm{disk}}} \int T_{\mathrm{b}}^{m} d\Omega, \qquad \text{Eq. 3}$$

where Ω^{disk} is the disk solid angle and T_b^m the best-fit modeled brightness temperature of each element of solid angle dΩ. The errors on T_b^{disk} are estimated from the least-squares fit. The results are almost insensitive to the choice of a priori model parameters. More details can be found in Janssen et al. [2009].

Table RADAR-6 summarizes all 40 distant radiometry observations of Mimas, Tethys, Enceladus, Dione, Rhea, Iapetus, and Phoebe during the Cassini mission. Note that some radiometer footprints are as small as about 0.4–0.5 satellite diameter. These observations are able to resolve large-scale features at the surface. However, in this report we have chosen to classify them as distant because no scatterometry data were acquired concurrently with the radiometry.

a The planetographic coordinate of the apparent sub-spacecraft point is given at the center of the scan. It may change a few degrees along the scan. L and T flag observations of the leading or trailing sides.

b The sub-solar point is given at the center of the raster scan. ☾ and ☼ flag observations of the day or night sides.

c The beam size at the center of the raster scan is expressed in satellite diameter. It is related to the encounter distance by the following relationship: beam size = distance*tan(0.37/2)/radius, where 0.37° is the antenna beamwidth and radius is the mean of the two equatorial radii of the satellite.

d 2.2-cm absolute brightness temperature over the satellite disk. The derived values include statistical and calibration uncertainties.

e Estimate of the disk-integrated emissivity. As in Ostro et al. [2006], we use the isothermal equilibrium temperature T_{eq} as a proxy for the effective physical temperature at 2.2 cm with $T_{eq} = 91.4\ (1-A_{Bond})^{1/4}$, where 91.4 K is the equilibrium temperature for a grey body at Saturn's distance from the Sun and A_{Bond} is the bolometric Bond albedo of the satellite. For this parameter, we use the up-to-date values published in Howett et al. [2010] based on CIRS observations. Note that these Bond albedo values are different from those used in Ostro et al. [2006] and should be more accurate. Indeed, prior to Cassini measurements, only much less accurate and complete Voyager and ground-based data were available, and the leading and trailing values had been measured solely for a few icy satellites. The emissivity is estimated by $T_{\mathrm{b}}^{\mathrm{disk}}/T_{eq}$.

f Radar albedo value for comparison. Only the values acquired during the same flyby and over (almost) the same disk are shown.

g Observations marked with a # are observations that are preceded or followed in an observation of the same disk in the orthogonal polarization.

SCATTEROMETRY-RADIOMETRY RESOLVED OBSERVATIONS

Over the course of the Cassini mission, RADAR had few opportunities to collect spatially resolved scatterometry and radiometry data during close-targeted encounters of icy satellites. For instance, during Cassini's 49th orbit around Saturn (Sept. 9–10, 2007), RADAR was assigned a time slot while the spacecraft was at a range of ~20,000 km from Iapetus. The SAR image obtained during this close encounter is described in Ostro et al. [2010] while the scatterometry data were processed

and analyzed by Wye [2011] and the radiometry data by Le Gall et al. [2014] (see Figure RADAR-38).

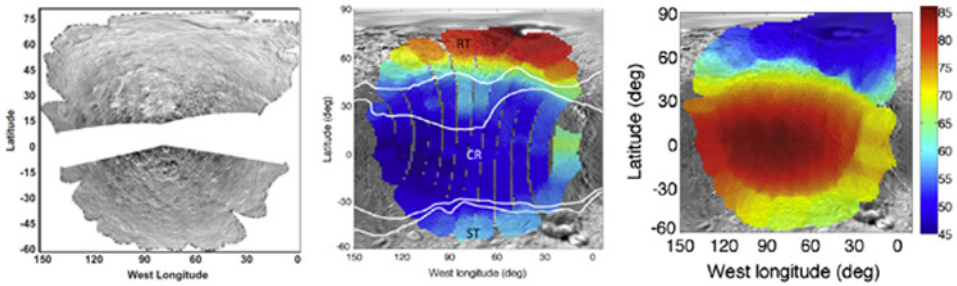

Figure RADAR-38. SAR-scatterometry-radiometry IA49-3 observation. (See Table RADAR-6). Left: SAR image of the leading side of Iapetus acquired during flyby IA49 (September 2007). For this SAR image, a cosine scattering law with exponent 1.5 was subtracted from the original image. Extracted from Ostro et al. [2010]. Middle: Scatterometry data collected during the IA49-3 experiment overlaid on an ISS base map (PIA08406). The normalized backscattering cross-sections are in linear scale and corrected to an incidence angle of 32° using the backscatter analysis conducted by Wye [2011]. Extracted from Le Gall et al. [2014]. Right: Calibrated antenna temperatures recorded during the radiometry IA49-3 experiment overlaid on an ISS base map of Iapetus (PIA08406). Extracted from Le Gall et al. [2014].

Table RADAR-7 lists all resolved scatterometry-radiometry observations of icy satellites during the Cassini mission and, when they exist, the published papers describing these observations.

d 2.2-cm absolute brightness temperature over the satellite disk. When possible, the values are derived as described in the section entitled Distant passive raster-scans.

e Observations marked with a # are observations that are preceded or followed in an observation of the same disk in the orthogonal polarization.

Note that flyby E16 was the only Enceladus' encounter dedicated to RADAR. The SAR image was acquired within 2 min centered around closest approach, while the spacecraft passed the moon at distance of about 500 km, has the highest spatial resolution (~50 m in the cross-track direction, ~200 m in the along-track direction) ever achieved for SAR imagery on any icy satellite. These high-resolution datasets and the concurrent radiometry were analyzed in Le Gall et al. [2017]. Medium-resolution radar/radiometry data were also acquired before and after the E16 closest approach—see the inbound and outbound low-resolution SAR images in Figure RADAR-39 and West et al. [2012]. Unfortunately, half of the concurrent radiometry data were contaminated by

emission from Saturn (and its rings), which was behind Enceladus' disk during the inbound leg of the observation [Ries and Janssen 2015].

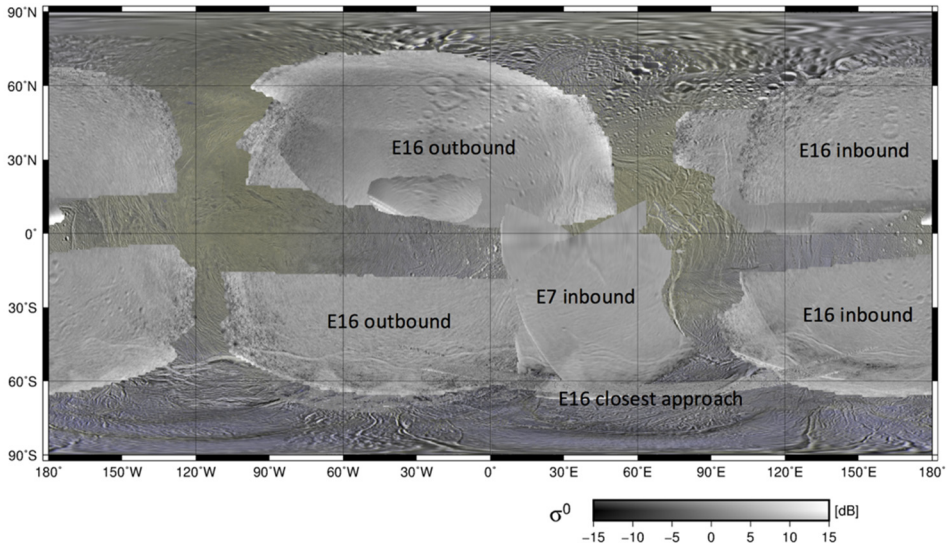

Figure RADAR-39. Mosaic of the EN120 (also called E7) and E16 SAR images of Enceladus overlaid on a color mosaic of Enceladus produced by the Cassini ISS (PIA18435). The measured normalized backscatter cross-sections are in dB and have been corrected for incidence-angle effects and biases due to thermal and quantization noises. Figure is extracted from the Supplementary Material of Le Gall et al. [2017].

Lastly, the first resolved observation of Enceladus was acquired during the inbound leg of the 7th targeted encounter of the moon (often referred to as E7 or EN120) that occurred on November 2, 2009. Following a distant observation, the spacecraft turned to offset the central beam to a suitable imaging area and RADAR collected high-altitude scatterometry imaging and radiometry data down to an altitude of about 30,000 km [Wye 2011]. The resulting low-resolution SAR image has some overlap with the E16 high-resolution SAR observation (see E7 inbound in Figure RADAR-39). However, the concurrent radiometry data cannot be properly calibrated because the receiver temperature was not stabilized during this observation.

Science results and open questions

In this section, we summarize the major science results obtained thanks to RADAR observations of Saturn's icy satellites. When possible, these observations are analyzed in light of observations at other wavelengths or by comparison with radio observations of other icy objects.

Measure of the degree of scattering in the subsurface

Among all the radar-detected planetary bodies in the solar system, the ice-rich satellites of both the Saturn and Jovian systems have the most unusual radar properties. Their reflectivities are very high and they exhibit peculiar polarization properties [Black et al. 2001]. The general understanding

gained so far about the radar properties of the Saturnian satellites icy surfaces, including Titan, at the Cassini 2.2 cm wavelength is that they are dominated by subsurface volume scattering [Ostro et al. 2006; Wye et al. 2007; Zebker et al. 2009a; Janssen et al. 2009].

More accurately, if refraction scattering from dielectric inclusions [Hagfors et al. 1985; Hagfors et al. 1997] or interface cracks [Goldstein and Green 1980] can play a role, the generally accepted explanation is that most icy satellites' radar behavior is related to an effect called the coherent backscatter effect [Hapke 1990; Ostro 1993; Black et al. 2001]. This effect is due to volume scattering from within the satellites' regolith, which, on icy satellites, can be regarded as an extremely low-loss and disordered random medium.

The high radar transparency of ice at temperatures as low as 100 K [Thompson and Squyres 1990; Matzler 1998; Lorenz 1998] compared with that of silicates indeed permits deeper radar sounding (10–100 wavelengths), longer photon path lengths, and thus higher order scattering from regolith heterogeneities (voids, rocks) producing large backscatter and reducing the emissivity (Figure RADAR-40). The purer and the more structurally complex the subsurface, the higher the radar albedo and the lower the emissivity. Both in its active and passive modes, the Cassini RADAR therefore measures quantities that are closely related to the degree of purity of the regolith and to its structural heterogeneity/complexity.

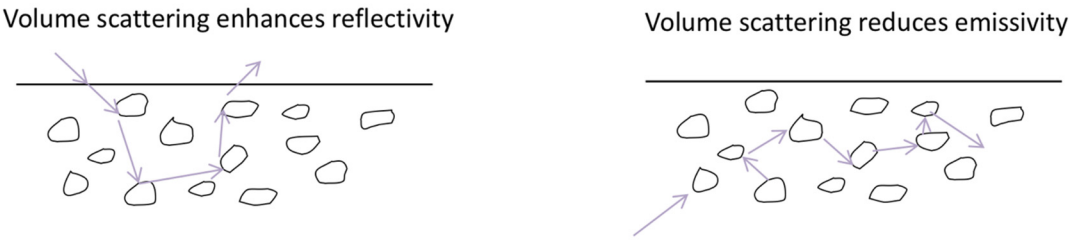

Figure RADAR-40. Effect of volume scattering on the measured reflectivity and emissivity. A low-loss and structurally complex regolith provides enhanced opportunity for scattering, which increases the reflectivity and reduces the emissivity (because it prevents the emitted waves from escaping the subsurface).

INTER-SATELLITE RADAR ALBEDO AND EMISSIVITY VARIATIONS

Figures RADAR-41, RADAR-42, and RADAR-43 show that active and passive signatures differ from one satellite to another—see also Black et al. [2007]; Ostro et al. [2006]—thus indicating various degrees of volume scattering in their subsurface, i.e., various degree of purity and/or complexity of their regolith and thus differences in their composition and/or the various processes that have modified their structure.

For Ostro et al. [2006], variations in terms of composition, rather than structure, is the main source of satellite-to-satellite variabilities. More specifically, they invoke an increase in surface contaminants of Saturnian satellites to explain the observed proportional decrease in radar albedo and the concurrent increase in emissivity in the order Enceladus/Tethys, Mimas, Rhea, Dione,

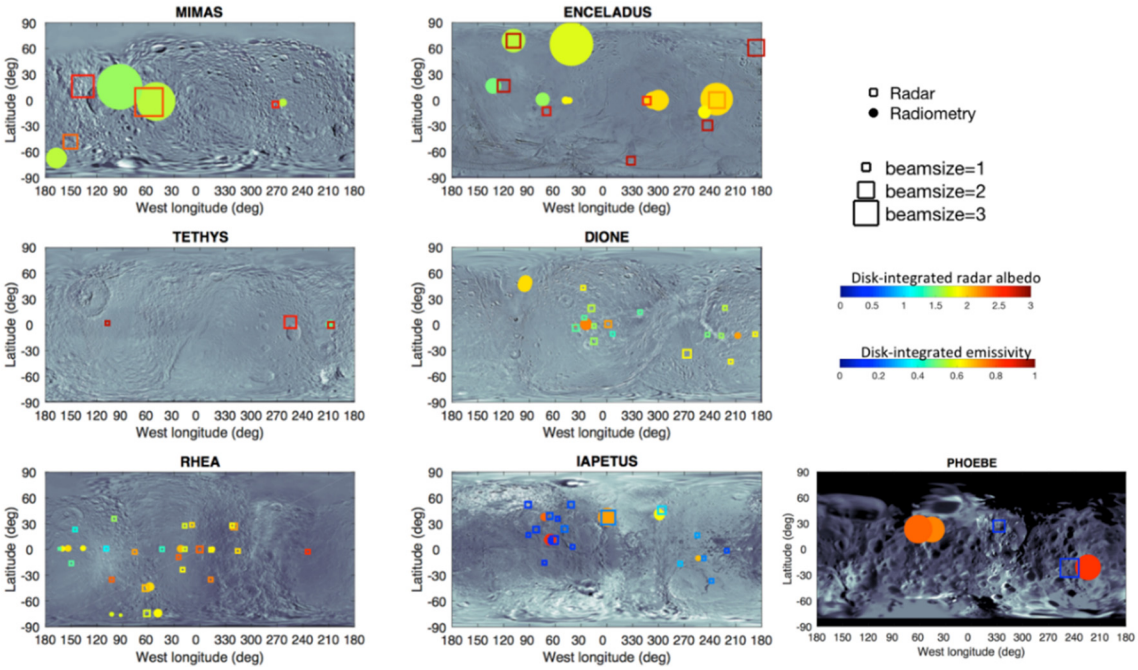

Figure RADAR-41. Sub-radar locations of distant active-radar and radiometry observations of Mimas, Tethys, Enceladus, Dione, Rhea, Iapetus, and Phoebe acquired during the Cassini mission, overlaid on the near-IR ISS mosaics of each satellite. The square symbols correspond to active stare observations while the circle symbols correspond to distant radiometry measurements. The color codes indicate the value of the derived disk-integrated radar albedo for the squares and that of the derived disk-integrated emissivity for the circles, respectively. The size of the symbols indicates the ratio between the beamwidth of the observation and the target angular diameter. The sub-Saturn longitude occurs at zero and the leading side is centered on 90° W longitude.

Iapetus, and Phoebe (see Figures. RADAR-42 and RADAR-43). An argument in favor of this hypothesis is the strong correlation between the radar and optical albedos of the satellites—see Figure 4 in Ostro et al. [2006]. This suggests that an increasing concentration of optically dark contaminant(s) in the near-surface leads to the attenuation of the high-order multiple scattering in the subsurface (water ice being transparent to radio wavelengths) and thus to smaller albedos and larger emissivities. Note that Phoebe, the dimmest of the targets, is nevertheless twice as radar bright as the Moon [Ostro et al. 2006]. The nature of the contaminant(s) remains unknown but Ostro et al. [2006] propose possible candidates including silicates, metallic oxides, and polar organics such as nitriles or complex tholins.

Taking a step further, the active radar and radiometry sequences shown in Figures RADAR-42 and RADAR-43 as well as the hemispheric dichotomies observed at 2.2 cm can be, at first order, explained by variations in term of surface contamination as the result of the competition between several effects including:

- The coating effect of the E-ring
- The coating effect of the vast debris ring from Phoebe

- The geological and thermal history of the icy satellite
- The efficiency of space weathering at the position of the icy satellite within Saturn's magnetosphere

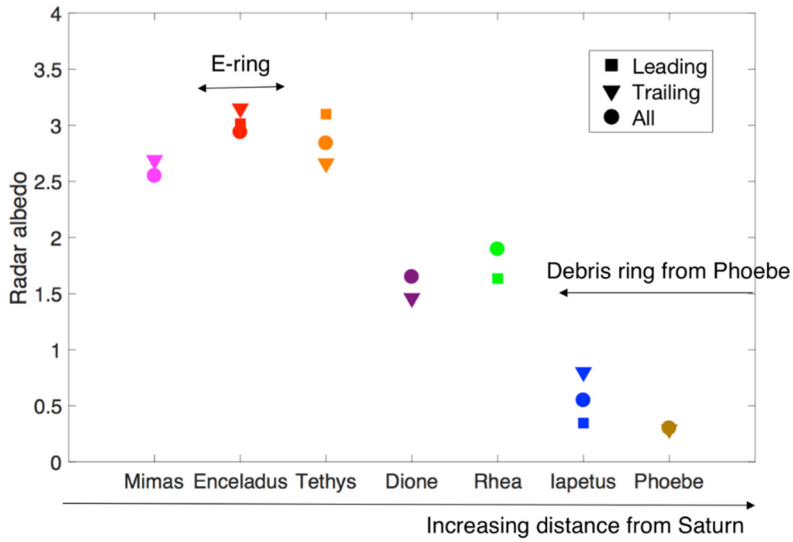

Figure RADAR-42. Radar albedos derived from Cassini active stare observations of Mimas, Enceladus, Tethys, Dione, Rhea Iapetus, and Phoebe. For each satellite, when available, values are shown separately for the leading and trailing sites (in the latitudinal band (−30°, 30°)) in order to reveal possible hemispheric dichotomy. The locations of the E-ring and the vast debris ring from Phoebe are indicated.

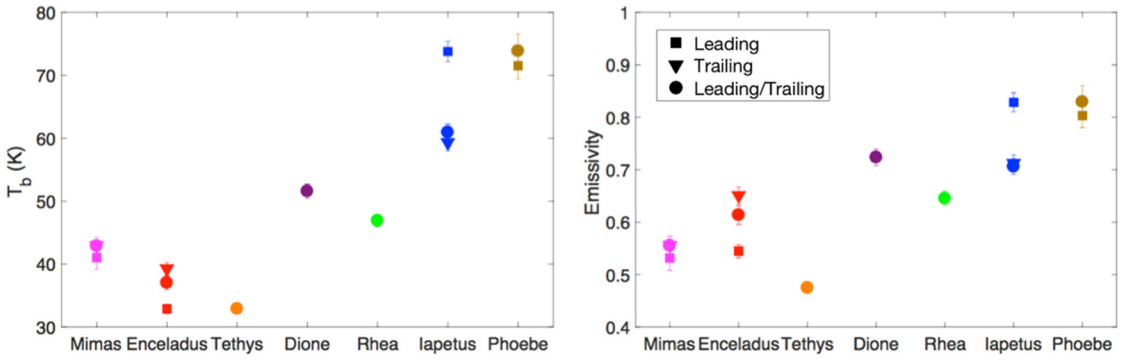

Figure RADAR-43. Disk-integrated brightness temperatures (left) and estimated emissivities (right) derived from Cassini passive distant observations of Mimas, Enceladus, Tethys, Dione, Rhea, Iapetus, and Phoebe. For each satellite, when available, values are shown separately for the leading and trailing sites (in the latitudinal band (−30°, 30°)) in order to reveal possible hemispheric dichotomy. Note that the error bars on the emissivity results only take into account the measurement errors, not the error related to the fact that the isothermal equilibrium temperature was taken as a proxy for the effective physical temperature of the near-surface. A more accurate method to constrain emissivity is described in Le Gall et al. [2014].

Around Enceladus, the E-ring guarantees the deposition at the surface of extremely clean water ice that may also be structurally complex and thus very favorable to volume scattering. The decrease in radar brightness from Enceladus outward would then be due to the outward decrease in E-ring flux [Verbiscer et al. 2007] and hence the endowment of the satellite surface with ultra-clean ice. At the other extreme (moving inward from Phoebe), on the contrary, the diffuse debris ring from Phoebe progressively coats surfaces with material of low reflectivity. Geological activity brings fresh water ice at the surface and, if not too ancient, should therefore be associated with especially high albedos. Lastly, the efficiency of space weathering decreases with the distance to Saturn, which may have various implications on the microwave signatures of the icy satellites. For instance, close to Saturn, the magnetospheric ion bombardment should favor ammonia depletion in the near-surface and thus a higher degree of a purity of the water-ice regolith [Lanzerotti et al. 1984; Ostro et al. 2006]. On the other hand, gravitational focusing enhances the meteoroid flux close to Saturn—for example, Morfill et al. [1983]—which should lead to a higher contamination by non-ice compounds.

The differences between Saturn's icy satellites at 2.2 cm wavelength are further discussed in the section entitled Intra-satellite variations: Hemispheric dichotomies.

VARIATIONS WITH WAVELENGTH/DEPTH

Hints on the vertical variations of the regolith can be inferred from comparison of radio observations at different wavelengths. The 13 cm wavelength radar albedos measured from the Arecibo radar system [Black et al. 2004, 2007], once converted into same-sense albedos—from total power albedos as described in Ostro et al. [2010]—are all lower than the albedos obtained with the Cassini radar instrument at 2.2 cm (see Figure RADAR-44).

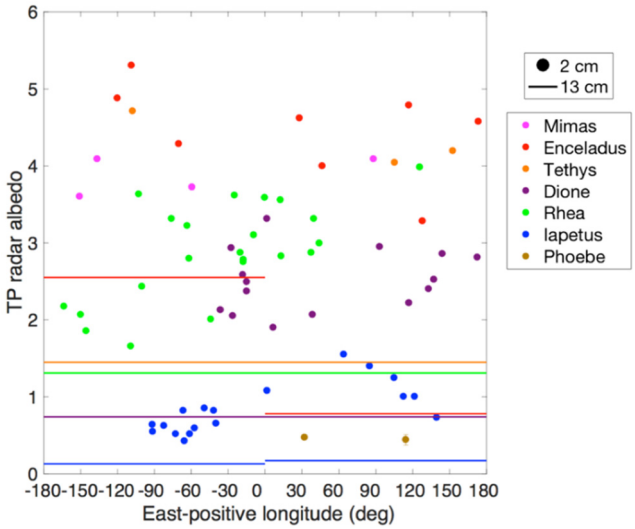

Figure RADAR-44. Total-power (TP) radar albedos of Saturn's icy satellites at the 2.2 cm (dots) and the 13 cm wavelengths (lines). The TP albedos at 2.2 cm were derived from the same-sense radar albedos measured by the Cassini radar as described in Ostro et al. [2010]. The TP albedos at 13 cm are Arecibo measurements averaged over the indicated longitude spans. See the caption of Figure 4 in Ostro et al. [2010] for more details.

The strong drop in radar albedo from 2.2 to 13 cm suggests that either the composition and/or structure is a function of depth everywhere (with e.g., electrical loss much greater at depths or a decrease with depth in the number density of efficient scatterers), or the regolith material is dispersive (with higher losses at higher wavelength). Ostro et al. [2010] favor the hypothesis of a decreasing ice cleanness with depth. Black and al. [2004] and Ostro et al. [2010] both invoke ammonia as the most likely contaminant: a lower abundance of ammonia within the upper one or two decimeters of the ice-rich regolith than at greater depths would account for the observations.

The specific cases of Enceladus and Iapetus for which Arecibo data show, respectively, a hemispheric dichotomy and no hemispheric dichotomy are discussed in the following subsections.

INTRA-SATELLITE VARIATIONS: HEMISPHERIC DICHOTOMIES

Almost all Saturnian icy satellites exhibit longitudinal variations in their microwave signatures, especially between their leading and trailing sides (see Figures RADAR-41, RADAR-42, and RADAR-43). These hemispheric dichotomies provide essential clues on the mechanisms that have primarily affected their near-surface.

IAPETUS' TWO-FACE

The most dramatic hemispheric dichotomy in the Saturnian system occurs at Iapetus, whose trailing side and poles are about an order of magnitude optically brighter than most of its leading hemisphere. The origin of this two-tone coloration has long been controversial, but there seems to now be a consensus toward an exogenic deposition of low-albedo materials probably originated in the region of Phoebe, or the vast debris ring from Phoebe, that crosses Iapetus' orbit—for example, Cruikshank et al. [1983], Buratti et al. [2002], Verbiscer et al. [2009], and Tosi et al. [2010b]. It has also been proposed that the darkening of the leading hemisphere is enhanced by the thermal segregation of water ice leaving behind a darker remnant material in the relatively warm equatorial region [Dalle Ore et al. 2012].

At 2.2 cm, the satellite's radar albedo and emissivity mimic the optical dichotomy, which implies that the leading side's optically dark contaminant must be present to depths of at least one to several decimeters [Ostro et al. 2006, 2010; Le Gall et al. 2014] (see Figures RADAR-41, RADAR-42, RADAR-43, and RADAR-44). On the other hand, at 13 cm, values of the radar albedo from the Arecibo radar system show no significant longitudinal pattern [Black et al. 2004] (see Figure RADAR-44). This strongly suggests that the thickness of the dark layer is no more than a few meters, which is also consistent with the discovery of small bright-ray and bright-floor craters within the dark terrain.

As a further argument, the thermal inertia of Iapetus' dark terrains inferred from Cassini IA49-3 resolved radiometry observations (see Table RADAR-6 and Figure RADAR-38) is much higher than that inferred from CIRS measurements [Howett et al. 2010], which sense only the uppermost layers of the surface [Le Gall et al. 2014]. This suggests a gradient in density with depth or, more

likely, that the radiometer has probed the icy substrate underlying the dark layer. Radiometry measurements also indicate a progressive thinning of the dark layer away from the equator.

In addition, Le Gall et al. [2014] show that the measured thermal emission during IA49-3 arises from several meters of the subsurface, which points to tholins, rather than iron oxide compounds, as the primary contaminants of the dark material. They also find that the dark terrains of Iapetus exhibit a 2.2 cm emissivity close to the emissivity of Phoebe (see Figure RADAR-43), which brings a further argument in favor of a common origin of their darkening agent.

ENCELADUS' YOUNG LEADING HEMISPHERE

Enceladus' 2.2 cm active observations show no dramatic leading/trailing asymmetry (see Figures RADAR-39 and RADAR-42), but passive observations, both unresolved (see Figure RADAR-43) and resolved (see Figure RADAR-45) do. Radiometry observations indeed show that the leading side of Enceladus is about 30% less emissive than its trailing side [Ries and Janssen 2015]. Such a dichotomy is also observed in Arecibo 13 cm measurements, which reveal a much brighter leading side [Black et al. 2007] (see Figure RADAR-44.)

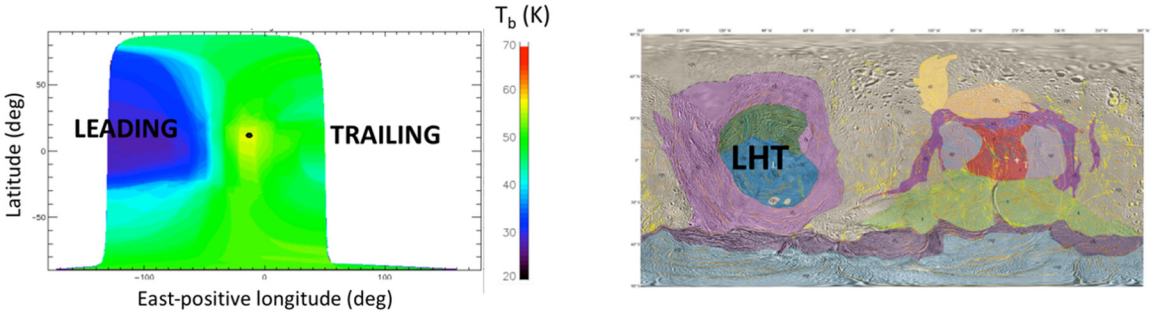

Figure RADAR-45. Resolved passive observations. Left: Deconvolved brightness temperatures measured during E16-Out1 (see Table RADAR-6). Credits: L. Bonnefoy. Right: Structural units of Enceladus as mapped by Crow-Willard and Pappalardo [2015].

Ries and Janssen [2015] propose that the leading side anomaly is an anomaly of scattering, associated with a seemingly young tectonized terrain called the Leading Hemisphere Terrain (LHT)—see Figure RADAR-44 and Crow-Willard and Pappalardo [2015]. In this picture, the LHT would be young enough (75–200 million years) to have been reprocessed (e.g., by micrometeoritic bombardment) only down to a depth shallower than the electrical skin depth at 2.2 cm (a few meters at most) contrary to the trailing side. This would be the reason why the leading/trailing dichotomy is not visible in 2.2 cm active data, which probe the subsurface down to a smaller depth than concurrent passive measurements and observations at 13 cm.

Alternatively, we note in Figure RADAR-42 that the trailing side of Enceladus is actually slightly brighter at 2.2 cm than its leading side. This suggests that, at the depth sensed by RADAR in active mode, the coating effect of the E-ring (which should be more widespread on the trailing side of Enceladus [Kempf et al. 2010]) prevails over the effect of space weathering and/or over the detection of the underneath leading-side young terrain. This would imply that the deposition rate of plume

particles at the surface of Enceladus is larger than estimated by Kemp et al. [2010] and, more specifically, larger than the reprocessing rate by micrometeoritic gardening [Cooper et al. 2001].

AROUND THE E-RING

The coating effect of the E-ring may also be responsible for the clear leading/trailing radar albedo dichotomy observed on Tethys and the hint of similar asymmetry observed on Mimas (see Figure RADAR-42).

We recall that for Rhea, Dione, and Tethys, which lie outside the densest part of Saturn's E-ring, the deposition of icy particles from Enceladus' plumes should be preferentially on the leading side. But Mimas and Enceladus, which are inside the E-ring, should be bombarded on their trailing side [Hamilton and Burns 1994; Buratti et al. 1998]. This is consistent with Figure RADAR-42, which shows a brighter leading hemisphere for Tethys while it is Mimas' trailing side that is brighter.

Cassini active observations also support the idea that the Pac-Man anomalies detected by the CIRS instrument are shallow. We recall that the CIRS instrument has detected, first on the leading side of Mimas and then of that of Tethys, a thermally anomalous extensive region shaped like the 1980s video game icon Pac-Man [Howett et al. 2011, 2012]. Both on Mimas and Tethys, the anomalous region coincides, in shape and location, with a region of preferential bombardment by high-energy electrons from Saturn's magnetosphere. The anomaly occurs because the MeV electrons penetrate into the subsurface gluing the water grains along their path and thus enhancing the thermal inertia. Evidence for a similar surface alteration by high-energy electrons was also detected on the leading side of Dione [Howett et al. 2014] but with a more tenuous expression as expected since the efficiency of the alteration must decrease with increasing distance to Saturn.

Given the small penetration depths of the MeV electrons into the subsurface (a few cm), the Pac-Man effect should not be detectable at 2.2 cm wavelength and the fact that we observe opposite albedo dichotomies on Mimas and Tethys (Figure RADAR-42) is a further argument for the dominant effect of coating by plume particles around Enceladus.

However, the Pac-Man effect may explain why slightly higher disk-integrated brightness temperatures were measured on the trailing side of Mimas (Figure RADAR-43). This can be confirmed or refuted by comparison of the radiometry data with a thermal model that accounts for the season and local hour of passive observations. In addition, the E-ring coating scenario implies the presence of at least a few meters of fresh water-ice material at the surface, which must be validated by model predictions of the deposition rate of particles from the plumes at the surface of Enceladus' neighbors.

DIONE'S PAST GEOLOGICAL ACTIVITY

The leading side of Dione is much brighter than its trailing side (see Figures RADAR-42 and RADAR-46). As for Enceladus, this is most likely the result of past geologic activity and the resultant resurfacing by fresh water ice. Most of Dione's leading side is indeed covered by smooth terrains [Schenk and Moore 2009] and must have a long resurfacing history [Kirchoff and Schenk 2015].

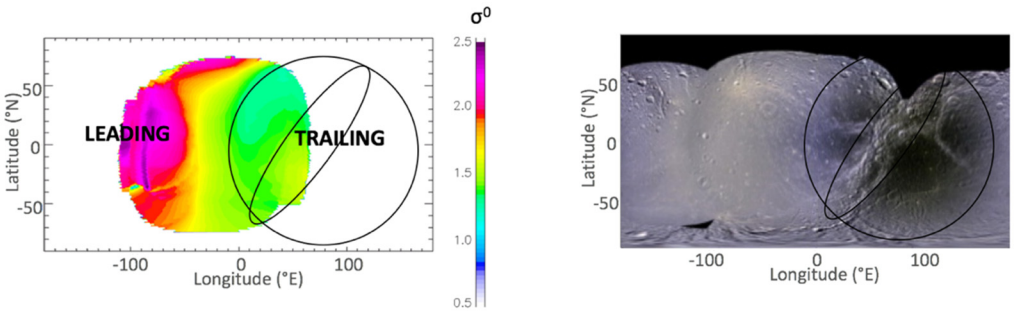

Figure RADAR-46. Trailing side of Dione. Left: Normalized backscattering cross-sections measured during DI 163-1. Credits: L. Bonnefoy. Right: Global mosaic of Dione composed of Cassini Imaging Science Subsystem images [Schenk et al. 2011].

RHEA'S PUZZLING HEMISPHERIC DICHOTOMY AND ENHANCED BRIGHTNESS

Figure RADAR-42, as well as the spatially resolved observations acquired during RH 127-3 (see Table RADAR-6), suggest that Rhea's leading side is radar-darker than its trailing side. Interestingly, Rhea has an optically brighter leading side—so, contrary to Tethys and Dione, there is an opposite correlation between the radar and the optical albedos. In addition, Rhea is surprisingly brighter (and concurrently less emissive) than Dione (see Figures RADAR-42 and RADAR-43). Rhea is also brighter than Dione at 13 cm (see Figure RADAR-44). The cause of this enhanced brightness is not well understood but it could be related to the weaker efficiency of space weathering at the location of Rhea's orbit as suggested by Scipioni et al. [2014] to explain VIMS observations.

Figure RADAR-47 summarizes the likely origins of the inter- and intra-satellites' radar albedo and emissivity variations.

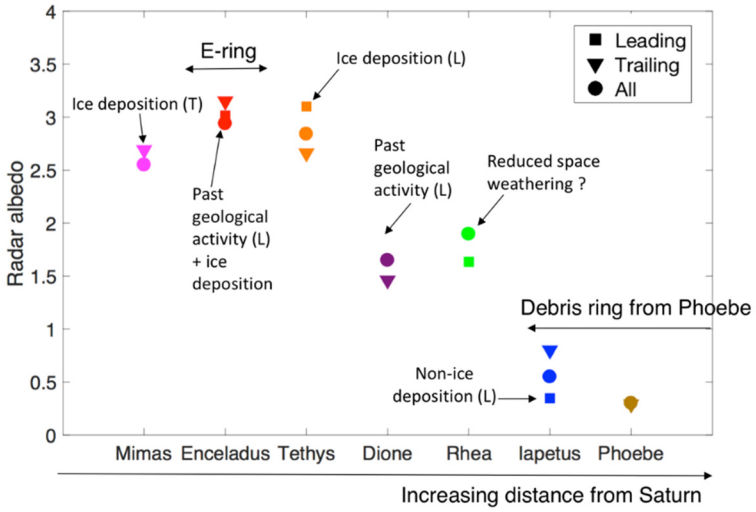

Figure RADAR-47. Radar albedos derived from Cassini active stare observations of Mimas, Enceladus, Tethys, Dione, Rhea, Iapetus, and Phoebe. (See section Distant Active Stares). For each satellite, when available, values are shown separately for the leading and trailing sites (in the latitudinal band (−30°, 30°)) in order to reveal possible hemispheric dichotomy. The possible mechanisms at the origin of the observed inter- and intra-satellite radar albedo and emissivity variations are indicated.

ENCELADUS' SOUTH POLE THERMAL ANOMALY

In 2005, the Cassini spacecraft witnessed for the first time water-rich jets venting from four anomalously warm fractures (also called sulci) near its South Pole [Porco et al. 2006; Spencer et al. 2009]. Since then, several observations have provided evidence that the source of the materials ejected from Enceladus is a large-scale underground ocean whose depth is still debated [Iess et al. 2014; Thomas et al. 2016].

In November 2011, during the closest approach of the 16th Enceladus encounter (flyby E16), RADAR had its first and only opportunity to closely observe Enceladus' south polar terrain (SPT), a few tens of km north of the active sulci (see Figure RADAR-48). At a distance of ~500 km from the surface, the instrument acquired a SAR image (see Figure RADAR-39) and recorded the 2.2 cm wavelength thermal emission of a ~500 km long, ~25 km wide, arc-shaped region centered at 63° S and 295° W and located 30–50 km north of the thermally active sulci identified as the sources of Enceladus' jets.

Le Gall et al. [2017] demonstrate that the brightness temperatures measured during E16 are too high for a purely exogenic explanation, with implications for endogenic processes and heat transport in the Enceladus' SPT. More specifically, they report the detection of prominent thermal anomalies that had not been identified before in the South Pole of Saturn's moon Enceladus (Figure RADAR-48). These anomalies coincide with large fractures, similar or structurally related to the four faults from which Enceladus jets are venting. Their presence implies a broadly distributed heat production and transport system below the south polar terrain of the icy moon with plate-like features. It also suggests that a liquid reservoir could exist at a depth of only a few kilometers under the ice shell at the South Pole—as also supported by interpretation of the libration, topography,

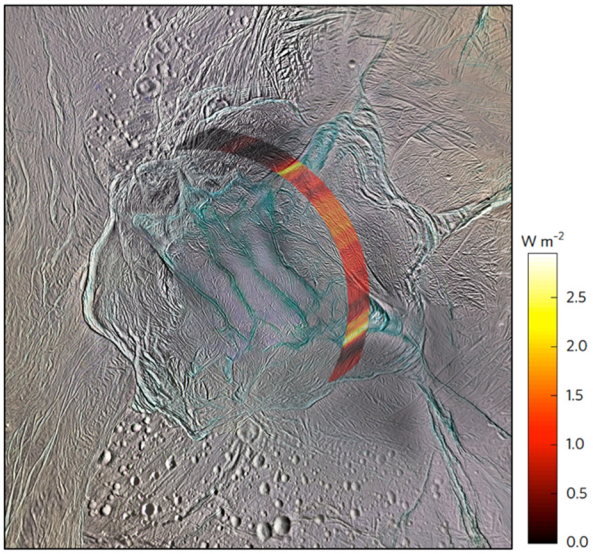

Figure RADAR-48. Minimum flux in excess in the region of Enceladus' SPT observed by the Cassini radar during the closest approach of E16. These values were derived from the E16 resolved radiometry observations by comparison with a thermal + radiative transfer model.

and gravity data [Čadek et al. 2016]—which has important implications for the search of habitable worlds in the solar system.

WHY ARE THEY SO BRIGHT?

Despite our good first-order understanding of the origins of the observed satellite-to-satellite variations and hemispheric dichotomies, an open question persists: why are these icy objects so bright at centimetric wavelengths? In the following subsection, we show that the radar albedos measured over most of Saturn's moons are enhanced beyond what can be explained by random scattering models commonly invoked for icy solar system surfaces. We then propose some explanations.

BACKGROUND: RELATIONSHIP BETWEEN RADAR ALBEDO AND EMISSIVITY FOR SATELLITES WITH IDEAL UNIFORM SURFACES

Radar reflectivity and thermal radiometry for any surface are related through Kirchhoff's law of thermal radiation, and the comparison of these quantities offers an approach to understanding the nature of planetary surfaces that is complementary to that using either radar or radiometry alone.

The emissivity of a surface at a given wavelength and its reflectivity at the same wavelength are related through the Kirchhoff's law of thermal radiation combined with the principle of conservation of energy, as follows:

$$e_p(\theta,\varphi) = 1 - A_p(\theta,\varphi). \quad \text{Eq. 4}$$

A_p is the reflectivity of the surface, i.e., the hemispheric albedo obtained by integrating the reflectivity of a wave incident from the direction (θ,φ) and for the polarization p over the hemisphere.

With radar applications specifically in mind, Peake [1959]—see also Ulaby et al. [1981, 1982]—derived an expression that relates the reflectivity of the surface to its bistatic radar cross-sections:

$$A_p(\theta,\varphi) = \frac{1}{4\pi}\iint_{upper\ hemisphere}\left(\frac{\sigma^0_{pp}(\theta,\varphi;\theta_s,\varphi_s)+\sigma^0_{pq}(\theta,\varphi;\theta_s,\varphi_s)}{\cos\theta}\right)\sin\theta_s d\theta_s d\varphi_s, \quad \text{Eq. 5}$$

where σ^0_{pp} and σ^0_{pq} are the bistatic cross-sections for the scattering of the incident wave into the direction (θ_s,φ_s) in respective orthogonal polarizations p and q.

The Cassini RADAR, like most radars, only measures the cross-section in the backscattering direction (i.e., for $\theta=\theta_s$ and $\varphi=\varphi_s+\pi$) in same-sense polarization (i.e., σ^0_{pp}). However, Janssen et al. [2011] show that for an idealized diffuse scattering surface following a cosine power law (i.e., $\sigma^0_{pp}(\theta,\varphi;\theta,\varphi)=Acos^n\theta$), the emissivity viewed in the (θ,φ) direction can be obtained from:

$$e_p(\theta,\varphi) = 1-\left(\frac{1+\mu_L(\theta,\varphi)}{2n}\right)A, \quad \text{Eq. 5}$$

where $\mu_L$is the linear polarization ratio : $\mu_L(\theta,\varphi) = \sigma^0_{pp}(\theta,\varphi;\theta,\varphi)/\sigma^0_{pq}(\theta,\varphi;\theta,\varphi)$. By definition, $\mu_L$is between 0 (no depolarization) and 1 (full depolarization).

Further, if the coherent backscattering effect [Hapke 1990] is considered:

$$e_p(\theta,\varphi) = 1 - \left(\frac{1+\mu_L(\theta,\varphi)}{2f_{cbe}n}\right)A, \quad \text{Eq. 6}$$

where f_{cbe} is between 1 (no coherent backscattering effect) and 2 (maximum coherent backscattering effect).

The disk-integrated radar albedo $A^{\text{disk}}_{\text{SL}-2}$ was derived from distant active stares based on the same assumption of a purely diffuse scattering surface (see the section entitled Distant Active Stares) and according to Eq. 2:

$$A = \frac{(n+1)}{2}A^{\text{disk}}_{\text{SL}-2}. \quad \text{Eq. 7}$$

The disk-integrated emissivity is thus related to the disk-integrated radar albedo as follows:

$$e^{disk} = 1 - \left(\frac{1+\mu_L(\theta,\varphi)}{2f_{cbe}n}\right)\frac{(n+1)}{2}A^{\text{disk}}_{\text{SL}-2}. \quad \text{Eq. 8}$$

It follows that if the surface is isotropic ($n = 1$) and fully depolarizing ($\mu_L(\theta,\varphi) = 1$):

$$1 - A^{\text{disk}}_{\text{SL}-2} \leq e^{disk} \leq 1 - \frac{A^{\text{disk}}_{\text{SL}-2}}{2}. \quad \text{Eq. 9}$$

If the surface is Lambertian ($n = 2$) and fully depolarizing ($\mu_L(\theta,\varphi) = 1$):

$$1 - \frac{3}{4}A^{\text{disk}}_{\text{SL}-2} \leq e^{disk} \leq\leq 1 - \frac{3}{8}A^{\text{disk}}_{\text{SL}-2}. \quad \text{Eq. 10}$$

Distant active and passive data acquired over icy satellites are discussed in the following subsection in light of this purely random-scattering model.

RADAR VERSUS RADIOMETRY, MODEL VERSUS OBSERVATIONS

Even if there is some variability that is primarily indicative of various degrees of cleanness of the water-ice regolith. Figure RADAR-49 shows that all Saturnian icy satellites, except maybe for Phoebe and Iapetus, are anomalously radar-bright.

Indeed, generic scattering models that depend on purely random scattering processes alone cannot explain the combined radiometric and radar distant observations of Mimas, Enceladus, Tethys, Dione, and Rhea. The distribution of the observed emissivities show an approximately linear relationship with the radar albedo as predicted by the modeling, but with a slope a factor of two larger than the most extreme model considered. The factor of two discrepancy between model expectation and observation already allows for maximum coherent scattering, and is well beyond the range that could be accommodated by any conceivable imbalance in the distribution of bistatic

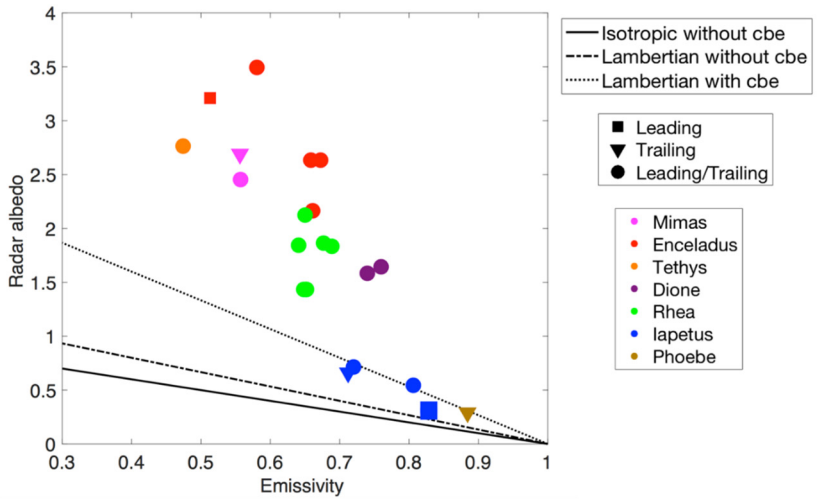

Figure RADAR-49. Disk-integrated same-sense radar albedos versus disk-integrated emissivities derived from the Cassini distant observations of Mimas, Enceladus, Tethys, Dione, Rhea, Iapetus, and Phoebe. When available, the values are shown separately for the leading and trailing sites (in the latitudinal band (−30°, 30°)). The black lines are predictions from the purely random-scattering model described earlier. The measured radar albedos are much larger than expected.

polarization, which is assumed to be the equal in the model. Further, the absolute uncertainties in both emissivity (0.02) and radar albedo (1.4) would have to be seriously underestimated to accommodate the difference as well.

A similar discrepancy has been observed on Titan, on a radar-bright region called Xanadu. Janssen et al. [2011] argue that on Xanadu the mechanism responsible for the enhanced backscatter is related to the presence of ordered structures on or within the surface. There are many theoretical possibilities for such an enhancement, for example a layer of corner cube reflectors, while the challenge is to select those that are geologically plausible for all Saturnian icy satellites. For example, Le Gall et al. [2010] have explained the high radar brightness of some river channels on Titan as due to layers of rounded ice river rocks created by fluvial processes. Maybe more relevant to the surface of Saturn's atmosphereless icy satellites, the unusual radar cross-sections seen in the percolation zone of the Greenland ice sheet were modeled as due to ice cylinders/pipes [Rignot et al. 1993; Rignot 1995]. The presence of cracks or fissures with a preferred orientation in the icy crusts of the Saturnian airless moons is another possibility to be examined.

More recently, Mitchell et al. [2018] have advanced other explanations to accommodate the extreme brightness of Enceladus including the presence of ferroelectric Ice XI, which has unknown backscattering properties, and the sintering of fine particles, which creates larger subsurface particles and/or layering effects that could enhance volumetric radar backscatter. More modeling and laboratory work are required to place more detailed constraints on these hypotheses.

Open questions

RADAR has provided unique insights into the thermal, structural, and compositional properties of the near-surface of Saturn's airless satellites, namely Mimas, Enceladus, Tethys, Dione, Rhea, Hyperion, Iapetus, and Phoebe. It has revealed a number of regional anomalies and satellite-to-satellite variabilities. However, many questions remain about the origin and evolution of Saturn's moons and, in particular, about their respective geological history and interaction with Saturn and its rings. Until the Cassini mission, microwave observations of Saturnian satellites were rare. RADAR observations have set the stage for future researches using ground-based measurements at multiple frequencies in the radio domain—with, for example, the VLA and ALMA radio interferometers or the Institut de Radio Astronomie Millimétrique (IRAM) radio telescope. These measurements will nicely complement Cassini's observations by exploring the thermophysical and compositional properties of the regolith of Saturn's moons at different depths and epochs. Furthermore, future missions to Saturn could include an instrument sounder similar to Mars Advanced Radar for Subsurface and Ionosphere Sounding (MARSIS) /Mars Express, Shallow Radar (SHARAD) / Mars Reconnaissance Orbiter (MRO), or Radar for Europa Assessment and Sounding: Ocean to Near-surface (REASON) / Europa Clipper. Such a radar could, in particular, determine the vertical extent and structure of the dark cover of Iapetus's leading side and confirm the recently advanced hypothesis that the liquid ocean of Enceladus is only a few kilometers under the ice shell at the South Pole of the moon.

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

ALMA	Atacama Large Millimeter/submillimeter Array
AO	Announcement of Opportunity
ASI	Italian Space Agency
CIRS	Composite Infrared Spectrometer
GCM	global circulation model
GCMS	Gas Chromatograph Mass Spectrometer
GhoSST	Grenoble Astrophysics and Planetology Solid Spectroscopy and Thermodynamics
HGA	high-gain antenna
IDS	Interdisciplinary Scientist
IR	infrared
IRAM	Institut de Radio Astronomie Millimétrique
ISS	Imaging Science Subsystem
JPL	Jet Propulsion Laboratory
MARSIS	Mars Advanced Radar for Subsurface and Ionosphere Sounding
MRO	Mars Reconnaissance Orbiter
PWA	Permittivity, Wave and Altimetry
RADAR	Titan Radar Mapper
REASON	Radar for Europa Assessment and Sounding: Ocean to Near-surface
RH	relative humidity
SAR	Synthetic Aperture Radar
SHARAD	Shallow Radar
TM	Traceability Matrix
VIMS	Visual and Infrared Mapping Spectrometer
VLA	very large array

Radio Science Subsystem

The Radio Science Subsystem (RSS) used the spacecraft X-band communication link, an S-band downlink and a Ka-band uplink and downlink to study structure, composition, pressure, and temperature of atmospheres and ionospheres, ring structure, surface properties and particle sizes, body and system masses, gravity fields and gravitational waves. The **science objectives** of RSS were to study the atmospheres and ionospheres of Saturn and Titan, properties of rings, and gravity fields of Saturn and its satellites. During Cassini's cruise phase, RSS was also used to search for gravitational waves coming from beyond our solar system. Some of these experiments measured Doppler shifts (frequency shifts) and other changes to radio signals that occurred when the spacecraft passed behind Saturn, moons, as viewed from Earth to derive information about the structure and composition of the occulting bodies, atmospheres, and the rings.

RSS consists of a Ka-band traveling wave tube amplifier, a translator, an exciter; an S-band transmitter; and various microwave components. RSS used the spacecraft's Radio Frequency Subsystem (RFS) and one or more of the three Deep Space Network (DSN) antenna complexes to obtain the required scientific data. The RFS sent radio signals from Cassini spacecraft to Earth (DSN) using the spacecraft's high-gain antenna (HGA). In route, the radio signal interacted with Saturn's moons, rings or Saturn's atmosphere.

Executive Summary

The Cassini RSS team conducted a wide-ranging series of experiments spanning the entire mission. En route to Saturn, the RSS team observed Cassini at solar conjunction, providing what is still today the most rigorous test of Einstein's theory of general relativity, and the single most frequently cited publication of the entire Cassini mission [Bertotti et al. 2003]. A second cruise experiment set new limits on the strength of low-frequency gravitational waves. Upon arrival at Saturn, a series of diametric ring occultations at three wavelengths revealed stunning detail in the rings at sub-km resolution, periodic structure in Saturn's C-ring (possible evidence of a pair of cometary collisions hundreds of years ago), incomplete clumps in the core of Saturn's F-ring, evidence of wake-driven periodic microstructure in rings A and B, and estimates of particle sizes through the main ring system. Companion Saturn atmosphere occultations over the course of the mission provided regional and seasonal information about the atmospheric thermal structure, including evidence of an equatorial oscillation, zonal winds, and complex wave structure. A suite of ionospheric observations revealed highly variable electron density profiles with evidence of ring/ionosphere interactions. Multiple Titan occultations provided accurate thermal profiles from the surface to the stratosphere over a broad range of latitudes and over the course of Saturn's seasons, and ionospheric profiles as well. Bistatic scattering experiments probed the reflectivity of Titan's surface and provided estimates of the dielectric constant of the liquid norther seas. An exquisite series of gravity field measurements during flybys revealed the presence of subsurface oceans on Titan and Enceladus, established firm measurements for the shape and degree of hydrostatic equilibrium for other icy satellites, and during the Grand Finale, determined the gravitational field of Saturn to extraordinary accuracy and determined the mass of Saturn's ring system to be lower than expected, providing strong evidence that the rings are younger than the planet itself.

En route to Saturn, the RSS team observed Cassini at solar conjunction, providing what is still today the most rigorous test of Einstein's theory of general relativity, … .

Top 20 RSS Science Highlights

Titan Science

1. **Measurement of Titan's hydrostatic gravity quadrupole and moment of inertia**, implying a partially differentiated body very different from its Jovian cousin Ganymede, with a low-density core made up by hydrated silicates.

2. **Seasonal variations in Titan's atmospheric thermal structure** from the surface to the stratosphere, with muted variations in the troposphere but larger in the middle atmosphere above 100 km, and a global minimum in the vertical profile of the zonal wind.

3. **Spatial and temporal variations of Titan's electron density structure**, with large low altitude secondary peak, possibly related to energetic ion precipitation.

4. **Bistatic observations of Titan's surface and Northern seas.**

Saturn Science

5. **Discovery of a strong differential rotation in Saturn's atmosphere**, extending down to 9000 km below the cloud level.

6. **Seasonal variations in Saturn's atmospheric thermal structure** from the cloud deck to the stratosphere, with evidence of an equatorial oscillation forced by vertically propagating waves.

7. **Spatial and temporal variations of Saturn's ionosphere**, likely affected by latitudinal variation of neutral molecules.

Enceladus Science

8. Discovery of Enceladus' subsurface ocean and interior structure.

9. Electron density observations at Enceladus.

Icy Satellite Science

10. Measurement of Rhea's quadrupole gravity field.

11. Measurement of Dione's quadrupole gravity field.

Ring Science

12. Measurement of a low mass of Saturn's rings.

13. Particle size determination of Saturn's rings.

14. Orbital properties of Saturn's rings.

15. Periodic microstructure in rings A and B.

16. Evidence for ancient impacts on Saturn's rings.

Cruise Science

17. Precision test of General Relativity.

18. Low-frequency gravitational waves.

19. Plasma turbulence in the inner heliosphere.

20. Precision navigation at solar conjunction.

RSS Instrument Summary

Radio Science experiments are typically divided into two categories: gravitation and propagation. For gravitation, the Cassini spacecraft serves as a point-mass probe within the gravity field of Saturn and its satellites; precision measurements of the Earth-Cassini distance and relative velocity can be used to infer the target body mass and higher order field components. Propagation experiments are radio occultation experiments where the occulting objects under study are planetary and satellite ionospheres and neutral atmospheres, rings, and solar plasma.

Figure RSS-1 shows typical radio science (RS) observational configuration for planetary occultations. The spacecraft transmits a signal that is refracted by the target atmosphere before being received on Earth at a ground station of NASA DSN. The direction of the arrow on the dashed ray path indicates that this is a one-way downlink observation. As the spacecraft moves, the ray probes more deeply into the atmosphere until it is absorbed or occulted by the planet itself. Stability of the signal during the observation depends on the quality of the reference oscillator onboard the spacecraft. Cassini was equipped with an ultra-stable oscillator (USO) to improve stability of its transmitted one-way signal. In two-way mode, a signal is transmitted from Earth and received at the spacecraft; this uplink signal can then be used to control the frequency of the downlink transmission. In general, the two-way mode provides better overall frequency stability than the one-way mode because of the superior quality of the atomic clocks at the ground stations. However, passage of the uplink signal through an atmosphere, ring, or plasma cloud, or reflection from a surface distorts the uplink signal making a USO-referenced one-way mode preferable. In three-

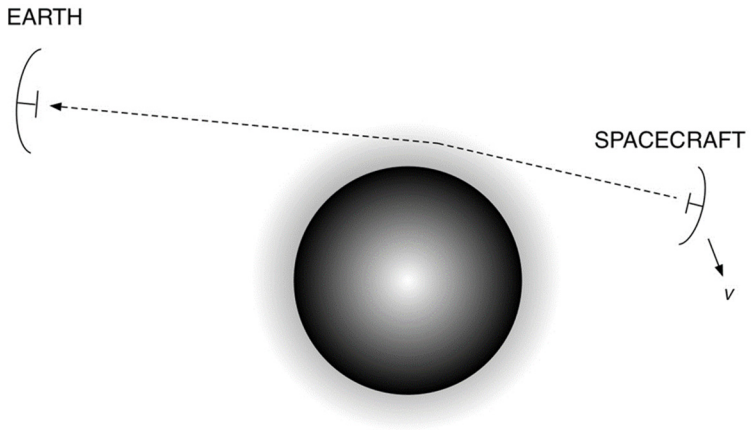

Figure RSS-1. Configuration for radio science observations at a generic planet. Spacecraft moving at velocity *v* gets occulted by the atmosphere then the planet itself.

way mode, one ground station transmits to the spacecraft and a different ground station receives; this is used when an observation spans the handover from one ground station to another. In the Cassini case, three-way was necessary because of the long one-way light time between Saturn and Earth, ranging from 68 to 84 minutes.

During occultations by Saturn, its rings, or its satellites, one-way operation yield observables which are inverted to give temperature-pressure and absorption profiles of neutral atmospheres, electron density profiles of ionospheres, and optical depth and particle size distribution profiles of rings. Most measurements are wavelength dependent and some may include polarization effects, so a wide range of transmitting and receiving equipment is desirable.

During close encounters, the spacecraft antenna is deflected from the Earth direction to point at satellite surfaces or Saturn's ring plane. Such one-way bistatic radar (BSR) experiments require the highest sampling rates of the receivers at the ground stations and contain the most interesting polarization information. Inversions can yield dielectric constant of target surfaces and size distributions for ring particles.

Cruise Phase Science

During the long Cassini phase, RS observations included gravitational wave experiments (GWEs) near solar oppositions and solar conjunction experiments (SCEs). In a GWE, subtle changes in the apparent Earth-spacecraft distance and/or relative velocity, which cannot be attributed to other causes, would indicate passage of gravitational wavefronts through space between Earth and Cassini. GWE observations were conducted in two-way mode for highest clock stability. When the spacecraft's radio signal is occulted by the Sun, then an SCE investigates the solar corona. Operationally, two-way data are collected at large solar radii; but one-way operation with open-loop reception is the practical choice for small solar radii and high solar activity. The shortest radio wavelengths are least affected by the solar plasma; multiple wavelength measurements yield total electron content along the radio path directly.

Radio Frequency Subsystem

The RFS, in conjunction with the Antenna Subsystem, provides communications between the spacecraft and ground stations of the DSN. It also provides a signal source for RS measurements. In earlier documentation—for example, Kliore et al. [2004]—a distinction was made between multi-use radio components (RFS) and RS-only components called the Radio Frequency Instrument Subsystem (RFIS) but that distinction is not maintained here and all radio components fall within the RFS. The RFS includes a pair of redundant X-band transponders for reception and transmission, an S-band transmitter, and a Ka-band transmitter. The USO provided an onboard highly stable time and frequency reference, but it failed in 2011. A Ka-band translator (KaT), which received at 34 GHz and transmitted coherently at 32 GHz, supported general relativity observations during Cruise; it failed before Saturn orbit insertion.

The RFS produces an X-band carrier modulated with data received from the Command & Data Subsystem (CDS), amplifies the modulated carrier, and delivers the signal stream to the Antenna Subsystem for transmission to Earth. It also receives and demodulates X-band commands from the ground via the Antenna Subsystem. At Saturn, where the one-way distance to Earth is 8.2–10.2 astronomical units (AU) and the one-way travel time is 68–84 minutes, commands and instructions from Earth have been received at 1000 bits per second (bps) by the HGA; and data have been transmitted to Earth at selectable rates ranging from 14,220 to 165,900 bps. Data can be recorded on the solid- state recorders for about 15 hours, while the HGA is not pointed at Earth; then they are played back for nine hours. About one gigabit of data can be returned each day via a 34-m DSN antenna; nearly four times that can be returned via a 70-m ground antenna. The two redundant recorders can record and read out nearly 2 gigabits of data simultaneously. The CDS handles combined data rates in excess of 430,000 bps from the instruments while carrying on its functions of command and control. Since RS observables are generated at the DSN, only a very small fraction of telemetry, such as equipment status and spacecraft attitude measurements, are of interest to RS.

The Antenna Subsystem includes the 4-meter diameter HGA reflector (which was also used for Sun shading in the early cruise phase); a frequency-selective subreflector; HGA feeds for S-band, X-band, Ka-band, and Ku-band; and two low-gain antennas (LGA). All antennas operate at X-band; only the HGA operates at S-band, X-band, Ka-band, and Ku-band. The X-band components are for communications and navigation as well as RS; the S-band and Ka-band components are only for RS and the Ku-band components are for the Cassini Titan Radar Mapper (RADAR). Table RSS-1 lists the RS bands.

Table RSS-1. Cassini Radio Science Bands and Wavelengths.

Band	Wavelength (cm)	Frequency (MHz) Uplink	Frequency (MHz) Uplink
S	13	N/A	2298
X	3.6	7175	8425
Ka	0.9	34316	32028

Notes: Separate S-band channels existed to receive the Huygens probe relay in two polarizations at 2040 and 2098 MHz. The X-band uplink polarization is left circular (LCP) when Transponder A is selected and right circular (RCP) when Transponder B is selected. The X-band downlink polarization is LCP when traveling wave tube amplifier A (TWTA-A) is selected and RCP when TWTA-B is selected.

Ultra-stable oscillator

Key to RS instrumentation onboard the Cassini spacecraft, the USO provided the highly stable reference generated on-board the spacecraft until it failed in 2011. The Cassini oscillator is in the class of highest performance thermally-controlled quartz crystal oscillators flown on planetary missions. It was manufactured by Johns Hopkins University, Applied Physics Laboratory. Figure RSS-2 shows the X-band output frequency of the USO over several years showing long-term aging behavior (without accounting for time dilation effects).

Figure RSS-3 shows the excellent Allan Deviation performance of the USO stability as a function of integration time from one representative test in 2011. These data in reality characterize

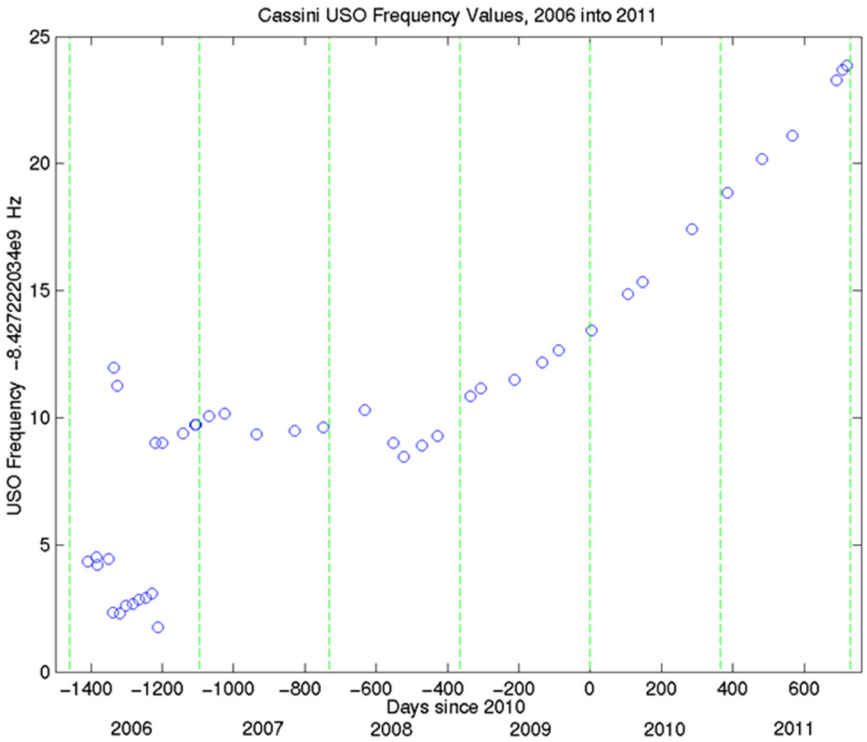

Figure RSS-2. The USO output frequency scaled to X-band by the Cassini transponder over several years, showing long-term aging process as expected.

the end-to-end performance of the radio systems on both the spacecraft and ground station, although independent calibration of the DSN stations have shown that these results are dominated primarily by the limit of the USO performance.

Attitude and Articulation Control Subsystem

The Attitude and Articulation Control Subsystem (AACS) maintains the spacecraft's orientation and consists of redundant Sun sensors mounted on the HGA, redundant stellar reference units mounted on the remote-sensing platform, three mutually perpendicular reaction wheels mounted in the lower equipment module (LEM), plus a fourth backup reaction wheel mounted in the upper equipment module (UEM). Redundant inertial reference units, along with an accelerometer to measure changes in the spacecraft's velocity, are located in the UEM.

The AACS points the selected communication antenna toward Earth and points the remote sensing pallet toward selected targets. It also points one of the two redundant main propulsion engines in the desired direction during engine burns and performs small trajectory correction maneuvers using the onboard thrusters. The AACS uses a pointing system known as inertial vector propagation that keeps track of spacecraft orientation, the direction of the Sun and distance to the Sun, Earth, Saturn, and other possible remote- sensing targets, and the spacecraft-relative pointing

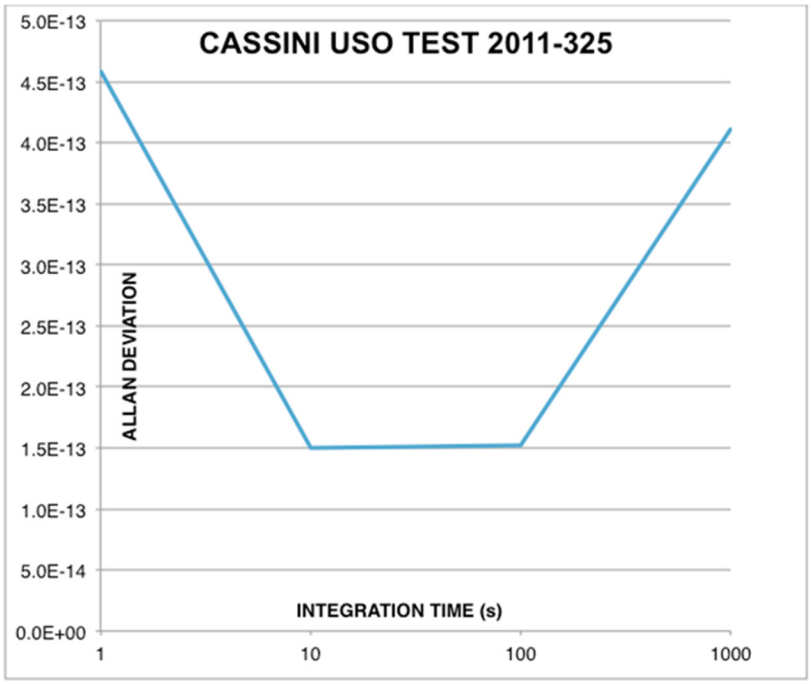

Figure RSS-3. Allan Deviation of the Cassini USO as a function of integration time from a representative test. Four points are plotted at 1, 10, 100, and 1000 seconds.

directions of all science instruments. This subsystem provides sufficient engineering data to support science data interpretation and mission operations.

Other Subsystems

The Propulsion Module Subsystem (PMS) is the largest and most massive subsystem. It consists of a bipropellant element for trajectory changes and a hydrazine element for attitude control, small maneuvers, and reaction wheel desaturation. The Power and Pyrotechnics Subsystem (PPS) converts the radioisotope thermoelectric generator (RTG) power output to provide a regulated 30-V direct-current power bus and provides the capability to turn various users on or off when commanded. Power conditioning equipment can detect over-current conditions and switch the affected user off. The pyrotechnic switching unit also provides redundant power conditioning and energy storage, and it controls the firing of pyrotechnic devices.

The Temperature Control Subsystem (TCS) maintains the temperatures of all critical spacecraft components within their specified limits via electrical temperature sensors. Even at 9 AU from the Sun, spacecraft orientations that expose radiator plates to the Sun can severely degrade the data collected by some of the science instruments. The TCS can turn electric heaters on or off, open or shut thermal louvers in the UEM, use small radioisotope heaters to raise the temperature of selected regions, and utilize thermal blankets and shields. Several instruments have radiator plates for cooling.

Ground Systems

RS data are acquired by the ground instrumentation at DSN stations at Goldstone, California; Canberra, Australia; and Madrid, Spain. During the Grand Finale orbits, additional electrostatic energy analyzer (ESA) ground stations at New Norcia, Australia and Malargue, Argentina, contributed to Cassini RSS experiments. The microwave signals are captured using 34 m or 70 m diameter antennas and are mixed to lower frequencies where they are sampled, averaged, and recorded for later analysis. Two-way and three-way uplink transmissions can be modulated with ranging codes, which allow determination of round-trip times after correlation with the modulation on the downlink signal. Status and performance of the uplink, downlink, and ground antenna systems is recorded in files of monitor data. RS data are acquired via two types of receivers: closed-loop and open-loop.

During the Grand Finale orbits, additional ESA ground stations at New Norcia and Malargue contributed to Cassini RSS experiments.

The ground stations are pointed via the following techniques. Conical scan is dynamical ground antenna pointing during which the boresight is offset from the predicted pointing by a small amount; the observed degradation in signal level is used to determine a new best pointing direction. This is repeated in such a way that the pointing follows a conical path around the best direction; it is not used when the signal is expected to undergo significant amplitude changes. The monopulse technique uses relative amplitude and phase between TE_{11} and TE_{21} circular waveguide mode signals generated in a special Ka-band feed. Aberration correction is a pointing adjustment to account for real motion of the signal source against the sky background during the one-way light travel time. During uplink, the antenna is pointed to the location where the spacecraft will be at the time the signal arrives rather than toward its geometric location at the time of transmission.

Closed-loop tracking receiver

In order to track a spacecraft signal carrier, the closed-loop receiver utilizes a phase-locked loop (PLL) that precisely measures and record the carrier's phase. The Doppler shift is estimated from the phase and converted to relative velocity. Separately, ranging code modulation is extracted and correlated with the uplink code to determine absolute range. The closed-loop tracking receiver provides a Doppler estimate every 0.1 seconds; ranging samples are generated at a rate that depends on the code repetition period and user-selected averaging interval. The tracking receiver also provides a signal to the antenna pointing process.

Open-loop radio science receiver

In open-loop reception, an independent broadband receiver is used without the PLL tracking mechanism described above. The radio science receiver (RSR) down-converts the spacecraft signal via a local oscillator heterodyne process guided by a prediction of the expected frequency.

Additional description of the RSR structure and data format and content is available in the DSN document 820-013, module 0159-Science; a functional description in Asmar et al. [2013]. It captures and records the predetection radio signal at a user-selected sampling rate via an analog-to-digital converter. The digital samples of the propagating electromagnetic wave are stored to disk. Because the received downlink signal can be precisely reconstructed, this mode of data acquisition provides great flexibility in signal processing. The RSR provides superior phase stability, captures the signal during high amplitude or frequency dynamics (where the closed-loop receiver would lose lock), is resilient to multipath effects, and preserves all the information contained in the signal. On the other hand, this method requires additional operational procedures, resources, and generation of predictions sometimes containing complex planetary atmospheric or other models. It also involves handling large file sizes and requires expertise in digital signal processing.

Each DSN complex has at least three RSRs, each capable of independently capturing the output from a different antenna feed, i.e., a different band polarization combination. Similar receivers are also available for very-long-baseline interferometry (VLBI) work; their output can be easily converted to the RSR format, and they can be used when Cassini RS observations require more support than the RSRs alone can provide. The Radio Science Systems Group (RSSG) remotely operates the RSR and VLBI Science Receiver (VSR) from Jet Propulsion Laboratory (JPL).

Key Objectives for RSS Instrument

The key RSS ring science objectives are listed below and discussed in further detail in the section entitled Science Results.

Titan Science

Gravity

Gravity provides unique and crucial information about the interior structure of Titan. When combined with other measurements, such as altimetry and rotation, gravity measurements enable a full tomography of the body. The high-level science questions addressed by the gravity science investigation include:

1. Is Titan in hydrostatic equilibrium?
2. How differentiated is the interior? Is Titan as differentiated as its Jovian cousin Ganymede?
3. What is the density of the core? What is its chemical composition?
4. Is Titan hosting an ocean at depth? If a subsurface ocean exists, what is its density (therefore, its enrichment with salts)?

5. What is the gravitational shape of the moon, and how does it compare with the physical shape?

6. If a higher degree gravity field is measurable, can gravity-topography correlations constrain the thickness of the outer ice shell?

Prior to Cassini, only the density of the moon was sufficiently well determined from Pioneer 11 and Voyager 1 and 2 radiometric measurements [Null et al. 1981; Campbell and Anderson 1989]. Although uncertainties and ambiguities are unavoidable, RSS has been able to answer directly or in combination with other instruments to all these questions, providing a comprehensive picture of the interior structure of the moon.

Atmosphere

The key objectives for Titan atmospheric science were to determine the surface-to-stratospheric thermal structure over a range of latitudes and seasons on Titan, from multiple radio occultation experiments; to measure the wavelength-dependent atmospheric extinction; to investigate atmospheric wave activity; to infer zonal wind characteristics; to characterize diurnal, regional, and seasonal variations in atmospheric structure.

Ionosphere

The key objectives for Titan atmospheric science were to determine the surface-to-stratospheric thermal structure over a range of latitudes and seasons on Titan, from multiple radio occultation experiments; to measure the wavelength-dependent atmospheric extinction; to investigate atmospheric wave activity; to infer zonal wind characteristics; to characterize diurnal, regional, and seasonal variations in atmospheric structure.

Surface—bistatic experiments

The Cassini RSS team carried out a number of bistatic experiments near the Brewster angle at Titan to determine reflectivity and dielectric constant estimates at its three radio wavelengths. A particular focus was to determine the dielectric constant of the liquids in the northern seas.

Saturn Science

Gravity

The key objective for Saturn gravity science was to determine measure gravitational mass (GM), the lower order gravitational moments, and the low-order tidal Love numbers to infer Titan's internal mass distribution from multiple gravitational flybys. During the nominal Cassini tour, the pericenters of the petal orbits were too far from the planet to measure the fine structure of the gravity and magnetic field, the only available tools to probe Saturn's interior. The Grand Finale Orbits (GFO)

brilliantly completed the investigation of the Saturnian system by peeking through the upper cloud deck down to the inner recesses of Saturn's core. In addition, the unique geometry of the GFO orbits, with the pericenters between the planet and the ring system, allowed the determination of the mass of the B-ring, a quantity of utmost importance to reveal the age, hence the nature, of the ring system.

Extensive numerical simulations were carried out in the years preceding the GFO to set the science goals for the RSS gravity investigation at Saturn. The team benefitted from the experience gained with the Juno mission, whose main goal was to probe the deep interior of Jupiter using the same observational tools (Doppler and magnetic measurements), although with dedicated and more accurate instrumentation. The science questions addressed by RSS-Gravity were:

1. To what depth is Saturn differentially rotating? How deep are the flows detected by optical imaging of the clouds?

2. What is the allowed range of core masses? What is the abundance of heavy elements in the interior of Saturn?

3. What is the mass of the B-ring? Are Saturn's rings young or did they form together with the planet?

For a review of the pre-Cassini understanding of the interior of Saturn and the expected improvements from gravity measurements, see Fortney et al. [2016], with earlier references therein. For the relation between the mass and the age of the rings, see Cuzzi and Estrada [1998]. The gravity harmonics of Saturn before the GFO were determined by Jacobson et al. [2006] from the orbital perturbations on the orbits of Saturn's moons.

Atmosphere

The key objectives for Saturn atmospheric science were to determine the surface-to-stratospheric thermal structure over a range of latitudes and seasons on Saturn, from multiple radio occultation experiments; to measure the wavelength-dependent atmospheric extinction; to investigate atmospheric wave activity; to infer zonal wind characteristics; to characterize diurnal, regional, and seasonal variations in atmospheric structure; to help constrain the H/He ratio in Saturn's atmosphere.

Ionosphere

The key objectives for Saturn ionospheric science were to determine the surface-to-stratospheric thermal structure over a range of latitudes and seasons on Saturn, from multiple radio occultation experiments; to measure the wavelength-dependent atmospheric extinction; to investigate atmospheric wave activity; to infer zonal wind characteristics; to characterize diurnal, regional, and seasonal variations in atmospheric structure; to help constrain the H/He ratio in Saturn's atmosphere.

Enceladus Science

Gravity

Enceladus was a special focus of interdisciplinary science in the Cassini mission. Indeed, two major objectives of the Cassini Satellite Surface Working Group were to acquire optical remote sensing observations of Enceladus and to measure its gravity field. This interest is explained by the intriguing characteristics of Enceladus, among which figure the remarkably high and uniform albedo and the presence of old and recent terrains. In the pre-Cassini era, the mean geometric albedo was known to be close to unity, and the total range of albedo over the surface is 20%. This was even more intriguing considering that Enceladus topography contains both old cratered terrains dating from the period of heavy bombardment and smooth terrains recently resurfaced, indicating endogenic activity. Buratti [1998] investigated the photometric properties of Enceladus and concluded that the satellite is completely covered by a young, bright surface layer. Buratti argues that the E-ring, whose thickness peaks at the orbit of Enceladus, is the most likely source for this layer, and that the E-ring itself is probably the result of active surface processes on Enceladus. Alternatively, the bright surface of Enceladus may result from dissipation associated with tidal interactions, perhaps with Dione.

This interest is explained by the intriguing characteristics of Enceladus, among which figure the remarkably high and uniform albedo and the presence of old and recent terrains.

Enceladus' mean radius was known to be ~250 km. How could such a small satellite have undergone substantial evolution? This may be due to the fact that ammonia ice, which plays an important role in lowering the melting point, may have been incorporated into Enceladus. Evidently, the surface properties alone are insufficient to provide information on the interior composition. To understand the nature and history of Enceladus and the other Saturn's satellites, modeling of the interiors and of the thermal evolutions was in order.

As far as Enceladus is concerned, even the most basic parameter, i.e., the mass density, was very poorly known (with about 50% accuracy). A determination of the mass of Enceladus and of its harmonic coefficients of at least degree 2 from data acquired during targeted flybys was deemed a crucial goal to determine its moment of inertia, and hence to constrain models of internal structure.

Atmosphere/ionosphere

The tenuous atmosphere/ionosphere of Enceladus was probed during a serendipitous RSS occultation.

Icy Satellite Science

The objective was to determine the masses (and, where possible, the gravity field) of the icy satellites (especially Dione, Hyperion, Iapetus, Phoebe, and Rhea) in order to determine their mean density to high accuracy, and hence constrain their bulk composition. For Dione and Rhea, which had multiple flybys with radio tracking during the closest approach, the goal was to find out whether these bodies are differentiated and to compare their internal structure to that of Titan and Enceladus.

The mass determination is essential for an improved understanding of their dynamical behavior and evolution. Tyler et al. [1981] determined the masses of Titan and Rhea from Voyager 1 Radio Science measurements at Saturn, and Voyager 2 permitted Tyler et al. [1982] to determine the masses of Tethys and Iapetus. Using the mass of Tethys in combination with the theory of the Tethys-Mimas resonance, they derived the mass of Mimas. Campbell and Anderson [1989] used the combined data set of Pioneer and Voyager data to redetermine the masses of Tethys, Rhea, Titan and Iapetus, but recommended the earlier ground-based determination [Kozai 1957] for Tethys. No mission, before Cassini, yielded a direct determination of the masses of Mimas, Enceladus, Dione, Hyperion, and Phoebe. Phoebe, on an inclined, retrograde orbit, may be a captured object. Determining its density is important to find out whether or not Phoebe is asteroidal in nature.

Ring Science

The primary objective of Cassini Radio Science Subsystem ring experiments was to take advantage of the capability of simultaneous observations at three wavelengths (0.94, 3.6, and 13 cm, or Ka-band, X-band, and S-band, respectively) over multiple occultation opportunities at large, intermediate, and small ring opening angle *B*, to investigate ring structure and physical properties, including:

- High-resolution profiling of radial ring structure and characterization of its variability with wavelength, longitude, ring opening angle, and time. Profiling of the relative abundance of millimeter to decimeter radius particles and characterizing of their variability across resolved ring features.
- Determination of the full particle size distribution over the approximate size range 1 mm to 20 m of broad ring features that can be resolved in the spectra of the near-forward scattered signal. Determination of the vertical ring structure, of the physical ring thickness, and of the particle packing fraction within such features.
- Determination of ring surface mass density, ring viscosity, and bulk density of particle material. Characterization of the variability of these parameters among global ring features (A, B, C …) and within local broad features.

Goals of studies of ring kinematics and dynamics included:

- Determination of the geometry of the Saturn ring system, including determination of Saturn's pole direction and precession rate and a highly accurate (few hundred meter) absolute radius scale of the rings.
- Investigations of ring morphology: A major goal of ring dynamics studies is to explain the presence of non-axisymmetric features such as eccentric ringlets and density waves, and nonequatorial features such as inclined ringlets and bending waves.
- Exploration of ring evolution by characterizing and modeling viscous stresses, and the transport of angular momentum and energy within the rings and their transfer between rings and satellites.

Cruise Science

During the long Cassini phase, RS observations included GWEs near solar oppositions and SCEs. In a GWE, subtle changes in the apparent Earth-spacecraft distance and/or relative velocity, which cannot be attributed to other causes, would indicate passage of gravitational wavefronts through space between Earth and Cassini. GWE observations were conducted in two-way mode for highest clock stability. When the spacecraft's radio signal is occulted by the Sun, then an SCE investigates the solar corona. Operationally, two-way data are collected at large solar radii; but one-way operation with open-loop reception is the practical choice for small solar radii and high solar activity. The shortest radio wavelengths are least affected by the solar plasma; multiple wavelength measurements yield total electron content along the radio path directly.

RSS Science Assessment

Table RSS-2 contains an assessment of RSS ring science based on the objectives in the original Announcement of Opportunity (AO) and the Cassini Traceability Matrix (TM) developed for the Equinox and Solstice missions. Each RSS ring science objective is paired with an AO and TM science objective, with the exception of the Solar Conjunction Experiment (a test of general relativity).

Table RSS-2. Matrix of RSS Science Objectives. Green indicates that RSS data with sufficient quality were obtained during the Cassini mission to contribute to a given science objective.

RSS Saturn System Science Results

Titan Science

Gravity

Titan played a special role in Cassini: it was at the same time one of the main science targets of the mission, and at the same time its true engine. Titan gravity was used to change the orbital elements of the spacecraft, enabling its complex and extraordinary tour of the Saturnian system. But Titan's gravity, in its fine details, revealed the interior structure of the moon by answering the Key Objectives for RSS Instrument-Titan Science-Gravity. Indeed, lacking an internal dynamo and in the absence of a detectable induction magnetic field, gravity and rotation are the only available tools to peek through the surface and reach the deep interior.

Cassini's observations have unveiled a variety of features and phenomena not found on any other solar system satellite, such as hydrocarbon lakes, river channels, and dune fields, making it a unique object.

Cassini's observations have unveiled a variety of features and phenomena not found on any other solar system satellite, such as hydrocarbon lakes, river channels, and dune fields, making it a unique object. While exogenic processes driven by the dense, hydrocarbon-rich atmosphere, play a crucial role in shaping the complex topography determined by Cassini's radar, contributions from endogenic processes are far less clear. Assessing the presence of active endogenic processes and understanding the origin of the complex topography revealed by Cassini's radar requires the knowledge of Titan's interior structure, which can be indirectly inferred from gravity and rotation data.

Prior to Cassini measurements, models of Titan's interior generally envisaged a core made up of silicates, surrounded by a layer of high-pressure ice, possibly a liquid water or water-ammonia ocean, and an ice-I outer shell, with variations associated with the dehydration state of the core or the presence of mixed rock-ice layers. It was generally expected that Titan could be significantly differentiated [Sohl et al. 2003], although models with higher moment of inertia factor (MOIF) and partial differentiation were also proposed [Fortes et al. 2007]. The determination of Titan's MOIF became therefore a crucial goal for RSS gravity investigations. The MOIF can be inferred from the quadrupole field under the assumption of hydrostatic equilibrium, a hypothesis that Cassini could easily test from the measurement of the J2/C22 ratio (equal to 10/3 for a relaxed body).

Models of Titan's interior envisaging small amounts of ammonia indicated that a subsurface ocean made up of liquid water could exist to the present day—for example, Tobie et al. [2005]. Such a liquid layer has profound implications for the geologic history of Titan and the source of methane. However, one can construct a fully frozen Titan by including only water and rock/metal as bulk

materials, excluding ammonia, and assuming that the crust contains little methane clathrate which acts to lower the thermal conductivity and plasticity of Titan's upper thermal lid [Tobie et al. 2006].

The first hint for a conductive layer came from the analysis of the electric signal acquired during the descent of the Huygens probe in January 2005 [Béghin et al. 2012]. The Huygens Atmospheric Structure Instrument and Permittivity, Wave, and Altimetry (HASI–PWA) observed an electromagnetic (EM) signal at around 36 Hz interpreted as the second harmonic of a Schumann resonance. This physical characteristics of the resonating cavity required a conductive layer at a depth of 65-km (±15-km) that was interpreted as the upper layer of a salty ocean. The measurement of a large obliquity from SAR processing of crossovers was also interpreted as an indication of an outer icy shell decoupled from the interior [Lorenz et al. 2008; Bills and Nimmo 2008].

A conclusive test for the presence of an interior ocean requires the measurement of Titan's time-variable gravity. Therefore, direct testing for the presence of an ocean within Titan's interior became a key goal of the Cassini-Huygens mission. The large eccentricity (e = 0.03) of Titan's orbit causes significant variations in the tidal field from Saturn and induces periodic stresses in the satellite body at the orbital period (about 16 days). Peak-to-peak variations of the tidal field (from pericenter to apocenter) are about 18%. If Titan hosts a liquid layer, the gravity field would exhibit significant periodic variations, controlled by the tidal Love numbers, defined for each spherical harmonic as the ratio between the perturbed and perturbing potential. For Titan the largest effect is by far on the quadrupole field, and the corresponding Love number is indicated by k_2 (assumed to be identical for all degree 2 harmonics).

Analysis of Titan's tidal response [Rappaport et al. 2008] shows that k_2 depends crucially on the presence or absence of an internal ocean. k_2 was found to vary from about 0.03 for a purely rocky interior to 0.48 for a rigid rocky core surrounded by an ocean and a thin (20 km) ice shell. Larger values of k_2, such as 0.7–0.8, are possible if the density of the ocean and the external shell is large (1.1–1.2 g/cm^3). A large k_2 entails changes in the satellite's quadrupole coefficients by a few percent, enough to be detected by accurate range rate measurements of the Cassini spacecraft.

CASSINI FLYBYS OF TITAN

Due to competition with other science goals, the opportunities for gravitational measurements were limited. Titan's main deviations from spherical symmetry are caused by centrifugal and tidal forces, associated respectively with the rotation about its spin axis and the gradient of Saturn's gravity. During the Cassini mission, 10 Titan flybys were committed to gravitational measurements. Table RSS-3 tabulates characteristics of the flybys. The flyby identification is shown in the first column. The color codes identifying each flyby in the table are used also in Figure RSS-4 and Figure RSS-5. The second column indicates the epoch of closest approach (C/A). The gravity signal is stronger for lower pericenter altitudes (third column) while Doppler noise due to interplanetary plasma turbulence decrease for larger Sun-Earth-Probe (SEP) angles (fourth column). T110 was carried out using Cassini's LGA, as the attitude was set by the needs of other instruments. The first four flybys provided the static gravity field and the moment of inertia factor of

Table RSS-3. Main characteristics of Titan's gravity flybys.

Flyby	Closest Approach (C/A) Date	Altitude	SEP
T011	27-FEB-2006 08:25:18 ET	1812 km	150°
T022	28-DEC-2006 10:05:21 ET	1297 km	131°
T033	29-JUN-2007 17:00:51 ET	1933 km	46°
T045	31-JUL-2008 02:14:16 ET	1614 km	30°
T068	20-MAY-2010 03:25:26 ET	1397 km	120°
T074	18-FEB-2011 16:05:17 ET	3651 km	131°
T089	17-FEB-2013 01:57:42 ET	1978 km	106°
T099	06-MAR-2014 16:27:53 ET	1500 km	111°
T110	16-MAR-2015 14:30:55 ET	2274 km	109°
T122	10-AUG-2016 08:32:00 ET	1698 km	113°

the body [Iess et al. 2010]. Two additional flybys (T68 and T74) were needed to ensure a robust determination of k_2 [Iess et al. 2012].

During gravity flybys the spacecraft was tracked from the antennas of NASA's DSN using microwave links at X-band and Ka-band frequencies (8.4 and 32.5 GHz), referred to a common uplink. The state-of-the-art instrumentation enables range rate measurements accurate to 20–50 micron/s at integration times of 60 s.

In order to obtain the optimal gravity measurements, the goal would be to obtain even global sampling of Titan's gravity; however, orbital limitations and competition with other Cassini goals prevented this. Figure RSS-4 shows ground tracks achieved within the limited observational opportunities and emphasizes the scarcity of high latitudinal sampling.

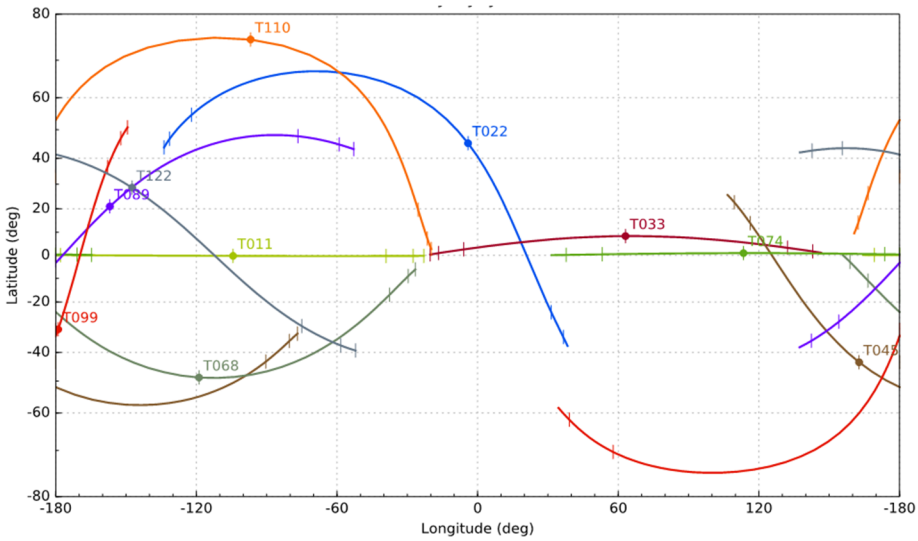

Figure RSS-4. Ground tracks of the 10 Titan gravity flybys showing uneven sampling of the moon's gravity. Each track corresponds to a time window of 3-hours centered at C/A, with tick marks for 30-minute intervals. Lack of coverage on high latitude regions produce larger uncertainties in the reconstructed geoid on those regions.

Figure RSS-5 shows the distribution of the mean anomalies among the 10 flybys. With Titan's orbital eccentricity being about one-half that of our moon at 0.0288, this leads to the ratio of the tidal field at apocenter relative to that at pericenter being about 84%, allowing for considerable response.

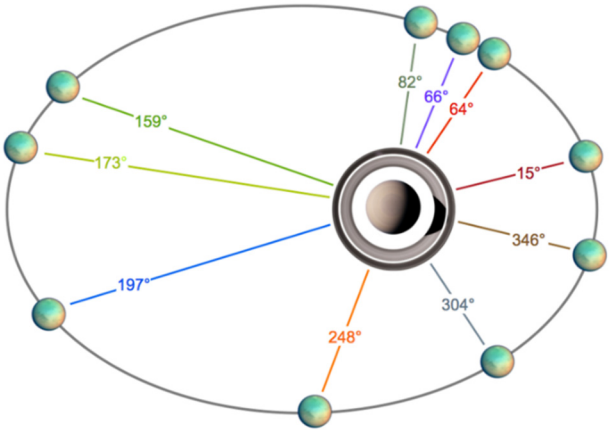

Figure RSS-5. Distribution of Titan mean anomalies of the 10 gravity flybys at the time of closest approach. Measuring Titan's gravity field at different mean anomalies allows a better determination of eccentricity tides (Love number k_2). If the tidal bulge has no phase lag, the tidal variation of the quadrupole gravity coefficients J2 and C22 peaks at pericenter (M = 0°) and apocenter (M = 180°).

Titan Gravity Results

The first four gravity flybys (T11, T22, T33, and T45) provided a determination of Titan's mass and gravity harmonics to degree 3. The quadrupole field was found to be consistent with a hydrostatically relaxed body shaped by tidal and rotational effects. The MOIF inferred from the Radau-Darwin equation is about 0.34, implying incomplete differentiation, either in the sense of imperfect separation of rock from ice or a core in which a large amount of water remains chemically bound in silicates. As has been suggested for Callisto, the proposed incomplete differentiation of Titan may have arisen because of a long accretion time (of order a million years), perhaps because both bodies are at large distance from the parent planet, measured in units of planet radii. The unexpectedly large MOIF has been interpreted in many ways, all ending up in a generally low core density consistent with hydrated silicates.

The equilibrium figure is a triaxial ellipsoid whose semi-axes a, b, and c differ by 410 meters (a–c) and 103 meters (b–c). The nonhydrostatic geoid height variations (up to 19 meters) are small compared to the observed topographic anomalies of hundreds of meters, suggesting a high degree of compensation appropriate to a body that has warm ice at depth. The construction of the geoid and gravity disturbances requires defining a reference ellipsoid. We define the reference ellipsoid as the equipotential surface around the sphere of radius equal to the mean radius of Titan, whose potential is composed of the sum of: (i) the gravitational potential produced by the monopole potential, $J_2^H = (10/3)C_{22}$, and C_{22} ; (ii) the tidal potential due to Saturn; and (iii) the rotational

potential. The equations and the values for the semi-axes of the reference ellipsoid (derived from SOL1 in Iess et al. [2010] are:

$$a = R_t\left[1 + \frac{14}{3}C_{22} + \frac{7}{6}q_r\right] = 2575.239 \text{ km},$$
$$b = R_t\left[1 - \frac{4}{3}C_{22} - \frac{1}{3}q_r\right] = 2574.932 \text{ km},$$
$$c = R_t\left[1 - \frac{10}{3}C_{22} - \frac{5}{6}q_r\right] = 2574.829 \text{ km},$$

for a reference radius R_t = 2575 km. The formal errors are less than 1 m. These values change by about the same amount if SOL2 [Iess et al. 2010] is adopted. A non-hydrostatic reference ellipsoid, constructed from the measured values of J_2 and C_{22}, would differ from the hydrostatic one by at most −9 m for SOL1 and only +0.2 m for SOL2. In both solutions $(a - c)/(b - c) \approx 4$, as expected for a synchronously rotating satellite in hydrostatic equilibrium subjected to the rotational and tidal deformation.

The axes of the reference ellipsoid are larger than the radii found from radar altimetry [Zebker et al. 2009] (a = 2575.15 ±0.02 km, b = 2574.78 ±0.06 km, c = 2574.47 ±0.06 km). The mean planetary radius (2574.73 ±0.09 km) determined by the Cassini radar is slightly smaller than the value of 2575 km adopted in gravity determinations. If this smaller value is used, the axes of the reference ellipsoid become 2574.969 km, 2574.662 km, and 2574.559 km. These values differ respectively by −181 m, −118 m, and +89 m from those determined from radar altimetry, a statistically significant difference especially for the long axis. This interesting discrepancy may stem from several mechanisms. Latitudinal changes of the ice shell thickness resulting from spatial variations of tidal heating [Tobie et al. 2012] and by the subsidence associated with the substitution of methane with ethane-rich liquids percolating into the crust which be composed of methane clathrate hydrates [Choukroun and Sotin 2012].

By combining radio tracking data acquired at different mean anomalies of Titan (see Figure RSS-5) Cassini RSS measurements detected the signature of the periodic stresses [Iess et al. 2012] induced by eccentricity tides. Precise measurements of the acceleration of the Cassini spacecraft during six close flybys between 2006 and 2011 (T11, T22, T33, T45, T68, T74) revealed that Titan responds to the variable tidal field exerted by Saturn with periodic changes of its quadrupole gravity, at about 4% of the static value. Two independent determinations of the corresponding degree 2 Love number yield k_2 = 0.589 ±0.150 and k_2 = 0.637 ±0.224 (2σ). Such a large response to the tidal field requires that Titan's interior is deformable over time scales of the orbital period, in a way that is only consistent with a global ocean at depth. The large value of k_2 points also to an ocean heavily enriched by salts, although the uncertainties are large. The large value of k_2 was confirmed by the yet unpublished analysis of the remaining gravity flybys (T89, T99, T110, T122).

Table RSS-4—from Iess et al. [2012] Table 1 and Table S3 (uncertainties are 2-σ.)—reports the estimated spherical harmonics coefficients for the unnormalized Titan gravity field (degree and

order 4). Eccentricity tides are also included in the model and described by the degree 2 Love number k_2 (last row).

The weak and not so well resolved higher degree gravity (3 × 3 and 4 × 4) was also used to attempt an estimate of the outer shell thickness [Hemingway et al. 2013]. The marked anticorrelation of the 3 × 3 gravity and topography was interpreted as an indication that Titan's ice shell is rigid (elastic thickness >50 km) and that several hundred meters of erosion/deposition have taken place over length scales of ~1000 km, suggesting aeolian transport. However, the gravity topography anti-correlation is much less evident in the latest results. Gravity-topography correlations (Figure RSS-6) were addressed by Mitri et al. [2014], who concluded that a 100 km thick outer ice I shell is underlain by a dense subsurface water ocean containing a high concentration of dissolved salts. The large correlation between the surface topography and the Bouguer anomalies are also consistent the presence of subsurface topographic features under the ice shell. Bouguer anomalies are produced by variations of the ice shell thickness where the surface topography is isostatically compensated. These authors concluded that the ice shell is typically thinner at the poles and thicker in the equatorial and middle latitude regions.

Durante et al. [2019] performed a subsequent analysis of Titan's gravity field and interior structure after Cassini. The results from less et al. [2012] indicated that Titan is subject to large eccentricity tides in response to the time varying perturbing potential exerted by Saturn. The magnitude of the response quadrupole field, expressed in the tidal Love number k_2, was used to infer the existence of an internal ocean. The new gravity field determination provides an improved estimate of k_2 of about 0.62, accurate to a level of a few percent. The value is higher than the simplest models of Titan suggest and the interpretation is unclear; possibilities include a high-density ocean (as high as 1300 kg/m^3), a partially viscous response of the deeper region, or a dynamic contribution to the tidal response. The new solution includes higher degree and order harmonic coefficients (up to 5) and offers an improved map of gravity anomalies. The geoid is poorly correlated with the topography, implying strong compensation. In addition, the updated geoid and its associated uncertainty could be used to refine the gravity-altimetry correlation analysis and for improved interpretation of radar altimetric data.

Figure RSS-6. Estimated gravity anomalies (*upper panel*) and related formal uncertainties (*lower panel*) from the analysis of the first six Titan gravity flybys (T11–T74 (4 × 4). The anomalies are computed in mGal over the reference gravity of the ellipsoid defined by the estimated monopole and quadrupole coefficients (GM, J_2, and C_{22}), the tidal field and the rotational state of Titan. Based on the solution SOL1.b from Iess et al. [2012].

Atmosphere

Titan is an interesting object to study, because it is a hybrid combining characteristics of Earth and Venus. Like Earth, its atmosphere is composed mainly of N_2 and it has a hygrological cycle, with methane assuming a role analogous to that of water on Earth. It has seasons, which are determined by the obliquity of Saturn, which is comparable to Earth's. On the other hand, Titan is a slow rotator, and its circulation is cyclostrophic—the winds aloft are globally much larger than the equatorial rotation of its surface, like Venus, but not at all like Earth, where the winds are much smaller than the equatorial surface rotation. Much of what we know about Titan's atmosphere initially came from the Voyager spacecraft flybys in 1980–1981. Although the Voyager soundings were limited, both spatially and in time (early northern spring), the small hemispheric thermal contrasts in Titan's tropospheres suggested that the seasonal response was muted there. In contrast, the large contrasts seen in the upper stratosphere suggested that there were large seasonal swings at those altitudes. A simple calculation of the radiative damping times at different atmospheric levels were consistent with these inferences, the response times being large in the lower atmosphere, and much smaller than the seasonal timescale in the middle atmosphere (stratosphere and mesosphere). The larger meridional temperature contrasts in the stratosphere implied strong zonal winds at these altitudes, especially in the colder northern hemisphere coming out of winter. The implied large seasonal variation expected in the upper stratosphere implied that there would be a large cross-equatorial transport of angular momentum from the northern hemisphere to the southern, as that hemisphere moved into its winter. Thus, there were many meteorological drivers to return to Titan (as Cassini did): first to observe the details of its hygrological cycle near the surface, but also to define better the global spatial structure of the atmosphere and also its seasonal behavior. The last offered a new probe to elucidate the maintenance of cyclostrophic wind systems, which are poorly understood. Titan brings the seasonality card to the analyst's table, which Venus lacks.

The review chapters by Flasar et al. [2014] and Lebonnois et al. [2014] summarize our current understanding of Titan's atmospheric temperature and wind structure, and its seasonal behavior, based in large part on Cassini observations.

There were 20 Cassini radio-occultation soundings of Titan's atmosphere (counting ingress and egress separately). These had relatively high vertical resolution, typically ~1 km through most of the atmosphere, decreasing in the lower troposphere, where differential refraction becomes important, to 10^2 m near the surface. With the failure of the Ultra Stable Oscillator in December 2010, the later occultations were executed in two-way mode. Here, the ground station transmitted a monochromatic signal at X-band to the spacecraft. Upon reception, the electronics onboard multiplied the received X-band signal by 880/749, generated S-band and Ka-band signals from this X-band signal by multiplying by 3/11 and 3.8, respectively, and coherently retransmitted the signal in S-band, X-band, and Ka-band back to Earth. Schinder et al. [2015] describe in detail how the experiment was set up and the received signal record analyzed.

The approach in analyzing radio occultations is to compare the frequency received at the Earth tracking station to what would be expected in the absence of the atmosphere of the target body through which the radio ray passes and is refracted. The difference is the residual frequency.

Knowing the geometry of the occultation, one can derive the bending angle of the ray, i.e., the angle between the incoming ray and that which exits the atmosphere. This can be inverted to retrieve a vertical profile of refractivity—for example, Kliore et al. [2004] and Schinder et al. [2011b]. For Titan, one can assume spherical symmetry in the inversion and use an Abel transform to invert the bending angle profile to retrieve refractivity. Saturn is oblate and the inversions requires ray tracing.

GLOBAL SPATIAL STRUCTURE OF ATMOSPHERIC TEMPERATURES AND ZONAL WINDS

VERTICAL AND MERIDIONAL STRUCTURE

Although the number of soundings were limited, the latitude coverage included high latitudes in both hemispheres, as well as a sampling of low and mid latitudes. Over half the soundings were obtained in northern late winter and early spring. Away from the surface, the troposphere showed little variation with latitude, consistent with the large radiative damping time. In the lowest few kilometers above the surface, variations on the order of a few kelvin appeared. In the northern winter and equinox seasons, variations were small in the summer hemisphere, and the largest variations were seen at high northern latitudes. Near the surface (at the base of the retrieved profiles), the temperature at 80° N was approximately 4 K cooler than at low southern latitudes. The tropopause region, near 40–50 km altitude, exhibited larger variations: high northern latitudes were 4 K cooler than temperatures at 30° S, for example, and even at high southern latitudes in late summer, tropopause temperatures were 2 K cooler [Schinder et al. 2012; Flasar et al. 2014].

Larger meridional contrasts were observed at higher altitudes, consistent with the decrease in radiative damping time. Again, during the northern winter-early spring season the largest contrasts were observed between low latitudes and high northern latitudes, up to 70 K between 100 km and 130 km altitude.

TRANSITION BETWEEN TROPOSPHERE AND STRATOSPHERE

The largest meridional thermal contrasts were observed in the winter/early spring hemisphere at high latitudes, where stratospheric temperatures were much colder than at other latitudes. However, the vertical structure of the transition between the tropopause region and the middle stratosphere—the transition between radiative damping times large compared to seasonal time scales and small damping times—was dramatic [Schinder et al. 2012]. At most latitudes, away from the winter polar region, temperatures above the tropopause region exhibited a rapid increase with altitude from 60 to 130 km, with the vertical gradient gradually becoming smaller at high altitudes. At the high northern latitudes in winter, the usual increase of stratospheric temperatures with altitude, abruptly changed at 80 km, with temperatures decreasing between 80 km and 100 km (by 10 K in the profile at 80° N). The effect decreases at lower latitudes in the winter hemisphere: near 50° N, the decrease has fallen to 1 K. At higher altitudes temperatures resume their increase with altitude, but offset from what one might have expected from the behavior of the temperate profile below 80 km in comparison with profiles observed at lower latitudes. In a manner of speaking, the temperature profiles have abruptly offset from lower

altitudes where there is little meridional (and seasonal) variation to higher altitudes, where these variations become larger. The temperature lapse rate in the transition is statically stable (subadiabatic). What causes it remains speculative, but a radiative origin might be a good guess. Composite Infrared Spectrometer (CIRS) spectra have suggested that organic condensates can form in the lower stratosphere at high latitudes in winter. They also indicate that these latitudes are rich in trace organic compounds that can act as effective radiative coolants. Possibly the increase in infrared opacity at these altitudes can affect the observed destabilization.

One of the most interesting results of the Huygens Doppler Wind Experiment was the minimum at 80 km in the vertical profile of the zonal wind at 10° S, which dipped to just a few meters per second. An analysis of the radio-occultation soundings, composited from 2006 to 2009 and based on the assumption of balanced flow, which relates the zonal winds to meridional gradients in geopotential heights along isobars, indicated that this minimum is global, i.e., it occurs over all latitudes. This is the same altitude, just described, for the abrupt destabilization in the temperature profiles, but only at high latitudes in the winter season. Whether this is coincidental remains to be determined. Possible sources could be damping by interaction of the mean flow with internal gravity waves, but a quantitative analysis remains to be done.

SURFACE TEMPERATURES AND PLANETARY BOUNDARY LAYER

LATITUDE DISTRIBUTION OF SURFACE TEMPERATURES

Because of the weak solar heating and the thickness of Titan's atmosphere (surface pressure ≈ 1.4 bar) the difference between surface temperature and that a few meters higher is expected to be small, so the contrasts discussed above likely hold for the surface itself.

Radio occultations have provided the only means from the Cassini orbiter to map temperatures in the lowest 1½ scale heights of Titan's atmosphere … .

VERTICAL STRUCTURE NEAR THE SURFACE

Radio occultations have provided the only means from the Cassini orbiter to map temperatures in the lowest 1½ scale heights of Titan's atmosphere [Kliore et al. 2004; Schinder et al. 2011b, 2012]. In the earlier part of the mission, when northern hemisphere was in winter and early spring, the occultation profiles had lapse rates in the lowest few kilometers that were close to adiabatic at in the southern hemisphere and at low latitudes in the northern hemisphere. Near 30° S the temperatures lay right on dry adiabats in the lowest 2 km, suggesting efficient vertical mixing from thermal convection. However, the dawn terminator profiles exhibit a more stable structure below the adiabatic layer within 200 m of the surface. This is reminiscent of the nocturnal inversions on Earth, where the surface cools more quickly than the overlying atmosphere during the night, and the atmosphere radiatively cools to the surface and forms a stable layer. However, radiative cooling on Titan is too inefficient to form such a layer over diurnal time scales (16 days), but a turbulent transport with a modest eddy diffusivity ~0.1 m^2/s would suffice.

At high latitudes in the winter hemisphere, temperature profiles become noticeably more stable at the lowest 5 km, being nearly isothermal in the lowest kilometer [Schinder et al. 2012]. Again, this probably reflects cooling to the surface, but over seasonal time scales. In this case, radiative cooling could affect the stable inversion, although turbulent diffusion could also play a role.

Seasonal behavior of temperatures and winds

Radio-occultation soundings near 65° N and S in 2014 and later, as the northern hemisphere moved toward the summer solstice and the southern toward winter, validated the inference of seasonal variation based on the observed meridional structure earlier in the mission. At 65° S the stratosphere above 80 km was rapidly cooling, at a greater rate at higher altitudes [Schinder et al. 2019]. The abrupt transition between 80 and 100 km that was observed at high northern latitudes was not yet evident. At 62° and 66° in the north, the sharp transition seen earlier at high latitudes was decaying, although a remnant persisted. Higher up, the temperatures had not yet attained the larger values seen in the southern hemisphere in late northern winter. Unfortunately, the Cassini tour did not extend a full half year, so a direct comparison that might provide evidence of hemispheric asymmetry is not possible.

Waves

As implied above, absorption of upwardly propagating waves (internal gravity and other types) could effect a drag on the zonal winds in the lower stratosphere, producing the observed minimum in the zonal winds. However, only preliminary analyses of the phase fluctuations (i.e., the small-scale fluctuations in the retrieved temperature profiles) has been done.

Ionosphere

Until the arrival of Cassini, the only direct information concerning the ionosphere of Titan came from the Voyager 1 radio occultation observation. After the careful reanalysis of the original data an electron density peak of about 2.7×10^3 cm^{-3} at an altitude near 1190 km for a solar zenith angle of 90° was found [Bird et al. 1997]. Now we have quite an extended collection of data about Titan's ionosphere from radio occultation, the Langmuir probe, and the ion-neutral mass spectrometer.

The first set of radio occultation observations by Cassini were published in 2009 [Kliore et al. 2008]. This paper presented eight electron density profiles. Figure RSS-7 shows the average of these profiles, along with the Voyager 1 and early Cassini Langmuir probe observations along with a 3-D magneto-hydrodynamic (MHD) model results. A fairly general agreement was found in that there was a density peak in the range of about $2–4 \times 10^3$ cm^{-3} at an altitude near 1200 km. There is a shoulder in the observed densities around a 100 km, which is very likely due to photoionization by soft X-rays. Both the entry and exit T31 results indicated a statistically significant secondary electron density peak near 500 km. Theoretical modeling by Cravens et al. [2008] indicate that ion

precipitation is quite possibly the source of this, somewhat intermittent, secondary peak. Further occultation results were presented in a subsequent paper [Kliore et al. 2011]. This paper presented data from 13 observations obtained by that time (overall only five more profiles were obtained during the lifetime of Cassini and these results were also submitted to the PDF and were similar to previous and published results). The peak electron densities of three of the observed electron density profiles were found to be significantly greater than the average of the others. Using the measured Cassini Plasma Spectrometer (CAPS) Electron Spectrometer (ELS) energetic electron spectra it was shown that these higher peak densities are very likely the result of electron impact ionization.

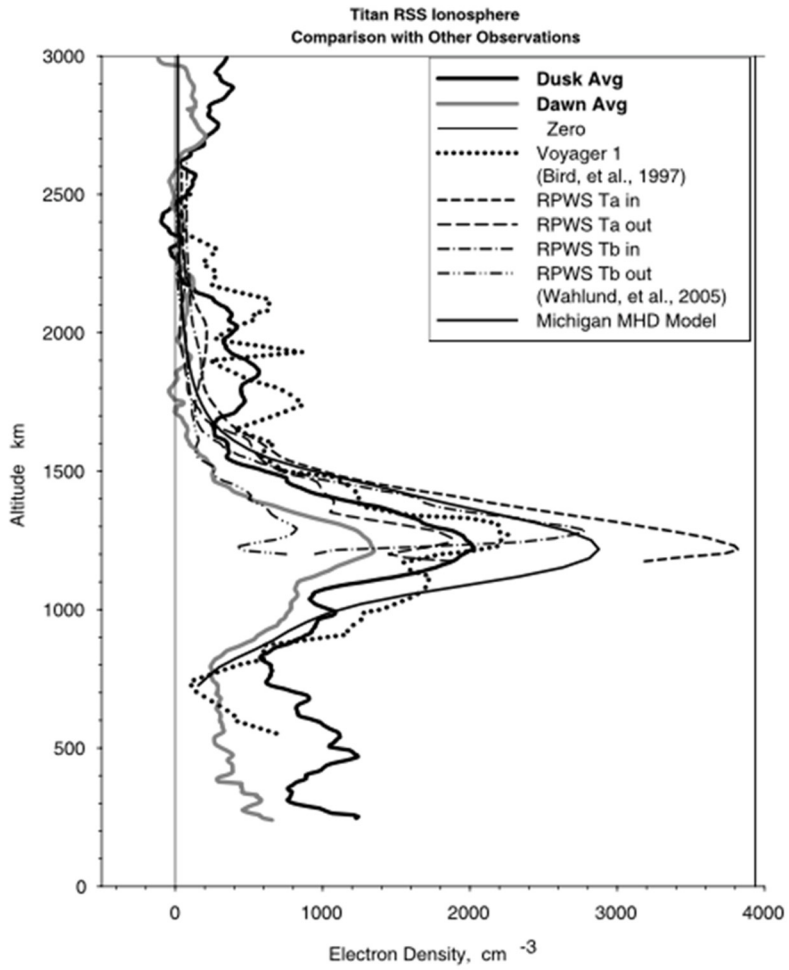

Figure RSS-7. Vertical profiles of electron density from Titan RSS occultations, compared with other observations.

Titan surface scattering results

BSR is the active probing of planetary surfaces by oblique reflection and scattering of microwave signals. Such observations provide statistical information on root-mean-square (rms) surface

slopes and on dielectric constant and density at scales comparable to the radio wavelength (centimeters to meters). An unmodulated radio signal, transmitted from the spacecraft, is scattered by the surface, and the echo is received at a ground station on Earth. A direct signal (from the spacecraft) is often received at the same time, providing a frequency reference for the echo. Fjeldbo [1964] utilized physical optics theory to explain the specular component of the echo as an aggregation of mirror-like reflections from properly oriented elements of the undulating surface. For typical spacecraft transmitters of 1–100 watts, surface echoes as small as 1 zeptowatt (10^{-21} W) can be detected. BSR experiments have been carried out on the Moon, Venus, Mars, and Titan using Soviet, U.S., and European spacecraft [Simpson 2007].

Differential Doppler effects between the direct and reflected paths separates the received echo from the carrier. Dispersion of the echo itself, caused by differential Doppler within the reflecting region, provides a measure of the rms slope of the undulations. Where echo dispersion is not large, the Doppler difference between the two primary paths can be used to infer large-scale topography of the surface. An incident signal with known polarization will generate a reflected signal with both the original and orthogonal components; application of Fresnel reflection theory to absolutely calibrated echoes in one polarization or to relatively calibrated echoes in orthogonal pairs can be used to recover the dielectric constant of the surface material. A simple model relating dielectric constant to porosity then allows estimation of material density.

The first Cassini detectable X-band RS bistatic echoes from Titan's surface were observed on flyby T14 on May 20, 2006 (DOY 140) (Table RSS-5), making Titan the most distant solar system object for which bistatic echoes were successfully detected. The echoes were weak but clearly detectable. Right circularly polarized sinusoidal signal was transmitted by Cassini and both the right and left circularly polarized (RCP and LCP) surface reflected components were observed at the 70 m station of the DSN at Madrid, Spain, Deep Space Station (DSS)-63).

Table RSS-5. Cassini Bistatic Radar Experiments

Start Date	Data Set	Target
2006-03-18	CO-SSA-RSS-1-TBOC1-v1.0	Titan
2006-05-20	CO-SSA-RSS-1-TBOC2-v1.0	Titan
2007-03-25	CO-SSA-RSS-1-TBOC3-v1.0	Titan
2007-07-18	CO-SSA-RSS-1-TBIS1-v1.0	Titan
2008-11-03	CO-SSA-RSS-1-TBOC4-v1.0	Titan
2009-03-27	CO-SSA-RSS-1-TBIS2-v1.0	Titan
2009-04-04	CO-SSA-RSS-1-TBOC5-v1.0	Titan

Cassini was maneuvered continuously to track the region of Titan's surface where mirror- like (quasi-specular) reflected signals may be observed. The ground receivers were tuned to compensate for the large Doppler shift due to relative spacecraft-Titan-Earth motion, allowing detection of the echoes near the center of the recording bandwidth (Figure RSS-8 and Figure RSS-9).

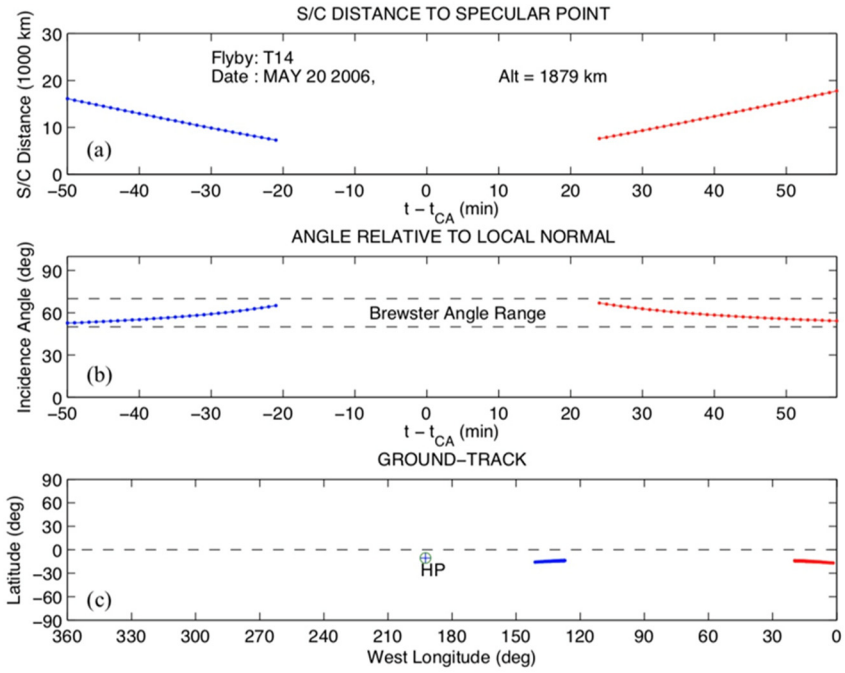

Figure RSS-8. *Panel (a)* and *Panel (b)* depict selected geometry parameters of the Cassini T14 observations and *Panel (c)* depicts the corresponding ground tracks. The Huygens Probe landing site is shown for reference purposes.

The experiment was designed to probe incidence angles θ close to the Brewster, or polarization, angle of likely surface compositions. Careful measurements of the system noise temperature allowed determination of the absolute power in each polarized echo component and, hence, their ratio. The polarization ratio, the known observation geometry, and Fresnel reflectivity were then used to determine the dielectric constant ε.

The T14 surface echoes were detectable on both the inbound and outbound sides, but were intermittent along the ground tracks, suggesting mostly rough terrain occasionally interrupted by patches of relatively flat areas. Polarization ratio measurements were obtained for two localized surface regions of similar latitude ~15° S, well separated longitudes ~14 and ~140° W, and incidence angle θ ~56° and ~64°, respectively. For both regions, the measurements implied surface dielectric constant ε ~1.6, suggesting liquid hydrocarbons, although alternative interpretations are possible [Marouf et al. 2006, 2008].

In Figure RSS-8 panel (a) and panel (b) depict selected geometry parameters of the Cassini T14 bistatic scattering observations. The parameters are plotted versus time relative to closest approach. Inbound (blue) and outbound (red) bistatic observations were implemented before and after the T14 ionospheric/atmospheric occultation (the empty gap in both panels). Panel (c) depicts the corresponding ground tracks. The Huygens Probe landing site is shown for reference purposes. The polarization ratio measurements were obtained for two localized surface regions of similar latitude ~15° S, well separated longitudes ~14 and ~140° W, and incidence angle θ ~56° and ~64°, respectively.

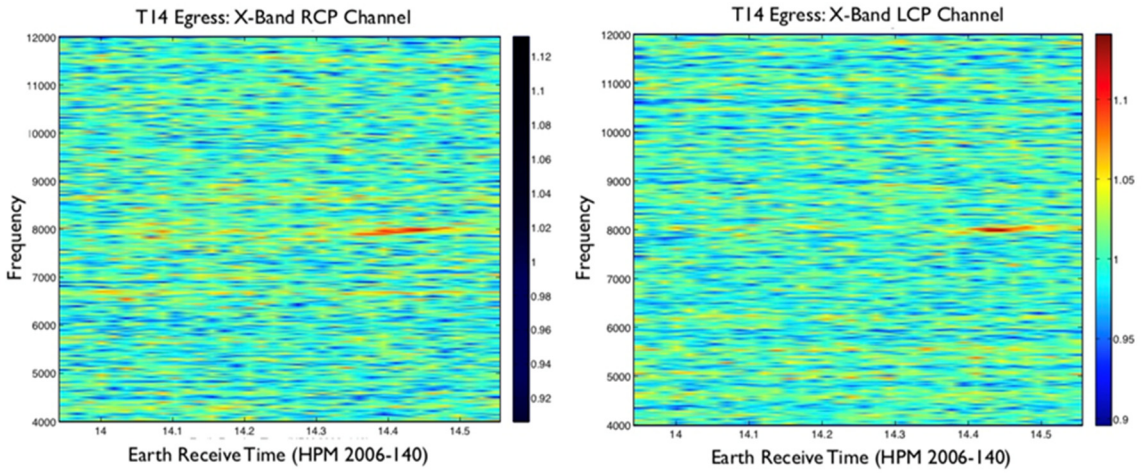

Figure RSS-9. Uncalibrated spectrograms of the first positive detection of bistatic echoes from Titan surface observed on the T14 flyby on May 20, 2006 (DOY 140). The weak echoes were simultaneously detectable in both the RCP and LCP 16 kHz bandwidth X-band channels of the 70 m ground station of the Madrid, Spain DSN complex (DSS-63).

Open questions

Ionosphere

It would be desirable to have more measurements at Titan to enable further examination of the lower ionosphere, which direct measurements cannot probe.

Gravity

The Cassini-Huygens mission provided answers to many key questions on Titan's interior structure. Titan is now a full-fledged member of the Ocean Worlds family, with a low-density core possibly in direct contact with silicates [Castillo and Lunine 2010]. However, major unsolved mysteries remain to understand its interior structure and the exchange processes between the interior, the surface and the atmosphere [Nixon et al. 2018].

The physical mechanism underlying the discrepancy between the gravity equipotential and the global shape is still an open question. The depth of the ocean and the thickness of the outer icy shell remain vaguely determined. Another unsolved mystery is whether the silicate core is in contact with the deep-water ocean, providing an interface similar to the terrestrial seafloor, one of the places where life may have emerged on Earth. Ruling out the existence of a high-pressure ice layer between the core and the ocean would have important consequences for the life-hosting potential of the moon.

Exchange mechanisms between the deep interior and the surface/atmosphere are certainly at play, but Cassini-Huygens has not provided clues on the nature, the extent and timing of these

processes. Whether or not ice convection is taking place in the icy shell is still an unresolved question. No active volcanism has been detected. The presence of methane into Titan's atmosphere requires geologically recent exchange between the interior and the atmosphere, as methane is irreversibly transformed in the atmosphere and its presence requires a supply mechanism. Similar arguments hold for ^{40}Ar, which is found in the atmosphere although its origin is in the decay of ^{40}K contained in the silicates.

Saturn Science

Atmosphere

INTRODUCTION

Saturn's oblateness, a result of its self-gravitation and rapid rotation, is sufficiently large that the usual Abel transform used to analyze spherical atmospheres, cannot be used to retrieve vertical profiles of refractivity from the bending angle ray as it traverses the atmosphere (leading to density, pressure, and temperature). This is particularly true in the troposphere, where refraction of the radio signal as it passes through the atmosphere becomes large. The difficulty emerges because the ray bends toward the local gradient in refractivity (or density in an atmosphere with uniform composition), and not toward the center of the planet, as would be the case with spherical symmetry. This means that the inversions must use ray tracing to retrieve refractivity profiles from the residual Doppler frequency.

Inverting the occultation data requires some assumption of symmetry. The assumption of at least local spherical symmetry is generally used for most atmospheres, but that doesn't work for rapid rotating oblate atmospheres. Here, the assumption used was that the atmosphere was axisymmetric and barotropic, i.e., the mean zonal winds were assumed to only vary with cylindrical radius. In this case, the resulting surfaces of constant density, pressure, temperature, and geopotential height coincide, and the inversion becomes tractable [Schinder et al. 2011a]. Of course, observations from remote-sensing instruments, like CIRS indicate that Saturn's atmosphere is baroclinic, particularly at low latitudes. One can use the occultations to check for consistency and obtain some measure of the error that the assumption of a barotropic atmosphere in the ray tracing introduces.

As with Titan occultations, those of Saturn after December 2010 needed to be done in the two-way mode, described earlier.

There were over 50 occultation soundings from Cassini, spanning low and high latitudes in both hemispheres.

THERMAL AND ZONAL-WIND STRUCTURE

Most of the analysis so far has concentrated on the equatorial region, where there are a large number of soundings within 10 degrees of the equator. The zonal winds can be derived assuming balanced flow, in which the meridional gradient of equipotential height is proportional to the mean zonal wind. A priori, there is no reason why the balanced flow relation does not hold down to the equator, but because the winds are proportional to 1/sin (latitude) in the geostrophic approximation, errors in the geopotential height magnify as one approaches zero latitude. The advantage of radio occultation soundings stems from the ability to refer the retrieved profiles to altitude (or planetary radius). This is possible since a reference body is tracked, namely the virtual image of Earth on the limb. Other remote-sensing instruments, like CIRS, cannot do this, unless they are in an occultation mode, for example tracking a star. In general, they can only obtain a temperature-pressure profile, and must impose a boundary condition, usually at a lower boundary. This becomes complicated in the thermal wind relation, because vertical gradients in the zonal wind must be along cylinders concentric with the rotation axis, rather than truly vertical, as is the case at higher latitudes.

The advantage of radio occultation soundings stems from the ability to refer the retrieved profiles to altitude (or planetary radius).

Retrieving zonal winds from the gradient wind balance first required applying a low-pass filter to the vertical profiles, to avoid small-scale fluctuations, perhaps from waves, from confusing meridional gradients. Then, to allow for the fact that the occultation soundings are not that densely distributed, the meridional distribution was smoothed. The results were encouraging: a vertical oscillation in the zonal winds was observed with a separation of ~2 pressure scale heights between maxima and minima, with peak-to-peak values of ~200 m/s, which is substantial.

SATURN'S SHAPE

Vertical profiles of pressure versus radius were retrieved from all radio occultation soundings, assuming a barotropic atmosphere and winds derived from cloud tracking, as described above. The shape of an isobar depends both on the gravitational potential and the centrifugal potential associated with the atmospheric rotation. The former is calculated using the measured J_n coefficients obtained from two-way radio Doppler tracking. Note that the partitioning between atmospheric winds and any assumed uniform interior rotation is not important, because what the cloud tracking measures are transit times across the visible disk, in other words the total angular rotation of the atmosphere, which determines the centrifugal potential in the atmospheric shell probed by the occultation soundings. With the retrieved profiles at latitudes spanning much of Saturn, the radius of the 1 bar and 1 mbar surfaces were determined as functions of latitude. Were the actual atmosphere barotropic corresponding to the wind model used, then the retrieved pressure surfaces would correspond to that used in the ray tracing. Instead, the retrieved pressures deviated from the model—which used the Voyager winds given by Sanchez-Lavega et al. [2000]—

by ±15 km, which is small compared to Saturn's pressure scale height at these altitudes, ~50 km. Currently the calculation is being redone using the Cassini winds reported by Garcia-Melendo et al. [2011].

Equatorial Oscillation

One of the interesting results from Cassini and ground-based observations is that Jupiter and Saturn exhibit quasi-periodic oscillations in the equatorial stratosphere similar to those observed on Earth. The ground-based observations provided a lengthy time record of several decades, but with limited vertical resolution. Cassini observations provided much more detailed vertical resolution, showing that the equatorial stratosphere consisted of alternating layers of warmer and colder regions. On Saturn, these were two pressure scale heights apart (~100 km). Because of thermal wind balance, these warm and cold anomalies are associated with peak to peak variations in the zonal winds with altitude of ~200 m/s. This structure appears to be zonally symmetric. Cassini observations enabled one to study the temporal evolution of this structure. The equatorial radio occultation soundings, separated by 4–5 years, showed that the pattern descended, but not in a rigid pattern [Schinder et al. 2011a]. This is reminiscent of the situation on Earth, where the oscillation is driven by the absorption of vertically propagating waves with eastward and westward zonal phase velocities.

Waves

Little quantitative analysis of the small-scale structure in the vertical profiles of temperature and pressure has been completed, but it is clearly of interest for studying phenomena like the equatorial oscillation.

NH_3

The extinguishing of the radio occultation signal around 1–2 bar results from a combination of refractive defocusing and absorption by species with large microwave opacities: NH_3, PH_3, etc. This area has yet not received much analysis.

Helium

The tropospheric helium abundance can be determined by using CIRS infrared spectra in the far infrared, using the collision-induced absorption in the translation continuum, and S(0) and S(1) lines of H_2. Helium does not absorb but affects the induced dipole moment of H_2. This analysis can be performed using CIRS spectra alone, but it is consistent with a wide range of helium mole fractions. A more sensitive approach is to combine radio occultations with thermal infrared spectra. For atmospheres with uniform composition, temperatures are proportional to the molecular mass. One can compute synthetic infrared spectra using retrieved occultation temperature profiles for various

assumed masses. The difficulty here is that this approach is that the inferred He mole fraction is smaller than interior modelers predict, which is not easily explained. No obvious systematic errors have been identified in the radio-infrared technique. This work is currently being prepared for publication.

Ionosphere

Until Cassini began to orbit Saturn the only information we had available concerning Saturn's ionosphere came from a handful of decades old radio occultation measurements of electron density profiles by Pioneer 11 and Voyager 1 and 2. Over the lifetime of the Cassini mission over 60 radio occultation observations were carried covering a latitude region from near the equator to 72°.

The results of the early radio occultation observations (12 profiles) were published in 2006 [Nagy et al. 2006]. The resulting electron density profiles all correspond to low latitudes (< 10°) and as all such observations at Saturn were within a few degrees of the terminator as a result of orbital geometry. There were significant orbit to orbit variations observed, an in order to see if noticeable differences existed between dusk and dawn observations averages were obtained as shown in Figure RSS-10. The mean peak densities for the dusk and dawn conditions are about 5.4×10^3

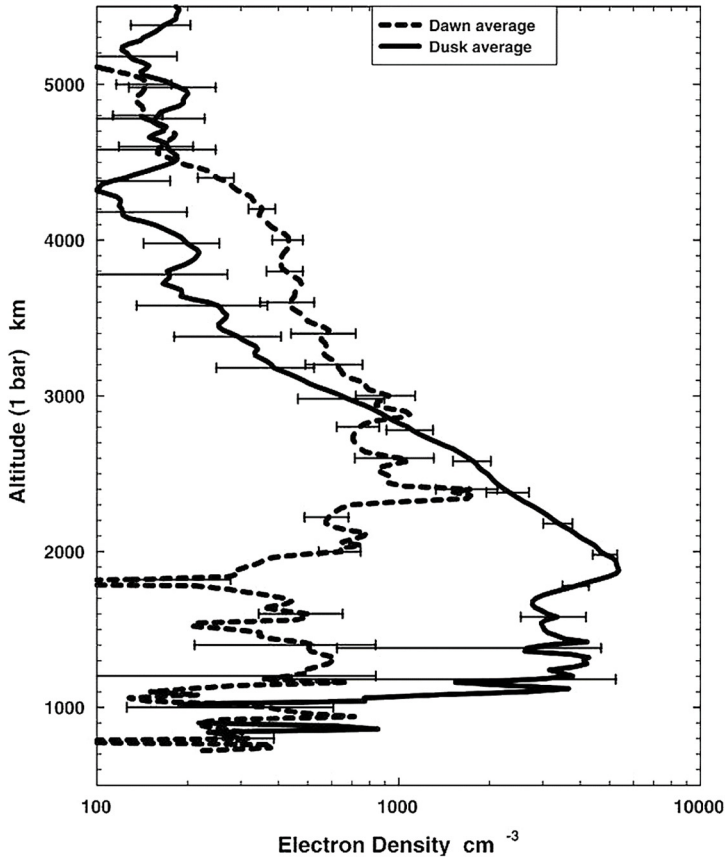

Figure RSS-10. Weighted averages of dusk and dawn electron density profiles.

and 1.7 × 10^3 cm^{-3} and the altitudes of the peaks are at about 1880 and 2360 km, respectively. The measured solar zenith angle for the dusk cases is 95.1 while it is 86 degrees for the observations. The model calculations have indicated that the main ion below and near the peak is H_3^+ and the lifetime of these molecular ions is short, less than a few hundred seconds and thus significant decay is plausible during the five hours of Saturn's nighttime. The decrease in the peak density and the increase in the height of the peak are consistent with such a decay. As the ionosphere decreases at night, it is the bottomside which decreases more rapidly, where the loss rates are higher. This can explain the decrease in the peak density and the rise of the peak height.

The mean observed topside scale heights for the dusk and dawn occultations are about 500 and 1230 km, respectively. It is very dangerous to assume that the topside is in diffusive equilibrium and that temperature gradients are negligible, however at that time there was no information on the plasma temperature and ion composition, thus the scale heights were used to make some estimates on the temperature. Assuming that H^+ is the major topside ion at dawn, the dawn scale height indicates a plasma temperature of about 625°. This value is not inconsistent with the Langmuir probe electron temperature measured during the proximate orbits [Wahlund et al. 2017]. If one assumes that the dusk temperature is at least as large as the dawn one, one arrives at a mean ion mass of about 2.46, which in turn implies the presence of about 72% H_3^+ or 7.7% H_3O^+ or other possible molecular ions; this is also not inconsistent with the Ion and Neutral Mass Spectrometer (INMS) results from the proximal orbits [Waite 2017].

The results of all (except for four, which will be analyzed in the future by Paul Withers, PhD, Boston University) ionospheric radio occultations were published in 2014 [Kliore et al. 2014]. Table RSS-6 shows important aspects of these results, along with numerous relevant parameters. Early indications that the electron densities increase with increasing latitudes was reconfirmed with these more complete results. The original idea to explain this trend was that particle impact ionization increases with latitude and plays a more important role in the total ionization rate [Kliore et al. 2009].

An alternate and/or supplemental suggestion was also raised in the 2014 paper [Kliore et al. 2014]. Connerny and Waite [1984] suggested that water inflow from the rings can rapidly convert H^+ into a molecular ion recombines dissociatively and, thus, lead to lower electron densities. The inflow of any other molecule, for example methane, will have the same effect. They called this the ring-rain effect. At that time, there was very little information on the presence of water, but the very little data on the presence and variation of stratospheric water abundances [Bjoraker 2013] was consistent with this suggestion. O'Donoghue et al. [2013] used the W. M. Keck Telescope to observe two bright H_3^+ rotational-vibrational infrared emission lines at Saturn. They reported that their observations was consistent with the so-called ring-rain suggestions of Connerney and Waite [1984]. They detected increased H_3^+ densities where the ionosphere is magnetically connected to the gaps between the rings. An attempt was made to see if this phenomena was noticeable with our ionospheric occultation results. There were only two observations corresponding to the Cassini Division and no noticeable effect was seen. It was somewhat surprising not to see such an effect if it is present, but it is important to note that the two possible opportunities do not provide a statistically meaningful answer.

Gravity

INTRODUCTION

The interior of Saturn is schematically separated into three layers: (i) a helium-depleted, molecular hydrogen envelope, where pressures reach the value of 2 Mbar; (ii) a metallic hydrogen layer, with pressures in the range 2–10 Mbar; and (iii) a heavy element core, with a mass in the range 5–20 Earth masses [Fortney et al. 2016]. Gravity, being determined by the internal distribution of masses, is the primary source of information in the construction of interior models of the planet. Saturn's magnetic field was also expected to provide important additional information, especially on the location of the envelope-metallic hydrogen boundary. If the H-He envelope is fully convective and well mixed, the atmospheric composition may give further constraints, distinct and complementary from those of gravity.

Saturn is a fluid and rapidly rotating planet whose internal mass distribution is largely driven by gravity and centrifugal forces.

Saturn is a fluid and rapidly rotating planet whose internal mass distribution is largely driven by gravity and centrifugal forces. The gravity field is therefore dominated by an axially and hemispherically symmetric component described by even zonal coefficients $J_{2n} \approx q^n$, where q is the ratio of the centrifugal and gravity acceleration at the equator. Deviations from this law are related to two effects: the radial density distribution, and differential rotation associated to flows in the envelope.

Determining the density distribution inside Saturn requires some assumptions on the equation of state (EOS). Due to the lower mass, the dependence of interior models on the assumed EOS is however less critical than for Jupiter. However, models suffer to some extent the uncertainty in rotation rate of the uniformly rotating deep interior.

Dynamical phenomena associated to zonal flows and differential rotation seen in optical images may generate peculiar perturbations in the gravity field. If the differential rotation associated to surface velocity is deep-seated, then internal dynamics affects the gravity field in two ways. Firstly, it perturbs the equipotential surfaces symmetrically, giving rise to a redistribution of mass that appears as a correction to the even zonal coefficients [Hubbard 1999] and a high degree field that does not follow the law $J_{2n} \sim q^n$. Secondly, any north-south asymmetry in the velocity field would necessarily lead to nonzero values for the odd zonal harmonics [Kaspi 2013]. Gravity results from the Juno mission at Jupiter verified these theoretical expectations and were interpreted as an indication of a diffuse core [Wahl et al. 2017] and a wind depth of 2000–3000 km [Iess et al. 2018; Kaspi et al. 2018]. Cassini has repeated these measurements at Saturn, revealing large differences between the two planets.

Another important result of Cassini gravity measurements during the GFO is the determination of the mass of the rings. This quantity, when combined with the percentage of silicate in the ice grains and with the dust flow (both measured by Cassini) can be related to the age of the ring system [Cuzzi and Estrada 1998]. While the masses of the A-ring and C-ring were determined with good accuracy from stellar occultations, the mass of the opaque B-ring remained matter of speculation. Prior to the GFO, Cassini's pericenter was always outside the A-ring, so that the gravitational effects of the rings on the spacecraft motion could not be separated from those of the oblateness of the planet. In the final phase of the mission, Cassini flew between the planet and the rings thus allowing to single out the gravitational pull from the B-ring.

Gravity observations during Cassini's Grand Finale orbits

The range rate of Cassini was the primary observable quantity for gravity determination. Range-rate measurements were obtained from the Doppler shift of a carrier sent from the ground at 7.2 GHz (X-band) and retransmitted back by the onboard transponder at 8.4 GHz. An auxiliary downlink at Ka-band (32.5 GHz) was also available. The nearly edge-on view of the GFO from Earth generated a particularly strong Doppler signature due to Saturn's gravity.

Of the 22 GFO (sequentially labeled as Rev271 through Rev293) six were selected for gravity measurements: Rev273, Rev274, Rev275, Rev278, Rev280, and Rev284. These orbits were chosen to minimize neutral particle drag and tropospheric noise (large spacecraft elevation at closest approach). Unfortunately, data near pericenter for Rev275 could not be used due to a configuration error at the ground station.

Cassini was continuously tracked through pericenter for 24–36 hours from the antennas of the DSN and from the ESA's ESTRACK antennas located in the southern hemisphere (Malargue, Argentina, and New Norcia, Australia). The gravity GFO represented a major coordination effort for the Radio Science group at JPL.

Two-way Doppler measurements at X-band make up 98% of the data. Noise from solar plasma was low due to the large solar elongation angle (> 142° on all six gravity orbits). The data quality was statistically equivalent in X-band and Ka-band data, with an RMS Doppler noise between 0.020 and 0.088 mm/s at 30 s integration time. The main characteristics of the gravity GFO are shown in Table RSS-7 and Figure RSS-11.

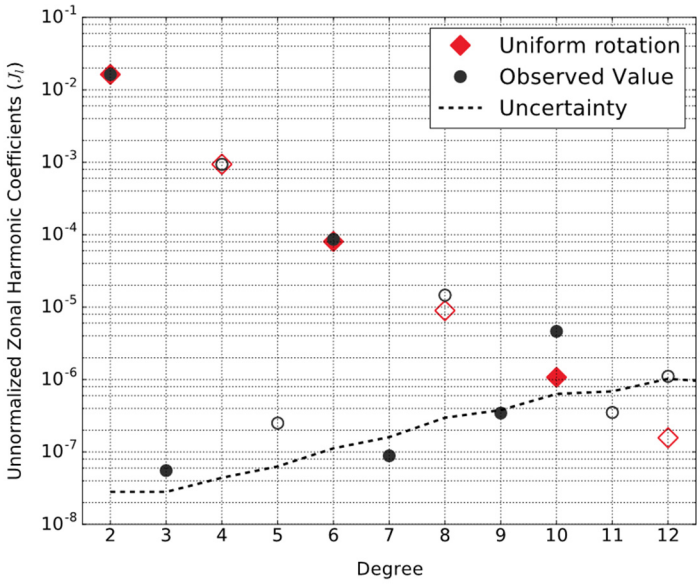

Figure RSS-11. Zonal gravity harmonic coefficients J_2–J_{12}. The dashed line shows the uncertainty from Table RSS-8. Positive values are marked as solid circles, negative values as empty circles. The red diamonds are the theoretical predictions for uniform rotation.

Table RSS-7. Parameters of the osculating orbit at C/A from the RSS reconstructed trajectory. Orbit inclination and C/A latitude are relative to the ring plane. The C/A altitude is relative to the Saturn 1 bar surface (equatorial radius of 60268 km, flattening of 0.09796). The reported noise level refers to the C/A pass only, for Doppler observables at 30 s integration time.

Parameter	Units	Rev273	Rev274	Rev278	Rev280	Rev284
Day (2017)		9 May	15 May	10 June	23 June	19 July
Eccentricity		0.92	0.92	0.92	0.92	0.92
Inclination	(deg)	63	63	62	62	62
EBO	(deg)	96	96	98	99	101
C/A altitude	(km)	2720	2668	3427	3409	2817
C/A latitude	(deg)	−5	−5	−6	−6	−7
SEP	(deg)	142	148	175	172	146
Noise RMS	(μm/s)	29	23	20	88	44

The X-band data were favored for our analysis because of the higher measurements signal to noise ratio (SNR) during ring occultation periods. As predicted, the radio link was lost when the line of sight passed through the densest region of the B-ring, causing a blockage of about 10 minutes. Diffraction and near-forward scattering resulted in a larger Doppler noise at Ka-band than X-band when the beam passed through the rings.

GRAVITY RESULTS

The gravity measurements carried out by Cassini during the Grand Finale orbits reveal a planet with many surprising features. Range rate measurements were successfully used to estimate the zonal field of the planet till degree 10 and the mass of the B-ring, as shown in Table RSS-8. Note: these are preliminary results; for authoritative results, refer to Iess et al. [2019].

Surprisingly, and differently from what was found on Jupiter by Juno, Saturn's gravity shows residual, unexplained, accelerations (at the level of 4×10^{-7} m/s^2) that affected the motion of Cassini and were detected by the Doppler tracking system. These accelerations were absorbed using three different models: stochastic accelerations, acoustic normal modes (zonal component only), and a static tesseral field. As the nature of the unexplained accelerations is unknown at the time of this writing, the stochastic model is preferred. A tesseral field must originate from deep-seated density anomalies in the region of uniform rotation in order to be seen as a static field over the two months of the gravity measurements. This cannot be excluded, although the magnitude of the accelerations and the large degree of the required field (from 8 × 8 to 12 × 12, depending on the assumed rotation period) militates against this hypothesis. In spite of these unexpected features, the solution for the zonal field and the ring mass, relevant for the interpretation, is stable and all parameters are sufficiently well determined.

Table RSS-8. Saturn's gravity harmonic coefficients (unnormalized; reference radius 60330 km) and B-ring mass (in units of Mimas' mass), obtained from the analysis of Cassini's Grand Finale gravity orbits. The uncertainties are 3-sigma for the zonal harmonics and 1-sigma for the B-ring mass.

	Value	Uncertainty
J_2 (× 10^6)	16290.573	0.064
J_3 (× 10^6)	0.059	0.023
J_4 (× 10^6)	−935.314	0.037
J_5 (× 10^6)	−0.224	0.054
J_6 (× 10^6)	86.340	0.087
J_7 (× 10^6)	0.108	0.122
J_8 (× 10^6)	−14.624	0.205
J_9 (× 10^6)	0.369	0.260
J_{10} (× 10^6)	4.672	0.420
J_{11} (× 10^6)	−0.317	0.458
J_{12} (× 10^6)	−0.997	0.672
B ring mass (M_m)	0.23	0.19

The main outcomes of gravity measurements [Iess et al. 2019] can be summarized as follows:

1. The even zonal harmonic coefficients J_6, J_8, J_{10} are so large that only a deep and intense differential rotation can explain their value. The analysis using two different methods (differential rotation on cylinders with the concentric Maclaurin spheroids and differential rotation with finite depth flows from the thermal wind equation) indicate that the flows extend to a depth of ~9000km and must involve a large

fraction of the mass of the planet. This differs from Jupier, where winds are shallower (~3000 km).

2. The favored EOS leads to a core mass in the range 15–18 Earth masses.

3. The mass of the B-ring is not very different from the Voyager-era expectations, pointing to a ring age in the range 10–100 million years. The estimate of the mass under different models for the unexplained accelerations is shown in Table RSS-9. The low value of the ring mass suggests a scenario where the present rings of Saturn are young, probably just 10 million to 100 million years old, to be consistent with their pristine icy composition. Nevertheless, the rings may have evolved substantially since their formation and were perhaps once more massive than they are today. Models for a young ring system invoke the chance capture and tidal disruption of a comet or an icy outer solar system body, suggesting that catastrophic events continued to occur in the solar system long after its formation 4.6 billion years ago.

Table RSS-9. Estimates of the ring masses for the three dynamical models (stochastic, tesseral field, normal modes), in units of Mimas mass (GM_M = 2.5026 km^3/s^2). The uncertainties are 1σ. The solution with the tesseral field shows larger uncertainties due to the large number of free parameters to be estimated. The reference solution (random accelerations) and the solution using normal modes are in good agreement. Although the masses of the three rings are highly correlated, their sum is well determined and consistent at the 1σ level.

	A-ring (M_M)	B-ring (M_M)	C-ring (M_M)	A+B+C-rings (M_M)

Open questions

We never got really high latitude occultations of Saturn. Non-radio science efforts includes quite a bit of modeling of Saturn's ionosphere given the proximal orbit observations. The loss of CAPS means that we have no direct information of the ion temperature in Saturn's ionosphere.

What accounts for the tesseral components of Saturn's gravity field?

What accounts for the differences between the overall structure of Saturn's and Jupiter's interior, as revealed by their gravity fields?

Enceladus Science

Gravity

After Titan, Enceladus has been the most observed satellite by the Cassini spacecraft during its exploration of the Saturnian system. Flybys of this small moon revealed a large plume ejected from the south-polar region, with the source being long fractures from which vapor and ice emerge as discrete jets [Spitale and Porco 2007]. Concurrent observations of sodium and potassium salts in the plume [Postberg et al. 2011], and the measured temperatures within the fractures [Spencer et al. 2006], strongly argue for the presence of liquid water in the subsurface source region. The plume exhibits a time variability well correlated to the predicted tidal stresses of the body [Hedman et al. 2013].

The endogenic (non-solar) power emitted from the south-polar region, derived from Cassini CIRS data, is 15.8 gigawatt (GW), with a 20% formal uncertainty [Howett et al. 2011]. This is equivalent to an average surface heat flux of about 20 mW/m^2 and is an order of magnitude larger than conventional estimates of tidal heating if Enceladus' current orbital eccentricity represents a so-called equilibrium resonant state with other satellites [Meyer and Wisdom 2007]. It indicates time-variability in its internal properties [Ojakangas and Stevenson 1986], in a resonant state with other nearby moons [Zhang and Nimmo 2009], or in the rate of heat transport. In any or all of these cases, a plausible internal structure is that of a liquid water ocean overlain by a (thermally conductive) crust [Howett et al. 2011].

Cassini Gravity Flybys and Data Analysis

The design of the Cassini spacecraft did not allow radio tracking from Earth during remote sensing observations. Therefore, only three of the 23 flybys of Enceladus have been used for gravity measurements. In these close encounters the spacecraft was continuously tracked from ground antennas while flying within 100 km of the moon's surface, twice above the southern hemisphere (in the flybys labeled E9 and E19) and once over the northern hemisphere (E12). Enceladus' quadrupole gravity field and degree-3 zonal harmonic coefficient J_3 were determined [Iess et al. 2014] from measurements of spacecraft range-rate. With a radius about 10 times smaller than that of Titan, and about the same density, the gravitational signature of Enceladus in Doppler measurements is much weaker than that of Saturn's largest moon. However, the small perturbation due to J_3 (about 0.2–0.3 mm/s) was still clearly detectable by the Cassini tracking system, whose accuracy was 0.02–0.09 mm/s on a time scale of $\tau \approx 60$ s.

Microwave links between the onboard transponder and ground stations of NASA's DSN enabled precise measurements of the spacecraft range-rate. In addition to gravitational forces, the RSS analysis accounted for the main non-gravitational accelerations, most notably neutral particle drag exerted by the substantial gas plume formed by the jets of the south-polar region. Flying by the moon at latitudes below −70°, the spacecraft interacted with the plume at distances up to 500 km from Enceladus' surface, although most of the effect is localized within 20 seconds from

closest approach. Given the uncertainties in the gas density along the spacecraft flight path, and the short time scale of the interaction, the effect of the drag could be modeled as an unknown, impulsive, vectorial acceleration at closest approach at E9 and E19. The orbital solutions yielded a velocity variation almost parallel to the spacecraft velocity, as expected for a drag force, of magnitude 0.25 mm/s for E9 and 0.26 mm/s for E19, comparable to the J_3 signature. The inclusion of the neutral particle drag in the south-polar flybys is therefore essential for obtaining Doppler residuals free of any signatures, essential for a faithful gravity solution.

As in other Cassini gravity analyses [Iess et al. 2010, 2012; Tortora et al. 2016] the solution for Enceladus' gravity field was obtained from a multi-arc analysis where all data from the three flybys were fitted using separate initial conditions for the spacecraft state vector at each arc (local parameters). The Enceladus state vector, the five degree-2 harmonic coefficients and J_3, were considered global parameters common to all arcs. To avoid biased estimates, the a priori uncertainties on the gravity coefficients were at least 30 times larger than the formal uncertainties obtained from the orbital solution. The non-gravitational accelerations due to anisotropic thermal emission from the three radioisotope thermoelectric generators and solar radiation pressure were modeled using values determined by the spacecraft navigation team from the past eight years of the Saturn tour. By processing the data into a multi-arc least squares filter, all local and global parameters were estimated (Table RSS-10). Furthermore, the solution was proven to be stable with respect to perturbations of the dynamical model, such as the estimation of a full degree-3 field.

The ratio J_2/C_{22} differs from the value required for hydrostatic equilibrium (J_2/C_{22} = 10/3), suggesting that the satellite is not in a fully relaxed shape. The equipotential surface of the tidal, rotational and gravitational potential (the latter limited to 2,0 and 2,2 harmonics) has semiaxis differences of $a–c$ = 6.00 km and $b–c$ = 2.07 km. The tesseral coefficients C_{21}, S_{21}, and S_{22} are null within 3σ, indicating that the adopted rotational model is correct and that the orientation of the principal axes is that expected for a tidally locked body with a fully damped pole. The estimated value of J_3 implies a 2.5 mGal, negative gravity anomaly at the south pole (Figure RSS-12).

Table RSS-10. Solution for the gravity field of Enceladus. Estimated gravity harmonic coefficients from the multi-arc fit of E9, E12, and E19 Doppler data.

Coefficient	Central Value ± 1σ
J_2 (× 10^6)	5435.2 ±34.9
C_{21} (× 10^6)	9.2 ±11.6
S_{21} (× 10^6)	39.8 ±22.4
C_{22} (× 10^6)	1549.8 ±15.6
S_{22} (× 10^6)	22.6 ±7.4
J_3 (× 10^6)	−115.3 ±22.9
J_2/C_{22}	3.51 ±0.05

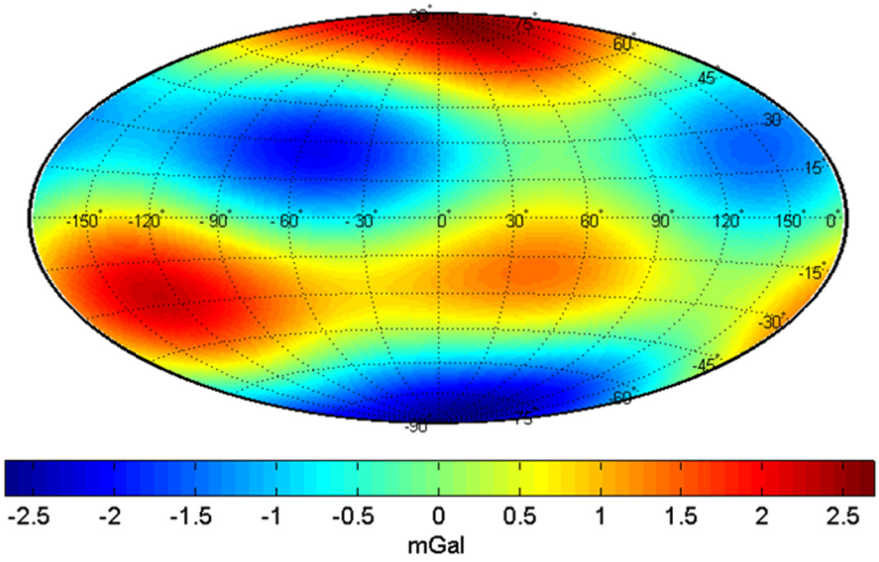

Figure RSS-12. The gravity field due to C_{21}, S_{21}, S_{22}, and J_3 as in Table RSS-10 is mapped onto the reference ellipsoid. The negative anomaly at the south pole, representing the asymmetry between the two hemispheres, is ~2.5 mGal.

INTERIOR MODELS

The interpretation of Enceladus gravity presented a greater difficulty and uncertainty than usual, given the strikingly different appearances of the northern and southern hemisphere, and the apparent confinement of endogenic activity to the high southern latitudes. Still, the deviation of J_2/C_{22} from 10/3 (the value for a laterally homogeneous body) is modest (of order 6%) and the non-degree 2 gravity is small (of order 2% relative to J_2), suggesting that there is some prospect of useful inferences.

The topography of Enceladus [Nimmo et al. 2011] is not that of a relaxed hydrostatic body under the action of tides and rotation in a synchronous orbit. Based on the global shape data which show a topographic depression at the south pole [Thomas et al. 2007], it has long been proposed that the liquid reservoir may be located only in the southern hemisphere [Collins and Goodman 2007], thus explaining why the activity is concentrated around the south pole [Tobie et al. 2008]. First interpretation of the topography and gravity data [Iess et al. 2014; McKinnon 2015] suggests that the ice shell is about 30–40 km thick at the south pole, and its thickness increases to about 60 km in the equatorial region. However, from these data alone, it is not possible to definitively conclude whether the ocean is global or only located in the southern hemisphere. More recently, the detection of a significant physical libration [Thomas et al. 2016] has indicated that the ice shell is mechanically decoupled from the rocky core, thus providing the first direct evidence for a global subsurface ocean. Thomas et al. [2016] have shown that the observed libration is consistent with an average ice shell thickness of 21–26 km, which is significantly less than the value predicted from gravity and topography. Čadek et al. [2016] show that the Cassini observations can be reconciled by considering isostatic compensation including the effect of a few hundred meter thick elastic

lithosphere. Their model predicts that the core radius is 180–185 km, the ocean density is at least 1030 kg/m^3, and the ice shell is 18–22 km thick on average. The ice thicknesses are reduced at poles decreasing to less than 5 km in the south polar region.

Interior modeling of Enceladus remains an active area of research and is important because its internal structure tells us about the thermal state, evolution, and energy budget of this ocean world.

Ionosphere

An unplanned opportunity to observe the Enceladus plume was discovered in a routine search, which indicated that the radio path will pass within a few hundred kilometers from Enceladus' south pole shortly before a scheduled Saturn occultation during orbit 125. The Cassini science engineers were able to adjust the orbit to obtain a plume occultation with the radio path passing about 45 km below the south pole. At the time of the passage of the Cassini radio line-of–sight (LOS) through the center of the plume, its velocity relative to Enceladus was about 13 km s^{-1}, and the distance of Cassini from Enceladus was about 577,400 km. The occultation was observed by two DSN stations near Canberra, Australia: (i) DSS-43 with a 70-m diameter antenna receiving S-band (~13 cm) and X-band (~3.5 cm) signals; and (ii) DSS-34 with a 34-m antenna receiving X-band and Ka-band (~1 cm) signals. The two frequencies from both stations were coherently differenced to obtain frequency data that is sensitive only to the electron plasma.

The differenced frequency residuals were inverted using an Abel integral inversion, cf. Kliore et al. [2004], for the case of circular cylindrical symmetry (with the axis of the cylinder being the north-south polar axis of Enceladus), to obtain the refractivity as a function of distance from the south pole axis, which then can be used to obtain the profiles of electron density shown in Figure RSS-13. This clearly indicates an electron density enhancement with a maximum density of

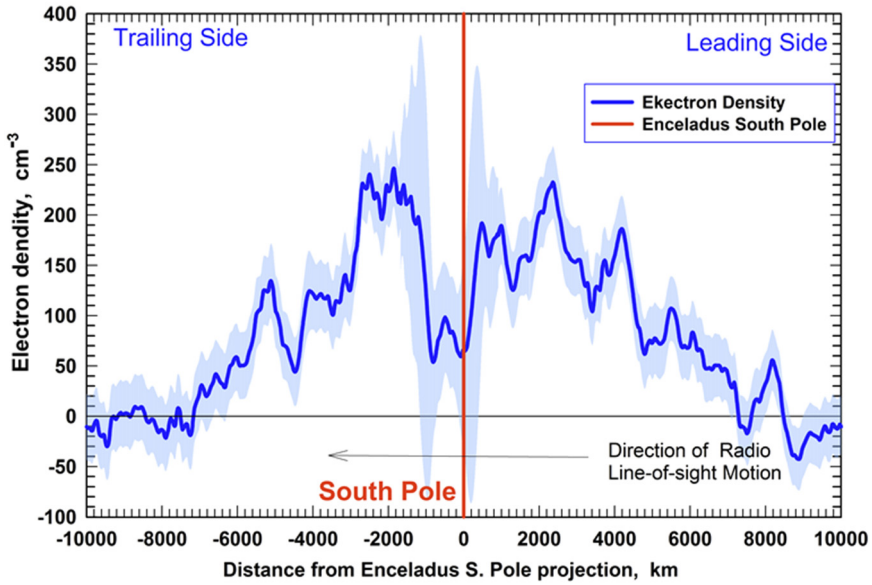

Figure RSS-13. RSS observations of Rev125 Enceladus occultation.

about 225 cm^{-3} on the entry (leading) side, at a distance of about 2000 km from the plume center, and approximately 245 cm^{-3} maximum density on the exit (trailing) side, also at a distance of about 2,000 km from the plume center, extending to about 7,000 km (~28 R_E), in both directions from the plume axis. A significant asymmetric drop in the electron density to about 50 cm^{-3} in the neighborhood of the Enceladus plume, beginning near the plume centerline on the leading side, and continuing for about 1,000 km on the trailing side, can also be seen clearly in the figure. A few smaller dips on both sides are also observable.

The Radio and Plasma Wave Spectrometer (RPWS) in situ observations [Morooka et al. 2011] based on both the Langmuir Probe and the upper hybrid emissions were taken along the E3, E4, E5, and E6 Cassini flybys, which were also close to Enceladus, but basically at right angles to the RSS results. Therefore, no direct comparisons between these data sets can be made, nevertheless, a few comparative statements are possible. The combined data sets indicate significant electron density plumes extending to about 28 R_E in both directions close to the equatorial plane. Both the RPWS and RSS electron density observations indicate a large drop of the density in the immediate vicinity of the Enceladus neutral density plume and smaller fluctuations further out in the wings. These observations are consistent with the direct RPWS measurements in terms of densities, but are in a direction about 72° away, which implies that the extended plasma plume extends in both directions in the equatorial plane. The large electron density bite-out is very likely caused by electron attachment to grains with sizes ranging from nanometers to micron-sized. We also showed by simple calculations that the peak electron densities observed outside this depletion region are consistent with photoionization of neutral gas plus removal by plasma transport.

These results were presented at numerous national and international meetings—for example, Kliore et al. [2006, 2010].

Open questions

What are the long-term spatial and temporal variations in the ionosphere of Enceladus, associated with its plumes originating from the southern hemisphere?

Icy Satellite Science

The determination of the gravity fields of the Saturnian satellites was one of the main scientific goals and responsibilities of the Cassini Radio Science team [Kliore et al. 2004]. Radiometric tracking data were acquired during the flybys of Phoebe, Iapetus, Hyperion, Dione, and Rhea, allowing an accurate determination of the masses of these satellites as well as the gravity quadrupole field of Dione and Rhea [Rappaport et al. 2005; Iess et al. 2005, 2007; Thomas et al. 2007; Mackenzie et al. 2008; Zannoni et al. 2015; Tortora et al. 2016]. These experiments consisted in using X-band and Ka-band coherent, two-way Doppler data and fit them in JPL's Orbit Determination Program in short data arcs. Doppler data were fitted using a spacecraft dynamical model that included the gravitational accelerations from all Saturn system bodies, as well as non-

gravitational accelerations from the spacecraft Radioisotope Thermoelectric Generators and from solar radiation pressure. The noise introduced by the Earth troposphere was calibrated at Goldstone (California) and Madrid (Spain) complexes of the DSN using an Advanced Media Calibration (AMC) system [Resch et al. 2002] at Canberra (Australia) the standard Tracking System Analytical Calibrations (TSAC) is used instead [Bar-Sever et al. 2007], being an AMC not available. AMC devices were specifically developed in support of the cruise Cassini radio science experiments (see the section entitled RSS Non-Saturn Science Results – Cruise Science) and consisted of water vapor radiometers, digital pressure sensors and microwave temperature profilers assembled in a single unit installed a short distance from the DSS-25 and 55 at Goldstone and Madrid, respectively. Since the loss of the Cassini onboard Ka-band transponder in 2003, which in the past allowed a full calibration of the solar and interplanetary plasma [Tortora et al. 2003, 2004], the Sun-Earth-Probe angle also became an important factor in determining the radio link frequency stability [Asmar et al. 2005] and, in turn, the achievable accuracy in the orbit determination and parameter estimation process. Thus, to mitigate the effect of the charged particles in the solar corona, interplanetary space, and the Earth ionosphere X-band uplink, Ka-band downlink (X/Ka) Doppler data were preferred to X/X data, if acquired simultaneously (Ka-band data are more immune to plasma noise); similarly, in order to maximize the phase stability, 2-way data were preferred to 3-way data, if acquired simultaneously.

A close encounter with Phoebe, was performed by Cassini just prior to the Saturn Orbit Insertion (SOI) maneuver, on June 11, 2004.

Phoebe

A close encounter with Phoebe, was performed by Cassini just prior to the Saturn Orbit Insertion (SOI) maneuver, on June 11, 2004. This was the only opportunity during the whole Cassini mission because, after SOI, its maximum distance from Saturn was designed to be smaller than Phoebe's orbital radius. Phoebe's C/A took place at an altitude of about 2000 km and a relative velocity of about 6.4 km/s.

For the determination of Phoebe's GM [Rappaport et al. 2005], X-band Doppler data and optical images of the Saturnian satellites were used. The optical navigation images were used to constrain Phoebe's ephemerides and determine its position relative to the spacecraft, so that the intrinsic correlation (in terms of satellite mass and spacecraft impact parameter) of a hyperbolic flyby could be removed.

Iapetus

Iapetus moves around Saturn on a large orbit of radius ~59 Saturn radii. For the first Cassini encounter (October 17, 2004), the distance at closest approach of Cassini to the satellite was 1.11×10^6 km, so large that the encounter barely deserves the name of flyby. However, Iapetus is a big body with a radius of 733 km, so even a distant encounter allowed to determine its mass. The

large distance at closest approach had a positive effect, in that the determination has only a weak dependence on the impact parameter, and more generally, on the relative orbit of Cassini with respect to Iapetus. Indeed, we expected the correlations between the mass of Iapetus and the orbital elements of both Cassini and Iapetus to be small. The relative velocity between Cassini and Iapetus at closest approach of the first flyby was 3.7 km/s. This relatively small velocity was an advantage since it resulted in a relatively large velocity change of Cassini, due to Iapetus, of about 3.2 cm/s, greater by more than three orders of magnitude than the sensitivity of the radio signal to velocity changes. The SEP angle at C/A was 87°. This implied a solar plasma noise of about 9.2×10^{-14} at 300 s integration time, i.e., larger than the noise introduced by the Earth troposphere [Asmar et al. 2005]. For this reason, the Cassini Radio Science Team requested Ka-band passes to reduce the detrimental effect of plasma noise on Doppler data. For the first Iapetus flyby, the data used for our determination [Iess et al. 2005] consisted of closed-loop tracking data acquired in the period from October 10–25, 2004. The set of data includes Doppler X/X and X/Ka data as well as ranging data at X-band. The Doppler data before and after C/A were compressed at 300 seconds, while those acquired on October 17 and 18 were compressed to 60 seconds.

The second Cassini encounter of Iapetus occurred on December 31, 2004. The distance at C/A of Cassini to the satellite was 123,363 km, the relative velocity was 2.0 km/s and the SEP angle was 165°. As explained in the section entitled Key Objectives for RSS Instrument, this short distance at C/A implied that the uncertainty in the distance at C/A was predominant on the uncertainty in the velocity change so that the estimation (and an update) of the satellite ephemerides was mandatory. The data used for our determination [Iess et al. 2005] consisted of closed-loop tracking data acquired in the period from December 28, 2004 to January 2, 2005. The set of data includes only X-band Doppler coherent with X-band uplink. The Doppler data were compressed at 300 seconds.

Hyperion

The Cassini flyby of Hyperion occurred on September 25–26, 2005. The C/A took place on September 26, 2005, 02:24:47 UTC at a distance of 618 km from the center of mass of the satellite and with a relative velocity between the spacecraft and the moon of about 5.6 km/s. The data used for our determination [Thomas et al. 2007] consisted of closed-loop tracking data acquired in the period from 07:54:07 UTC of September 25 to 21:29:11 UTC of September 26, 2005. The data set was originally designed to comprise four segments of observation: two of them just before and after C/A, acquired over the Goldstone and Madrid complexes, respectively, and two additional passes—the so-called gravity science enhancement (GSE)—to be acquired far from C/A (in the wings of the hyperbolic flyby) about 12 hours before (Madrid) and after (Goldstone) C/A. However, due to a complex-wide failure, all data to be acquired over the Madrid complex on the egress part of the flyby just after C/A were lost, leading to a significant degradation in the GM estimation error. Thus, the exploitable data set consists only of three segments of observation (two before and one after C/A) where the Doppler data are a combination of two-way and three-way, X/X and X/Ka data, predominantly sampled at 60 s.

Dione

During its time in the Saturn system, Cassini has performed five close flybys of Dione, three of which included radio tracking during closest approach: one in December 2011, and two in summer of 2015. As in previous works, the gravity field of Dione was estimated by reconstructing the spacecraft trajectory during these encounters, making use of precise measurements of the Doppler shift of a highly stable microwave radio link between Cassini and the ground station antennas of NASA's DSN.

The available data were analyzed [Zannoni et al. 2015] in a multi-arc fit estimating a fully unconstrained quadrupole gravity field for Dione, the Dione and the spacecraft initial state vectors for each flyby, and modeling parameters for the non-gravitational accelerations. The stability of the solution was tested by perturbing the dynamical model in various ways, including estimating a full 3 × 3 gravity field and changing the a priori uncertainties. The Saturn system dynamics were modeled on the basis of the most recent satellite ephemerides.

Rhea

Before Cassini's arrival in the Saturn system, only the gravitational parameter GM was known from the analysis of Pioneer and Voyager data [Campbell and Anderson 1989]. Using this and the estimated volume (from camera images), a bulk density of about 1200 kg/m^3 was derived, relatively small and compatible with a mixture of about 75% by mass water ice (density 1000 kg/m^3) and 25% rock-metal (density 3000 kg/m^3).

During its mission in the Saturn system, Cassini performed four close encounters of Rhea, of which only two were devoted to gravity investigations. The first gravity flyby, referred to as R1, according to the numbering scheme used by the Cassini project, was performed on November 26, 2005, during the main mission, and the second and last gravity flyby, referred to as R4, was performed on March 9, 2013, during the Solstice mission.

Radiometric data acquired during the first encounter (R1) were used to estimate the gravity field of Rhea. A first estimate [Anderson and Schubert 2007] was obtained under the assumption of hydrostatic equilibrium, i.e., constraining the unnormalized gravity coefficients J_2 and C_{22} to a ratio of 10/3. From this estimation, by applying the Radau-Darwin relation the authors obtained a normalized moment of inertia of about 0.3911 ±0.0045 (a value of 0.4 would imply a constant density interior). The authors concluded that the satellite's interior is a homogeneous, undifferentiated mixture of ice and rock, with possibly some compression of the ice and transition from ice I to ice II at depth.

In parallel, the radiometric data acquired during R1 were independently analyzed by the Cassini Navigation team [MacKenzie et al. 2007] and by the Cassini Radio Science team [Iess et al. 2007]. Both analyses estimated the moon's GM and quadrupole gravity coefficients J_2 and C_{22}, obtaining different solutions, but consistent at the 2σ level, as a result of different analysis approaches. The two approaches were then combined to obtain a joint best unconstrained

estimation of the quadrupole field [MacKenzie et al. 2008]. The solution obtained is not statistically compatible with hydrostatic equilibrium, hence, no useful constraint on Rhea's interior structure could be imposed. Hydrostatic equilibrium was also ruled out by applying this constraint to the estimated quadrupole field coefficients, and this led to a significant degradation of the orbital fit at closest approach. To explain the non-hydrostatic ratio J_2/C_{22}, the authors theorized that a large collision occurred after the completion of the thermal evolution of the satellite, causing a redistribution of mass and a reorientation of the tidal bulge.

Successively, Anderson and Schubert [2010] stated that the differences in the previously published gravity fields are probably caused by a mismodeling of the non-gravitational acceleration acting on Cassini caused by anisotropic thermal emission. To avoid this issue, Anderson and Schubert [2010] restricted the analysis to a subset of data around the closest approach (± 2000 s), where the information from Rhea's quadrupole gravitational field is confined. They obtained a new solution in agreement with Anderson and Schubert [2007] using the hypothesis of hydrostatic equilibrium. Moreover, they concluded that non-hydrostaticity is not supported by the data.

To resolve these discrepancies, a second and final gravity flyby was planned in Cassini's Solstice.

To resolve these discrepancies, a second and final gravity flyby was planned in Cassini's Solstice. R1 was characterized by a very low inclination, about 17° at the closest approach (C/A), in order to decorrelate the estimation of J_2 and C_{22}, while R4 was designed to be nearly polar, with a high inclination at C/A, about 106°. However, the C/A of R4 was about 999 km, twice as high as R1 (about 502 km), thus significantly reducing the information content about Rhea's quadrupole gravity field in this second flyby. The SEP angle was larger than 110° during both encounters, thus range-rate measurements were only slightly affected by the harmful effect of solar plasma.

During the encounters, Doppler data at X-band (8.4 GHz) and Ka-band (32.5 GHz) were acquired by the antennas of NASA's DSN at the three complexes of Goldstone, Madrid, and Canberra. In addition to data obtained around the closest approach, the analysis also used data obtained up to two days before and after the closest approach, during standard navigation tracking passes. The additional data allow an improvement of the orbit determination, in particular, the estimation of Rhea's ephemerides and Rhea's GM, because of the stronger constraints that are imposed on the relative trajectories between Cassini, Rhea, and Saturn.

It is important to note that the closest approach of R1 was tracked only in three-way mode, meaning that the receiving and transmitting stations were different. This represents a suboptimal condition, due to the possible delay between the reference oscillators of the two different uplink and downlink stations. During R4, the closest approach was tracked in two-way mode.

Dual frequency X-band uplink and Ka-band downlink (X/Ka) Doppler data were preferred to the standard X/X data when available, to reduce the effects of the dispersive noise sources, mainly the solar corona and the Earth ionosphere. Two-way Doppler data were preferred to three-way

data in the same band when both were available, to remove the errors due to the clock synchronization between the uplink and downlink ground stations.

When only two-way X/X data and three-way X/Ka data were available, the selection was made on a case-by-case basis.

When available, the wet path delay due to Earth's troposphere was calibrated using measurements from advanced water vapor radiometers [Resch et al. 2002]. When not available, the Earth's troposphere was calibrated using a combination of weather data and dual frequency GPS measurements [Bar-Sever et al. 2007].

The mass estimation results obtained by the Cassini Radio Science team for Phoebe, Iapetus, and Hyperion are summarized in Table RSS-11, along with the rank of each solution (the number of estimated variables) and the tropospheric calibrations used.

The gravity field results obtained by the Cassini Radio Science team are summarized in Table RSS-12 for Rhea.

Table RSS-11. Mass estimation results for the Saturn icy satellites encountered by Cassini.

Saturn Icy Satellite	Estimated GM (km^3/s^s)	Solution Rank	Estimation of Cassini SV	Estimation of Satellite SV	Use of Optical Navigation Images	Tropospheric Calibrations[1]
Phoebe	0.5517 ±0.0007	13	Yes	Yes	Yes[2]	TSAC
Iapetus	120.2064 ±0.0631	7	Yes	No[3]	No	TSAC
Hyperion	0.375 ±0.003	13	Yes	Yes	No	TSAC

[1] AMC = Advanced Media Calibration, TSAC = Tracking System Analytical Calibrations.

[2] The use of optical navigation data for Phoebe's flyby helped constraining the relative distance between the spacecraft and the satellite.

[3] The ODP version used for Iapetus data analysis did not possess the capability to estimate and update the planetary satellite ephemerides as part of the orbit determination procedure.

Table RSS-12. Estimated values and 1-σ formal uncertainties of Rhea's quadrupole gravity unnormalized coefficients for the Cassini Radio Science Team solution [Tortora et al. 2016], compared to the results published in MacKenzie et al. [2008] and Anderson and Schubert [2010]. MacKenzie et al. [2008] did not provide the correlation between J_2 and C_{22}, a zero value was assumed. Anderson and Schubert [2010] solution was obtained by constraining the J_2/C_{22} ratio to the hydrostatic value 10/3. A priori values and uncertainties used by RSS are also shown in the first column.

	Unit	(a priori)	RSS Team	(MacKenzie et al. 2008)	(Anderson and Schubert 2010)
J_2	(× 10^6)	930 ±600	946.0 ±13.9	931.0 ±12.0	892.0 ±1.6
C_{21}	(× 10^6)	0 ±300	−19.9 ±11.0	0 ±0.0	0 ±0.0

S_{22}	(× 10^6)	0 ±250	−15.3 ±5.0	3.8 ±3.8	0 ±0.0
J_2/C_{22}		3.9 ±4.8	3.91 ±0.10	3.92 ±0.9	3.33 ±0.0
corr J_2-C_{22}		0.0	−0.34	0.0 (N/A)	1.00

The results obtained by the Cassini Radio Science team, summarized in Tables RSS-11 and RSS-12, represent a major improvement in the knowledge of the Saturn icy satellite gravitational parameters, with respect to the pre-Cassini published results [Campbell and Anderson 1989; Jacobson 2004]. These more accurate results, along with the satellite geometrical information coming from the Cassini Imaging team, were used by the Cassini Radio Science team to build interior models and allow their geophysical interpretation for some of the encountered icy satellites.

Open questions

- How close to hydrostatic equilibrium are the icy satellites? What does this say about their internal structure and geophysical history?

Ring Science

During a ring occultation observation, Cassini transmits three coherent sinusoidal signals simultaneously through the rings. They are generated from the common onboard USO, allowing measurement of their amplitude, frequency, and phase, as well as their relative phases.

As a transmitted signal passes through the rings, the ring material perturbs it. Two signal components can be identified in the measured spectrum of the perturbed signal. The first is the direct signal, a narrow spectral line that is the remnant of the coherent incident sinusoid after being attenuated and phase shifted by ring material. The time histories of estimated average power and phase change of the direct signal provide a measured extinction and phase shift profile. The extinction is characterized in terms of an optical depth and, with the help of a reconstructed spacecraft trajectory, is used to compute an optical depth versus radius profile of the ring system as a function of wavelength. The initial profile is diffraction-limited. Accurate measurement of the signal phase allows reconstruction of the profile to remove diffraction effects [Marouf et al. 1986].

The second component is the near-forward scattered signal, a frequency-broadened signal that originates from incoherent superposition of the signals scattered by ring particles located within the intersection of the main-lobe of the Cassini high-gain antenna and the rings plane (antenna footprint). The Doppler shift caused by the relative motion of the spacecraft, ring particles, and ground station broadens the spectrum of this signal component. The time history of the scattered signal spectra can be used to determine the size distribution of large (> 1 meter) particles as well as other physical properties [Marouf et al. 1983; Zebker et al. 1985].

RSS ring occultations during the Cassini Prime Mission

Twenty-four one-sided radio occultations of Saturn's rings were observed during the Cassini Prime Mission (Table RSS-13), with additional occultations observed through the Grand Finale orbits. The spacecraft trajectory was chosen so that the path of the radio signals transmitted from Cassini to an observing ground receiving station would be interrupted by the ring system.

The Prime Mission occultation observations sampled a broad range of ring-opening angles, *B*. In particular, a set from Revs 7 to 14 of mostly diametric occultations captured relatively large angles, 19.5–23.5°, allowing detailed profiling of the optically thick ring B for the first time. Another set from Revs 53–67 of mostly chord occultations sampled small ring opening angles ~6-10°. The limited intermediate range of angles, 14–15°, was sampled by occultations from Revs 28, 44, and 46. These 24 occultation cuts also sampled a broad range of ring longitudes both inertial and Earth-relative.

Table RSS-13. RSS Ring Occultations Completed During Cassini Prime Mission.

Occ #	YYYY-DOY[1]	Cassini Rev #	Ingress/Egress/Chord	B (deg)[2]

Radial structure in the rings

A major objective of the RSS ring occultation experiments was to determine highly accurate orbits of the rings and to investigate the dynamics and kinematics of ring and gap edges. This work was carried out in collaboration with the Visual and Infrared Imaging Spectrometer (VIMS) and Ultraviolet Imaging Spectrograph (UVIS) teams, in order to combine the full set of occultation data obtained from Cassini instruments. A series of four major papers summarized the results of this joint effort: the edge of Saturn's B-ring [Nicholson et al. 2014a], the C-ring [Nicholson et al. 2014b], the Cassini Division [French et al. 2016], and a determination of the absolute radius scale and pole direction of Saturn [French et al. 2017]. Representative examples of the results from these papers are shown in Figure RSS-15 and Figure RSS-16.

Figure RSS-15 shows the broad influence of Titan's 1:0 inner Lindblad resonance (ILR) over the inner C-ring—from Nicholson et al. [2014b]. Figure RSS-16 shows the structure of the inner C-ring—from Nicholson et al. [2015b]—from the RSS Rev 007 occultation.

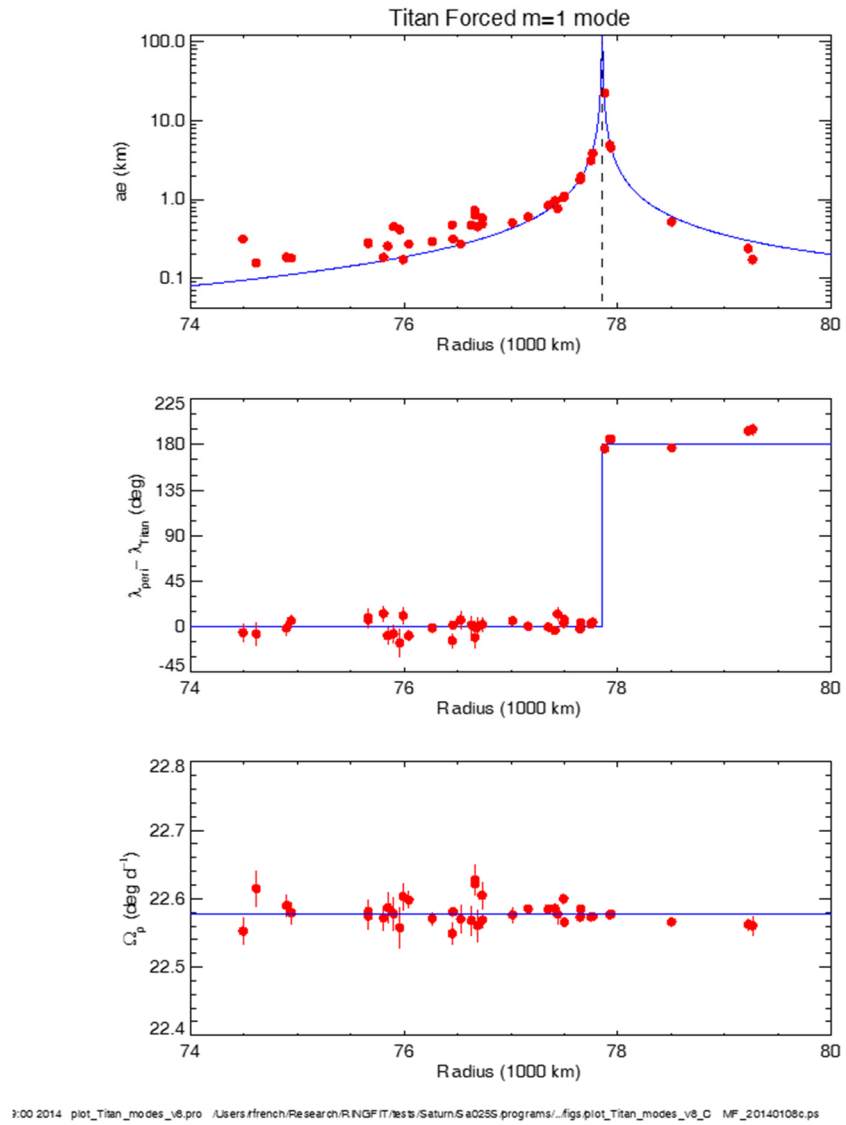

Figure RSS-15. Fitted amplitudes, phases, and pattern speeds versus radius for perturbations induced at a distance by the strong Titan 1:0 ILR. *Upper panel*: curve shows the predicted amplitude, based on a simple test-particle model. *Middle panel*: shows the phase of the perturbation relative to Titan. Note: the orientation changes by 180 from inside to outside the resonant radius, in accord with the same model. *Lower panel*: shows the best-fitting pattern speed compared to Titan's mean motion of 22:577 deg/day. Figure from Nicholson et al. [2014b].

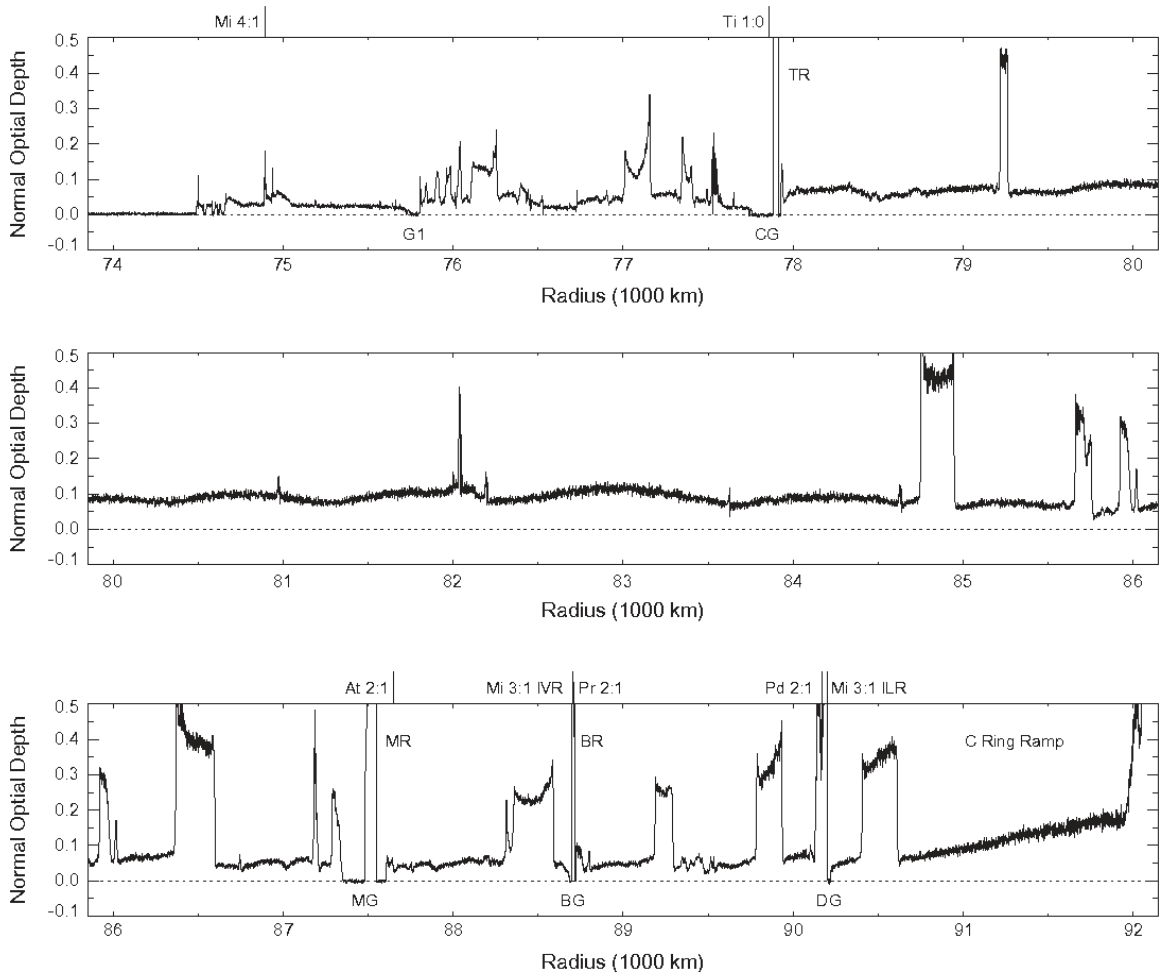

Figure RSS-16. An optical depth profile of the C-ring, derived from the Cassini radio occultation on Rev 7. Abbreviations refer to the Titan ringlet (TR) and Colombo gap (CG), the Maxwell gap and ringlet (MG, MR), the Bond gap and ringlet (BG, BR), and Dawes gap (DG). Tick marks across the top of the plot indicate the locations of significant satellite resonances with Ti = Titan, Mi = Mimas, At = Atlas, Pr = Prometheus, and Pd = Pandora.

From nearly edge-on occultation observations of the C-ring later in the mission, RSS measurements revealed a conspicuous periodic beating pattern between two km-scale waves (Figure RSS-17). From spectral measurements of the power spectrum of the waves and direct model fits, the observations can be interpreted as 10-meter scale vertical corrugations in the C-ring with horizontal wavelengths of order 1 km, increasingly tightly wound as one approaches Saturn (Figure RSS-18). This hints at the possibility that two ancient impacts in the 1300s tilted Saturn's rings—detailed analysis remains to be completed for this provocative possibility.

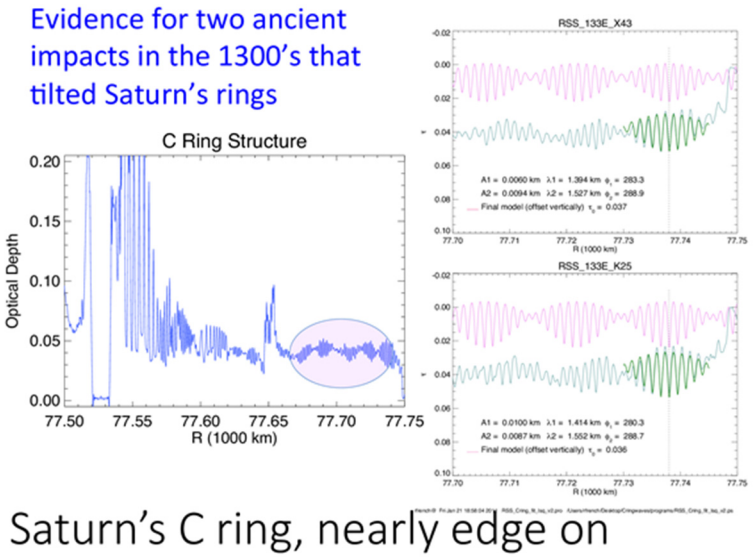

Figure RSS-17. Optical depth profile of the inner C-ring from a nearly edge-on RSS ring occultation.

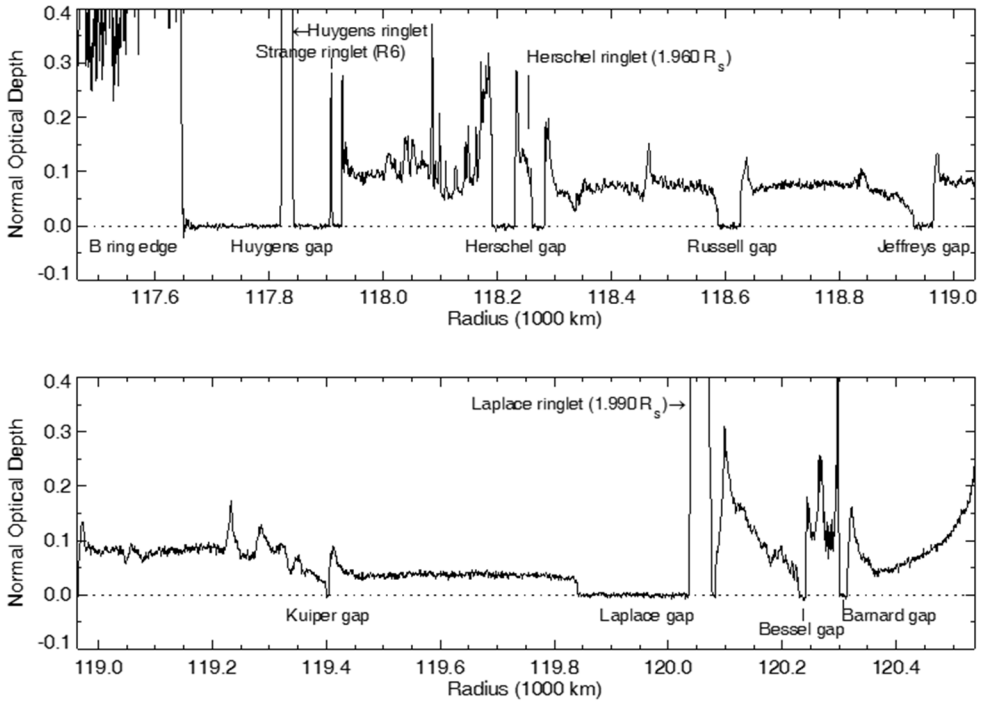

Figure RSS-18. Prominent ringlets and gaps in the Cassini Division shown in an optical depth profile from the Cassini RSS egress occultation on Rev 7. Figure from French et al. [2016].

Among the interesting results found from the analysis of the Cassini Division occultation data is evidence of anomalous precession rates for noncircular features, as shown in Figure RSS-19 from French et al. [2016].

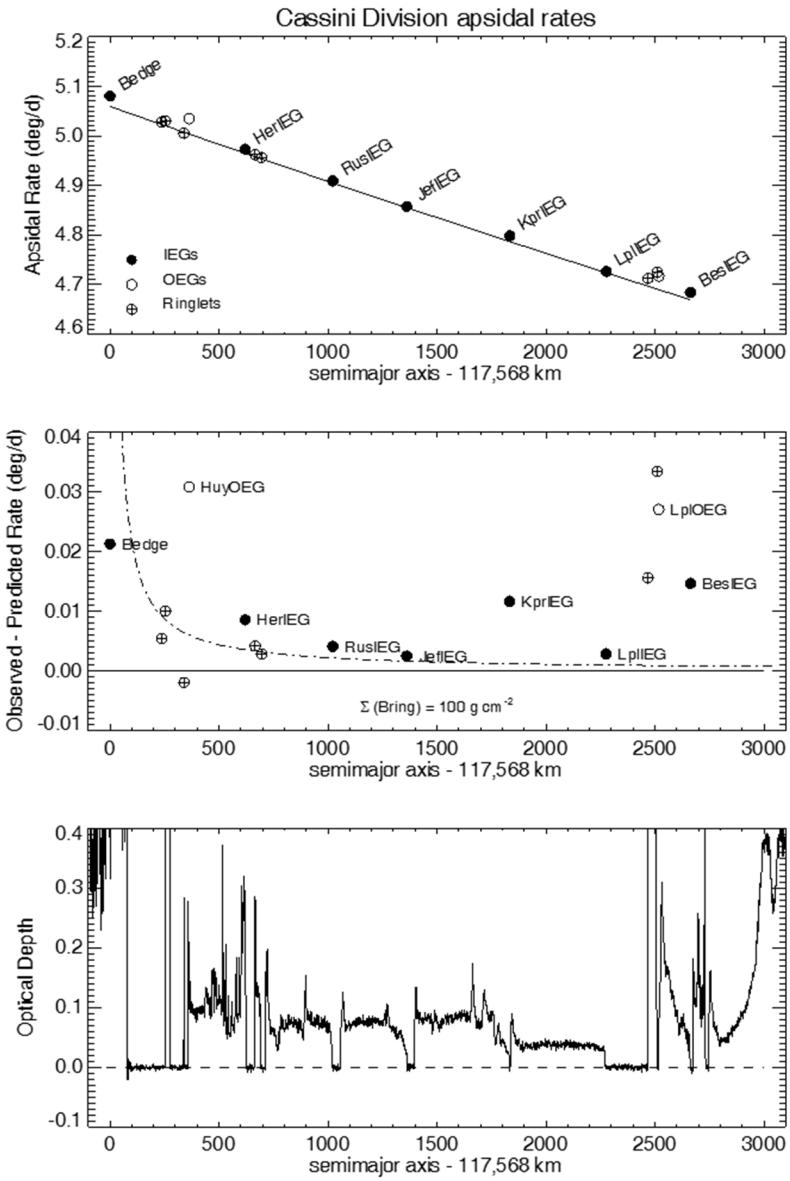

Figure RSS-19. Results found from the analysis of the Cassini Division occultation data *Upper panel*: fitted apsidal precession rates versus mean radius for eccentric features. Note: the quasi-regular sequence in the precession rates for the gap inner edges. The solid line shows the predicted precession rates, calculated from Saturn's zonal gravity coefficients. *Middle panel*: The differences between the fitted and calculated precession rates in the upper panel, using the same symbols. The dot-dashed curve shows the contribution to the apsidal precession rates from the nearby B-ring, assuming a uniform surface mass density of 100 g cm^{-2}. *Lower panel*: Optical depth profile, for context. Figure from French et al. [2016a].

Additional targeted studies of individual ring features were also conducted by the RSS team, including the identification of an m = 2 Saturn-driven density wave in the Maxwell Ringlet [French et al. 2016b]. Figure RSS-20 shows the results of a simulation of the strongly nonlinear density wave embedded in a highly eccentric ringlet.

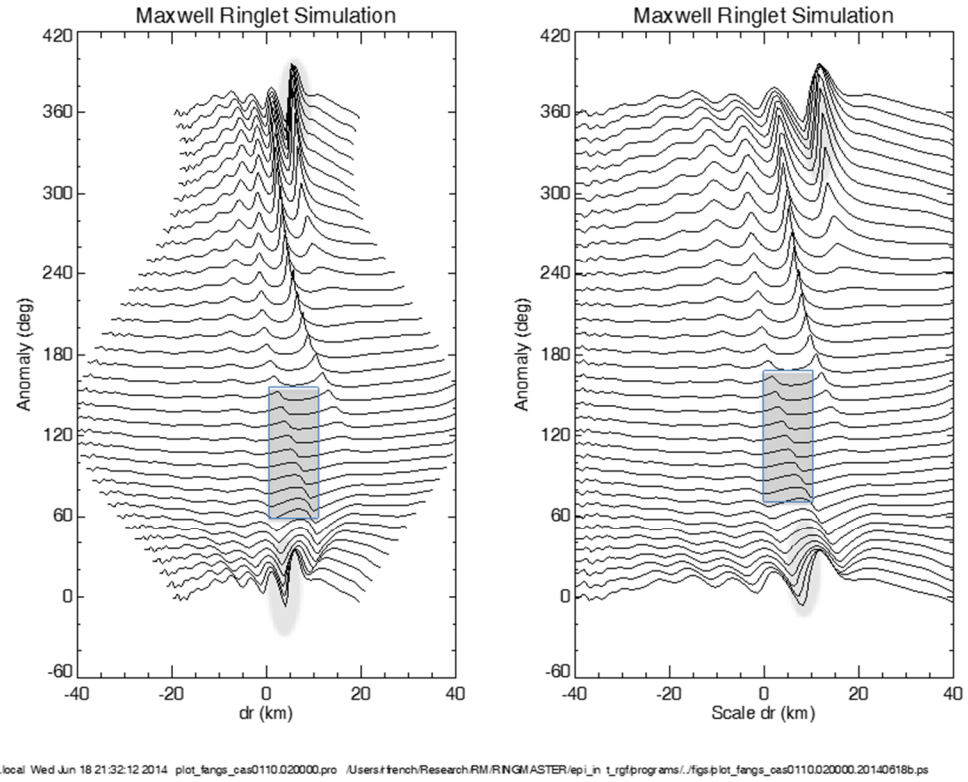

Figure RSS-20. Simulation of non-linear density wave embedded in the eccentric Maxwell Ringlet.

In a recent study of Saturn's F-ring [Cuzzi et al. 2018], RSS F-ring observations, such as those shown in Figure RSS-21, were used to provide evidence for an incomplete core of the F-ring, with arcs of material confined by an unusual resonance with Prometheus.

Density waves in Saturn's rings

Saturn's rings are replete with density waves, and the RSS ring occultations are a rich resource for investigating their properties. Rappaport et al. [2009] developed a novel procedure to analyze nonlinear density waves using multiple occultations, with the goal of determining the underlying unperturbed optical depth of the material in the wave region, and other properties of dynamical interest (Figure RSS-22).

A comparison of density wave profiles observed from RSS, VIMS, and UVIS (Figure RSS-23) shows the exquisite quality of all three occultation techniques.

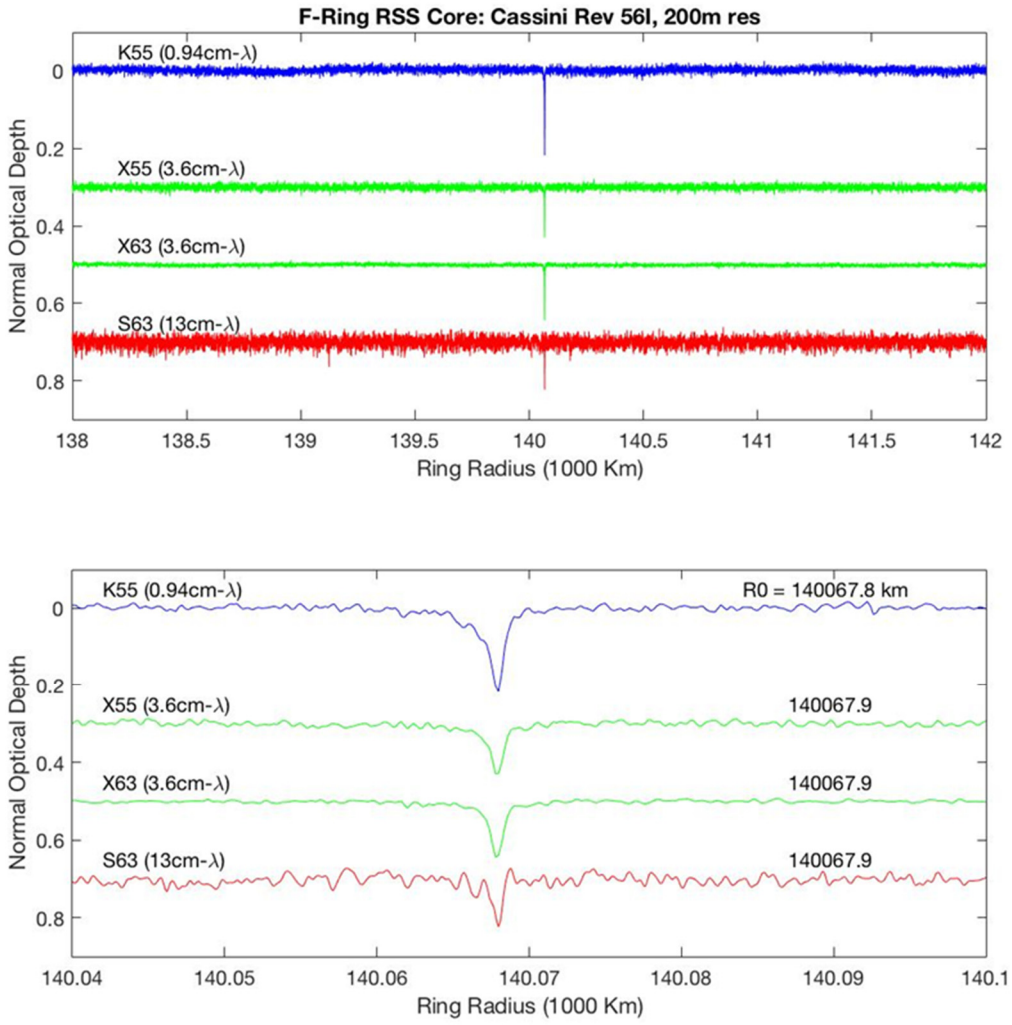

Figure RSS-21. Example Cassini RSS F-ring core detection (ingress occultation on Rev 54, December 19, 2007). The core was detectable in the 0.94, 3.6, and 13 cm-wavelength measurements (Ka-band, X-band, and S-band, respectively; blue, green, and red lines). The measurements were acquired by two of the NASA DSN stations at the Madrid, Spain, complex. DSS-63, a 70-m station, acquired X-band and S-band; DSS-55, a 34-m station, acquired X-band and Ka-band, hence, the four profiles in each panel. The measurements were reconstructed to remove diffraction effects, yielding 200 m radial resolution optical depth profiles. The upper panel shows the profiles over a broad 4000 km wide region outside the outer edge of the A-ring, primarily to provide a free-space baseline for the experiment. A single feature of optical depth large compared with the baseline noise fluctuations is evident in all three bands at ring radius of about 140,100 km. The stretched radius scale of the lower panel (60 km wide) reveals a single feature about 900 m wide of wavelength-dependent peak normal optical depth < 0.2. The narrow RSS F-ring core was detectable in 23 out of 66 ingress or egress Cassini RSS ring occultations completed between May 2005 and August 2013 (~35%). The S-band core was not detectable in all 23.

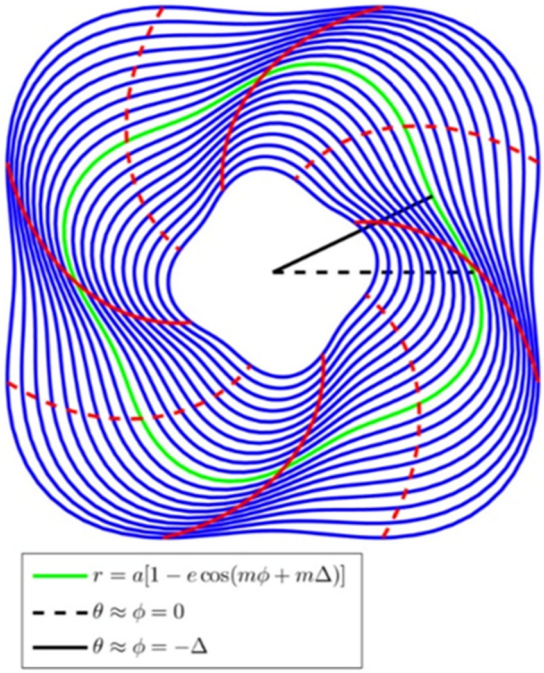

Fig. 1. Streamlines of a 4-lobe ($m = 4$) density wave, such as Mimas 5:3. The lag angle Δ provides the relative shift in angle of one streamline to the next. The loci of constant profile phase ψ corresponding to the density maxima ($\psi = 2\pi n$ with $n = 1$ to 5, solid line) and minima ($\psi = \pi$ modulo 2π, dashed line) are also shown to illustrate the geometrical meaning of ψ. A streamline has been singled out, to show the phase angle Δ.

Figure RSS-23. Occultation profiles of the Janus/Epimetheus 2:1 density wave in the B1 region. The resonance locations for Janus and Epimetheus shift when the satellites perform their horseshoe orbit swap every four years and are between 96,210 and 96,250 km. Figure from Colwell et al. [2009].

Particle size distribution

The three-wavelength capability of the RSS observations provides the opportunity to measure the wavelength dependence of the ring optical depth, which can be related to the ring particle size distribution using scattering theory. Figure RSS-24 shows an example of the differential extinction over eight different ring features [Cuzzi et al. 2009]. Figure RSS-25 shows the optical depth contrasts at multiple wavelengths, and the inferred minimum and maximum particle sizes, based on an analysis of RSS occultation data [Cuzzi et al. 2009].

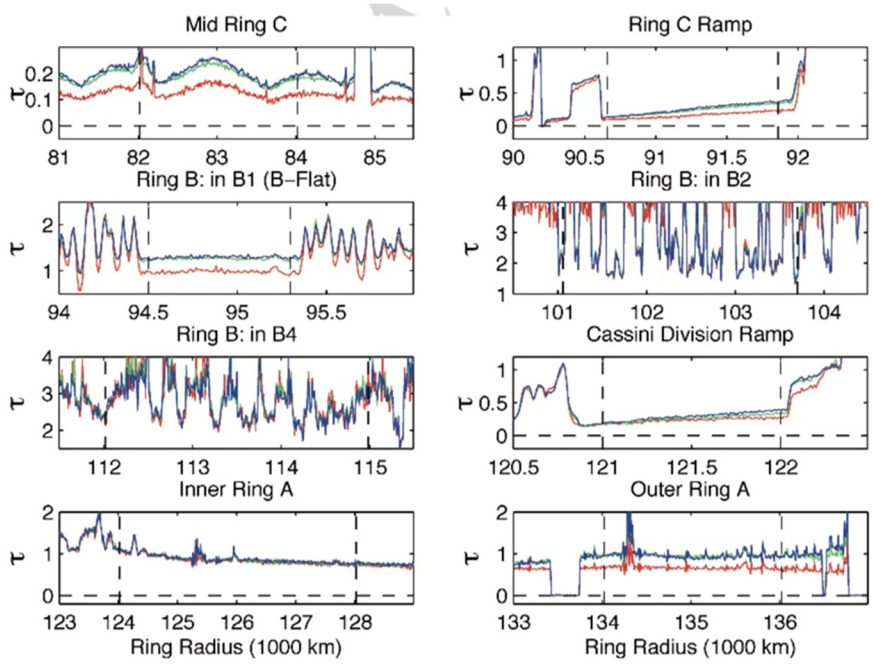

Figure RSS-24. Three-wavelength RSS optical depth profiles of eight ring features identified for examination of the constraints imposed by observed interesting differential extinction, or lack thereof, on parameters of a power-law size distribution model. Figure from Cuzzi et al. [2009].

Periodic microstructure in Saturn's rings A and B

Radio occultation of Saturn's rings by the Cassini spacecraft on May 3, 2005, revealed several remarkable phenomena in rings A and B. In limited regions of the rings, the observations indicate the presence of fine-scale structure characterized by periodic variations in optical depth of period 100–250 meters, which we refer to as periodic microstructure (PM). Our discovery of these structures [Thomson et al. 2006] is based on observation of diffraction effects in 0.94 cm and 3.6 cm wavelength coherent sinusoidal signals transmitted from Cassini through the rings, and received at the ground stations of the DSN. Figure RSS-26 shows the geometry of the ring occultation experiment used to determine the ring microstructure, seen in the spectra illustrated in Figure RSS-27.

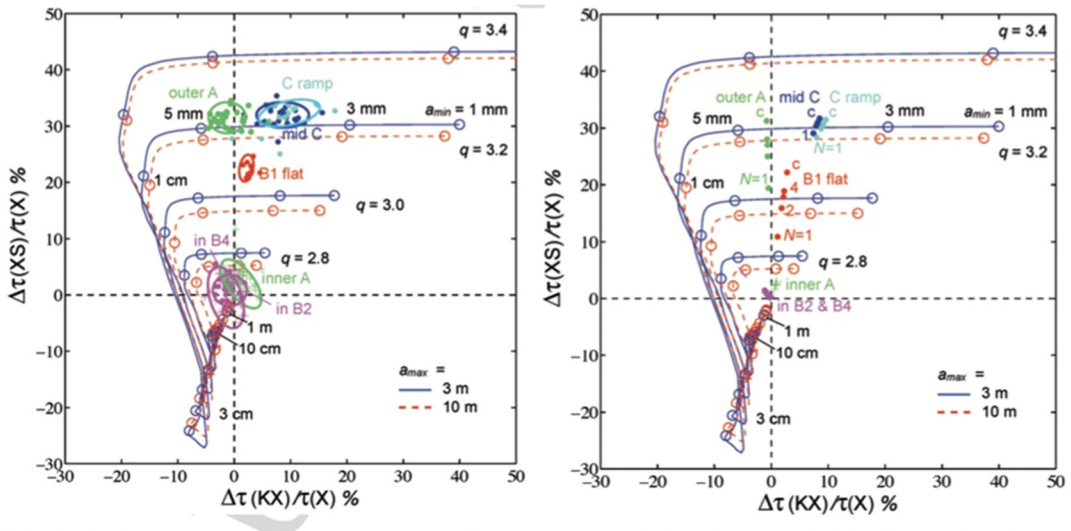

Fig. 15.3 (*Left*) Comparison of the measured X-S (*vertical axis*) and Ka-X (*horizontal axis*) differential optical depth with predictions of a power-law size distribution model of the indicated parameters. For a given power-law index q, the predicted differentials are plotted using the minimum radius a_{min} as a parameter. Points $a_{min} = 0.1, 0.3, 0.5, 1, 3, 10$, and 100 cm are as identified. For each case, dependence on a_{max} is illustrated for the two cases $a_{axn} = 3$ (*solid blue*) and 10 m (*dashed red*). The seven clusters are the values measured for seven of the ring features identified in Figure 3, as labeled. Individual points within each cluster are 80 km resolution samples. The comparison is based on the assumption of a classical (many-particle-thick) ring model. (*right*) Same figure, except that the measured values are scaled based on the thin layers ring model. The five points for each feature correspond to number of layers fours N = 1 to 4 and the classical model result 'c', as labeled. Each point is an average over the radial width of the corresponding ring feature (Marouf et al. 2009)

Figure RSS-25. Optical depth contrasts at multiple wavelengths and the inferred minimum and maximum particle sizes. Figure from Cuzzi et al. [2009].

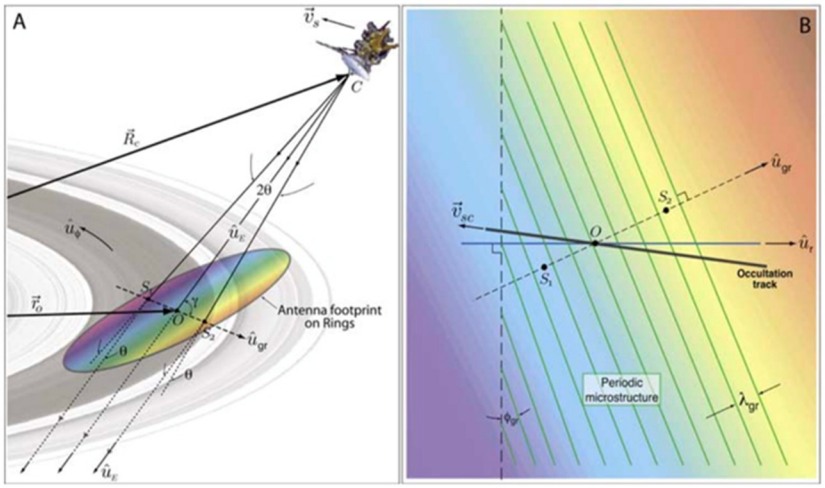

Figure 1. Geometry of the ring occultation experiment. (a) Line-of-sight ray linking Cassini and Earth is directed along $\hat{u}_E$ and pierces the ring plane at point **O**; $\hat{u}_{gr}$ is in the plane of the rings, and defines the orientation of the periodic structure. Points S_1 and S_2 correspond to locations in the ring plane where first-order diffraction grating lobes of the structure originate and propagate along $\hat{u}_E$ to the Earth-based receiver. The grating lobes are directed at angle $\pm\theta$ relative to $\hat{u}_E$. All angles shown are in the plane defined by $\hat{u}_E$ and $\hat{u}_{gr}$. Color within the antenna footprint represents variations in Doppler shift of signals scattered to Earth by the rings; footprint size is exaggerated for clarity. (b) View is of the ring plane. Signals diffracted to Earth from S_1 and S_2 are Doppler-shifted by f_{D1} and f_{D2} relative to the signal along the line-of-sight, represented by the colors at S_1 and S_2. $\hat{u}_r$ is a radial unit vector pointing from the center of Saturn to **O**, and $\vec{v}_{sc}$ is the projection in the ring plane of Cassini velocity $\vec{v}_c$.

Figure RSS-26. The geometry of the ring occultation experiment used to determine the ring microstructure. Figure from Thomson et al. [2006].

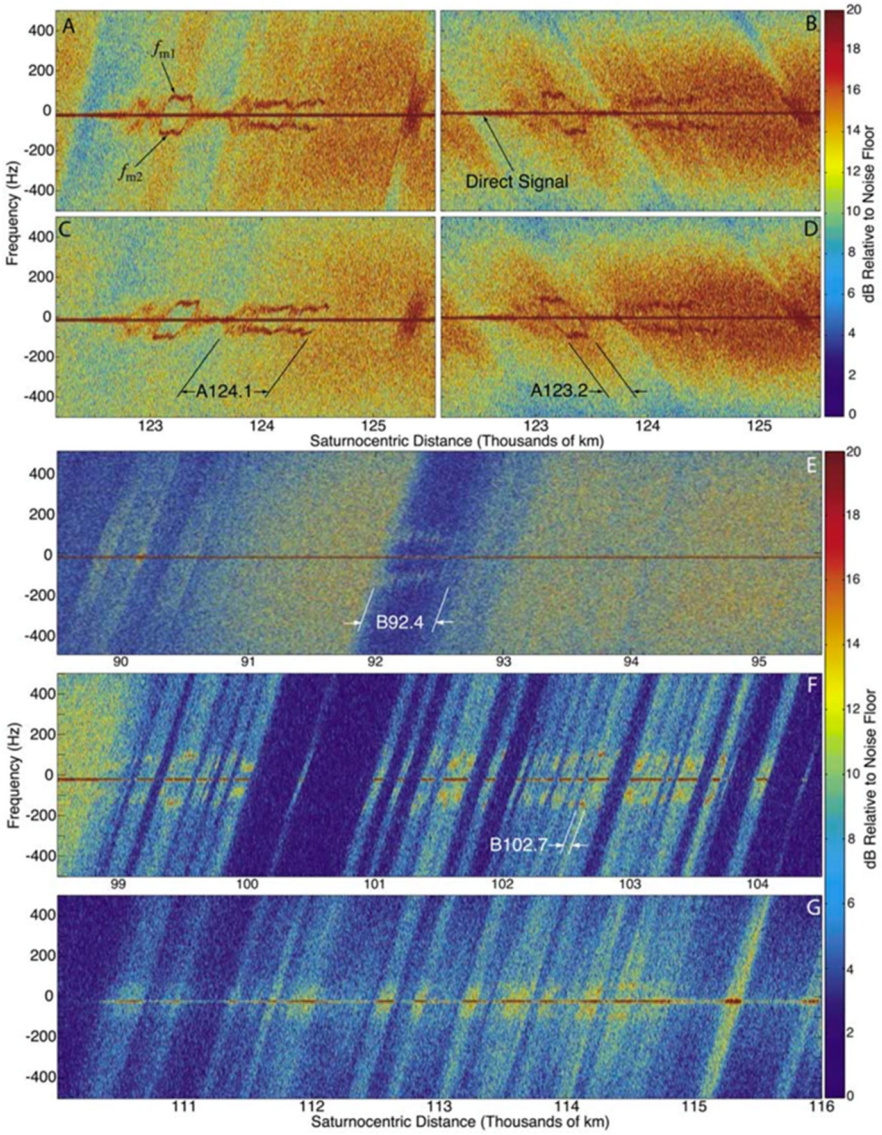

Figure 2. Spectrograms of 3.6 cm-λ signal observed during May 3, 2005, ring occultation (a, e, f, g) ingress and (b) egress; and on August 2, 2005, occultation (c) ingress and (d) egress. The direct signal is the horizontal brown line near the center of each panel. The diffraction signature of periodic microstructure appears as roughly parallel horizontal lines displaced ±70–100 Hz from the direct signal in Ring A (Figures 2a–2d) and ±50–120 Hz Ring B (Figures 2e–2g). The signature is clearly evident for the two indicated features in inner Ring A, over the roughly 500 km inner part of region B1 (Figure 2e) and over most of the detectable subregions of the ≈5000 km-wide region B2 (Figure 2f). It is more muted over most of region B4 (Figure 2g). Other evident broadband features correspond to energy forward scattered by the background wake structure in the rings.

Figure RSS-27. The geometry of the ring occultation experiment seen in the spectra. Figure from Thomson et al. [2006].

Open questions

After more than a decade of ring observations at Saturn, fundamental questions remain about the origin of ring structure and confinement mechanisms for sharp-edged ring features.

- What confines the Titan and Maxwell ringlets?
- Is it a coincidence that the Maxwell ringlet harbors a density wave?
- Did the driving resonance behind the density wave contribute in some fashion to the formation of the ringlet?
- Did the Titan ringlet form in response to its near-resonance with Titan itself?
- Where did the C-ring plateaus originate?
- What drives the host of normal modes detected in sharp ring and edge gaps?
- Is there detectable radial evolution of ring features on the time scale of decades and centuries?

RSS Non-Saturn Science Results

Cruise Science

Gravitational wave experiment

Introduction[1]

One of the cruise-phase Cassini science investigations was to use Cassini's precision Doppler tracking capability to search for GWs. The idea [Estabrook and Wahlquist 1975] is that Earth and Cassini act as electromagnetically-tracked free test masses. The Earth-spacecraft relative velocity is continuously measured via Doppler shifts of microwave links referenced to a ground-based precision frequency standard. Such as system can be used to search for low-frequency (~10^{-6} to 10^{-1} Hz) GWs.[2]

Signal response

Figure RSS-28 shows the effect of a burst GW incident on the Earth-Cassini system. The Doppler responds to a projection of the time-dependent wave metric, in general producing a three-pulse

---

[1] *Much of this report, including the figures, comes from Armstrong, et al. [2003], and Armstrong [2006].*

[2] *Gravitational wave bands conventionally divide based on detector technology [Thorne 1987]: extremely-low-frequency (~10^{-18} to ~10^{-15} Hz) search programs are based on mapping the intensity and polarization of the cosmic microwave background; very-low frequency observations (~10^{-9} to ~10^{-6} Hz) use pulsar timing observations; low-frequency (~10^{-6} to ~10^{-1} Hz) observations currently use Doppler tracking of spacecraft (in the 2030s, a laser interferometer in space); high-frequency (~10 to ~10^{3} Hz) observations involve ground-based laser interferometers. The ground-based LIGO detectors made the first detection of GWs in 2015, for which the 2017 Nobel Prize in physics was awarded.*

response to a pulse of incident gravitational radiation: one event due to buffeting of the Earth by the GW, one event due to buffeting of the spacecraft by the GW, and a third event in which the original Earth buffeting is transponded a two-way light time later. The amplitudes and locations of the pulses depend on the arrival direction of the GW with respect to the Earth-spacecraft line, the two-way light time, and the wave's polarization state [Estabrook and Wahlquist 1975]. Technical details of the detector, including polarization response, are in references in Armstrong [2006].

The Cassini experiment is distinguished by its 5-link radio system. This system (X-up, X-down coherent with X-up, Ka-down coherent with X-up, Ka-up, Ka-down coherent with Ka-up) allowed essentially perfect rejection of plasma scintillation noise, a dominant noise source for earlier-generation spacecraft observations—for example, Tortora et al. [2004]; Asmar et al. [2005]; Mariotti and Tortora [2013]. Cassini observations also benefitted from an Advanced Media Calibration unit—water vapor radiometer and microwave temperature profiler—which allowed measurement and removal of a substantial fraction of propagation noise from the neutral atmosphere [Keihm et al. 2004]. Discussion of the noise budget is in Bertotti et al. [2003]; Asmar et al. [2005]; and Armstrong [2006].

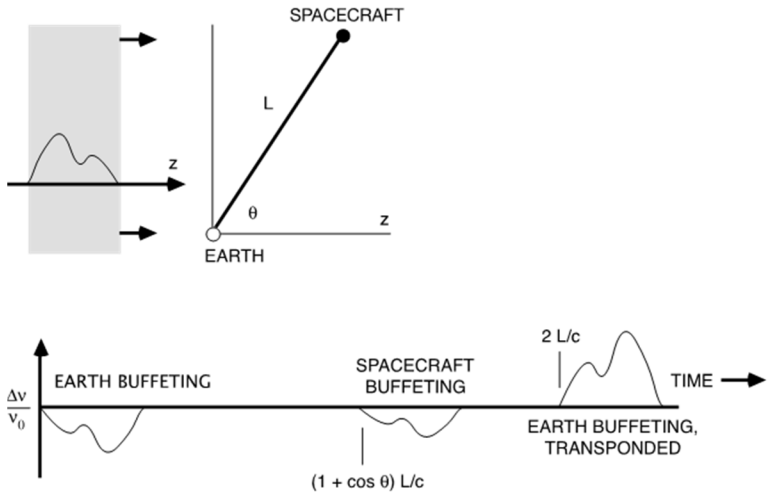

Figure RSS-28. Schematic response of two-way Doppler tracking to a GW [Estabrook and Wahlquist 1975]. The Doppler exhibits three pulses having amplitudes and relative locations which depend on the GW arrival direction, the two-way light time, and the wave's strain amplitude and polarization state. The sum of the three pulses is zero, so the pulses overlap and partially cancel when the characteristic time of the GW pulse is comparable to or larger than the light time between the Earth and spacecraft.

Three GW observing campaigns were done during Cassini cruise: (i) November 25, 2001 to January 4, 2002; (ii) December 5, 2002 to January 14, 2003; and (iii) November 10, 2003 to November 28, 2003—the last being done with X-up and X-down only due to the failure of the Cassini Ka-band translator.

The spectrum of the propagation-corrected data from the first observing campaign is shown in Figure RSS-29. The associated 1000-second Allan deviation (fractional frequency variation), for

the full 40 days of the observation, is 6×10^{-15}. The velocity noise is thus about 1 μm/sec in a 1000-second integration. These are the most sensitive deep space Doppler measurements ever made.

Sensitivity is conventionally stated as the sky- and polarization-averaged sinusoidal signal strength required to achieve a given signal to noise ratio in a specified integration time, as a function of Fourier frequency. This is shown in Figure RSS-30 for a signal-to-noise ratio of unity in a 40-day integration. This ~10^{-16} value (in the ~decade Fourier range of best sensitivity) is also the SNR = 1 sensitivity limit for sinusoidal GWs or linear chirps.

For GW signals having more complicated Fourier composition the sensitivity is lower and in general depends on waveform shape and angle-of-arrival of the GW relative to the Earth-Cassini line. Figure RSS-31 shows the characteristic strain sensitivity for generic burst waves (bandwidth = center frequency) averaged over the sky and polarization states.

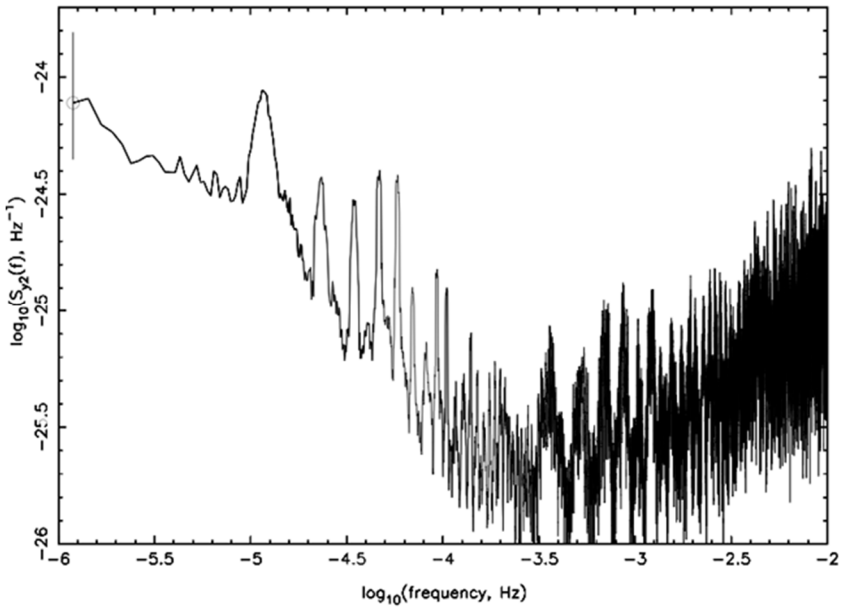

Figure RSS-29. Spectrum of two-way Doppler for the 2001–2002 Cassini observations. The associated 1000s Allan deviation is 6×10^{-15}, corresponding to 1 μm/sec velocity noise on a 1000s integration time [Armstrong et al. 2003].

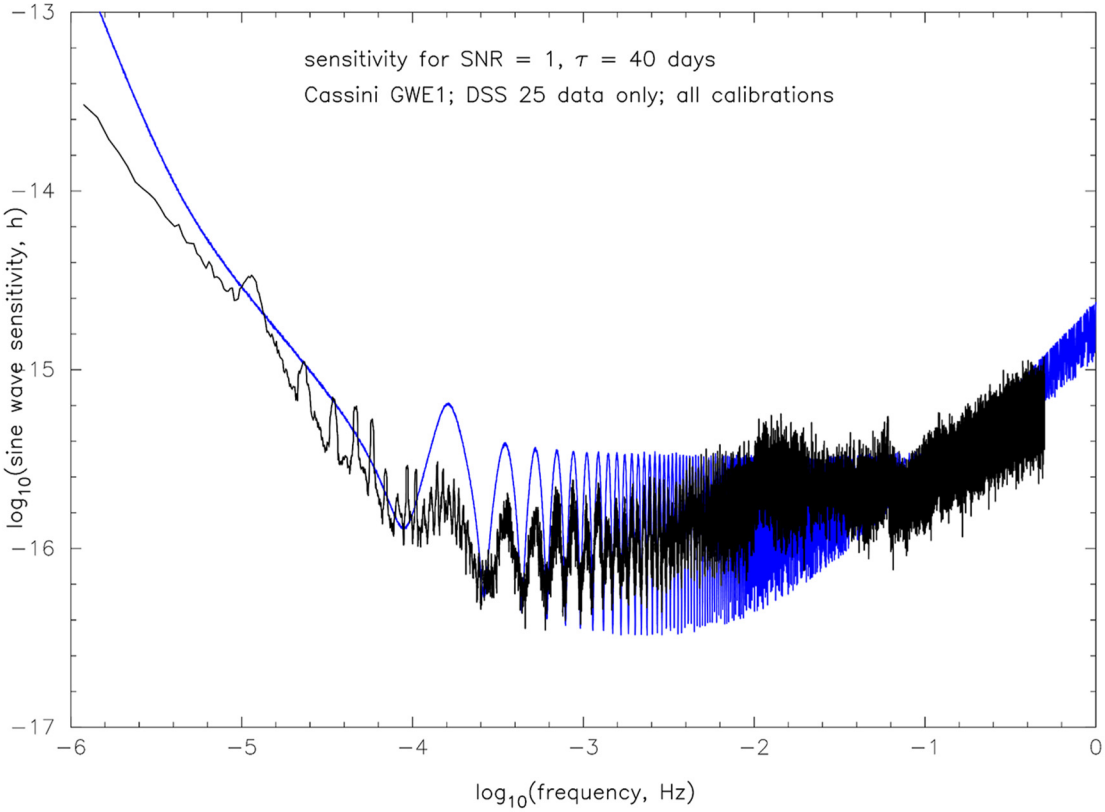

Figure RSS-30. Sensitivity of the Cassini 2001–2002 gravitational wave observations, expressed as the equivalent sinusoidal strain sensitivity required to produce SNR = 1 for a randomly polarized isotropic background, as a function of Fourier frequency. This reflects both the levels, spectral shapes, and transfer functions of the instrumental noises and the GW signal transfer function. Black curve: sensitivity computed using smoothed version of observed Doppler spectrum. Blue curve: sensitivity computed from pre-observation predicted noise spectrum. Figure from Armstrong [2006].

The Cassini data can also be used to bound the level of a stochastic background of GWs [Armstrong et al. 2003]. This is shown in Figure RSS-32 relative to the density required to gravitationally close the universe. These limits are about three orders of magnitude more stringent than any others from Doppler tracking.

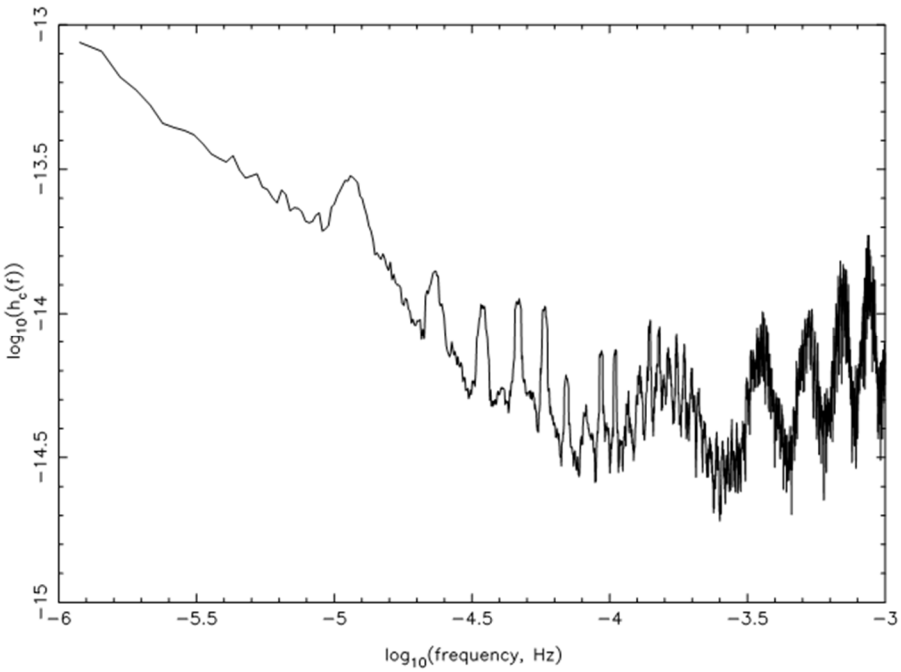

Figure RSS-31. Sensitivity of the Cassini 2001–2002 burst gravitational wave observations, expressed as characteristic strain sensitivity (GW bandwidth = center frequency) averaged over the sky and polarization state. Figure from Armstrong [2006].

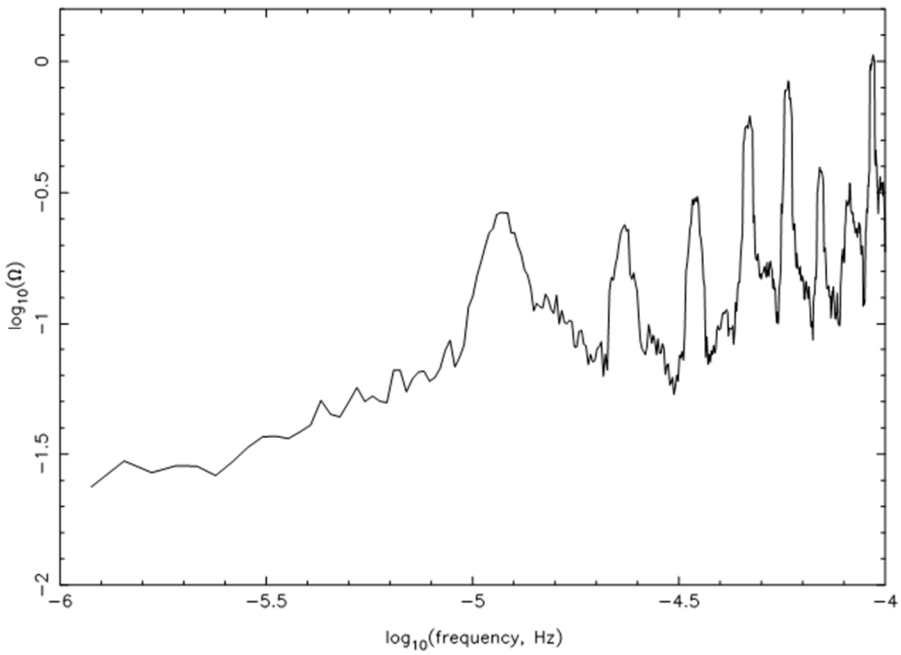

Figure RSS-32. Upper limits to GW energy density (bandwidth = center frequency) divided by the critical density required to close the universe of an isotropic GW background. Figure from Armstrong et al. [2003].

Solar conjunction experiment

INTRODUCTION[3]

In addition to the gravitational wave experiment, another cruise-phase Cassini science investigation was to use Cassini's radiometric data to measure the space components of the Sun's metric tensor. In the parameterized post-Newtonian formalism, this quantity is controlled by a parameter (γ) which is unity in General Relativity but may assume slightly different values in other metric theories of gravity. The measurement of γ with Cassini is based upon a new observable quantity: the frequency shift induced on a radio wave when the spacecraft is near solar conjunction. The calibration of the large frequency fluctuations induced by the solar corona, necessary in order to guarantee the required signal stability, was performed using the novel Cassini radio frequency system, based on a multi-frequency link.

PREVIOUS TESTS AND CASSINI'S EXPERIMENTAL CONFIGURATION

During a SCE, radio-metric data are used to measure the space curvature produced by the Sun. The parametrized post-Newtonian (PPN) parameter γ was estimated by other space-based experiments which allowed to bound the value of γ-1 to less than 0.001 using range measurements to the Viking landers [Reasenberg et al. 1979], an experiment carried out more than 20 years before Cassini's one, and more recently, using Very Long Baseline Interferometry techniques [Eubanks et al. 1997].

The measurement of γ with Cassini is based upon a new observable quantity: the frequency shift induced on a radio wave when the spacecraft is near solar conjunction. For this experiment, the geometry is particularly favorable and the relativistic relative frequency shift is on the order of 10^{-9}. On the other hand, this large Doppler signal is obtained only at small impact parameters, when the radio beam, well inside the solar corona, exhibits large frequency fluctuations. The solar plasma calibration, made possible by the multi-frequency link [Bertotti et al. 1993; Tortora et al. 2003, 2004; Mariotti and Tortora 2013], plays a crucial role in the experiment. In this method, the sky-frequencies in the three bands (X/X, X/Ka, Ka/Ka) are coherently combined to remove the effects of the solar plasma, the major noise source in the Doppler observable. Furthermore, the use of water vapor radiometers and microwave temperature profilers [Resch at al. 2002; Keihm et al. 2004], developed for the Cassini RSE, provides a precise calibration of the frequency shift due to the troposphere. The predicted stability of the radio link, once all media calibrations were applied, was in the order of 10^{-14} at integration times of 1000 s, showing that the Cassini experiment may have provided a measurement of γ to a level between 10^{-5} and 10^{-4}, one or two orders of magnitude better than previous experimental tests.

CASSINI EXPERIMENT

The increase Δt produced by the gravitational field of the Sun (with mass M_S and radius R_S) in the roundtrip light-time between the ground antenna and the spacecraft, respectively, at the distances r_1 and r_2 from the Sun, is [Will 1993]:

$$\Delta t = 2(1+\gamma)\frac{GM_S}{c^3}\ln\left(\frac{4r_1r_2}{b^2}\right), \quad \text{(Eq. 1)}$$

where G is the gravitational constant and b (<< r_1, r_2) the impact parameter. The motion of the spacecraft and Earth produces a change in b and Δt, equivalent to a change in distance, hence to a relative radial velocity. The corresponding fractional frequency $y_{gr} = \Delta v/v$ shift for a two-way radio signal is [Iess et al. 1999]:

$$y_{gr} = \frac{d\Delta t}{dt} = -2(1+\gamma)\frac{GM_S}{c^3 b}\frac{db}{dt} = -(1\times 10^{-5}\ \text{sec})(1+\gamma)\frac{1}{b}\frac{\mathrm{d}b}{\mathrm{d}t}. \quad \text{(Eq. 2)}$$

For a spacecraft much farther away from the Sun than Earth, db/dt is not very different from the Earth's velocity v_E = 30 km/sec. In the Cassini solar conjunction the peak value of y_{gr} is 6×10^{10}. The Cassini experiment, exploiting this new observable [Iess et al. 1999; Bertotti and Giampieri 1992], has been carried out from June 6, 2002 to July 7, 2002, when the spacecraft was on its way to Saturn, around the time of a solar conjunction (Figure RSS-33).

The gravitational signal and the tracking passes which provided useful data [Iess et al. 2003] are shown in Figure RSS-34.

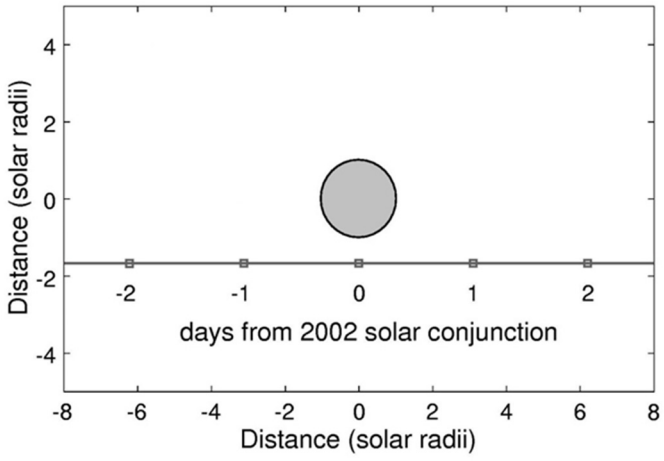

Figure RSS-33. Geometry of the 2002 Cassini solar conjunction. Cassini's motion in the sky relative to the Sun, as a function of days from the 2002 solar conjunction; coordinates are in solar radii. The conjunction, at which the spacecraft (at a geocentric distance of 8.43 AU) Sun and Earth were almost aligned (in this order), occurred on 21 June 2002 with a minimum impact parameter b_{min} = 1.6 R_S, and no occultation.

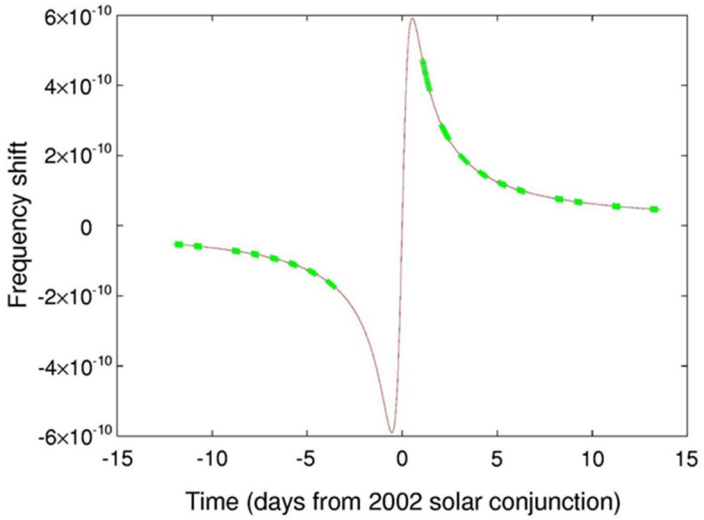

Figure RSS-34. The gravitational signal. The two-way relativistic frequency shift y_{gr} due to the sun and the available 18 passages, each lasting about 8 hours. Unfortunately, no data could be acquired for three days just before conjunction, due to a failure of the ground transmitter; moreover, the tracking data acquired near closest approach were particularly noisy. A much larger plasma noise was detected in some passes after conjunction and was fully removed by the multilink technique. Remarkably, in these days Solar and Heliospheric Observatory (SOHO) observations have shown large coronal mass ejections (CME) traversing the radio beam.

The main reason why the Doppler method has not been applied before is the overwhelming noise contribution due to the solar corona. The Cassini mission has overcome this hindrance with: a) high-frequency carriers in Ka-band, in addition to the X-band for standard operation; and b) a multi-frequency link in which three different phases are measured at the ground station. The resulting measurement errors are four orders of magnitude smaller than the relativistic signal (Eq. 2).

The dynamical model used in the orbital fit of Doppler data is particularly simple, thanks to the large distance from the Sun, the location of the spacecraft in interplanetary space and the lack of unknown gravitational perturbations by solar system bodies. JPL's Orbit Determination Program has been used in the integration of the equations of motion and the orbital solution, based upon planetary ephemerides and ancillary data, such as station location and Earth orientation parameters.

We have used up to 12 free solve-for parameters: a) the six components of the state vector at the start of the experiment; b) the three components of the non-gravitational acceleration due to the RTG in the spacecraft frame; c) the specular and diffuse reflectivity of the high gain antenna, which determine the magnitude (and the direction) of the non-gravitational acceleration due to solar radiation pressure; and d) the relativistic parameter γ. Consider-parameters (quantities not solved-for, but whose uncertainty is taken into account in the solution) include the dry troposphere, the station location, polar motion, and the Earth Love numbers (which intervene in the solid tide model).

Among the five parameters which control the nongravitational acceleration, three (the nonradial components of the thermal thrust from the RTG and one of the two optical coefficients of the high gain antenna) are poorly determined. It is, therefore, appropriate to investigate a solution including

only the other two, namely the radial acceleration due to the RTG and the diffuse reflectivity of the antenna; by so doing, most nongravitational perturbations are accounted for at a level consistent with the accuracy of the tracking data. The value of the other three parameters, the specular reflectivity and the nonradial components of the RTG acceleration, together with their uncertainties, have been taken from a separate fit carried out on the data from the Cassini solar opposition experiment, as mentioned earlier. This is our main orbital fit (see Figure RSS-35), with only nine parameters to be determined. The a priori uncertainty of the parameters which are not estimated, but affect the solution (such as the station geocentric coordinates and those derived from the gravitational wave experiment) has been included in the computation of the covariance matrix.

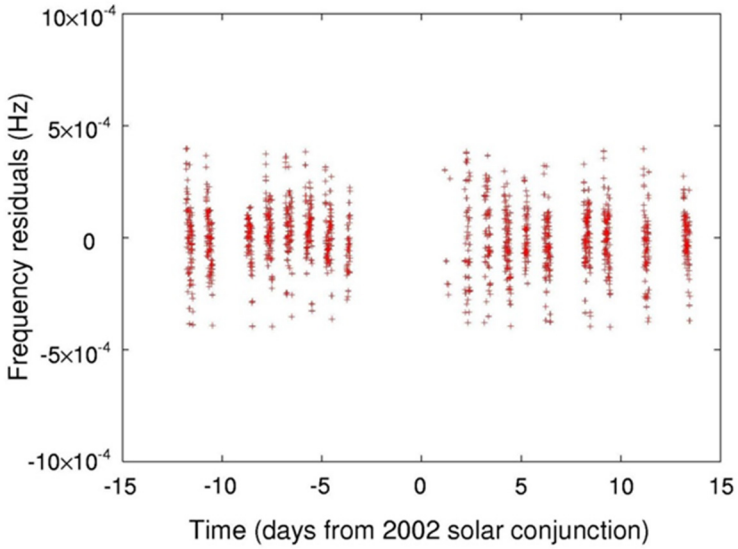

Figure RSS-35. The Doppler residuals. Two-way frequency residuals, relative to an 8.4 GHz carrier, as a function of time (in days from solar conjunction), obtained from the final 9-parameter fit on the calibrated data. The rms value of the 1094 data points (compressed at a 300 s integration time) is 1.2×10^{-4}, Hz corresponding to a one-way range rate of 2.2×10^{-6} m/s; this is an unprecedented accuracy for tracking data at solar conjunction.

Our result [Bertotti et al. 2003] $\gamma = 1 + (2.1 \pm 2.3) \times 10^{-5}$ agrees with Einstein's, with an accuracy ≈ 50 times better than published measurements. While a fundamental force such as gravity must always be investigated as accurately as possible, our result approaches a sensitivity at which, theoretically, deviations from General Relativity are expected.

Conclusions

The question, at what level violations of General Relativity can be expected, does not have a satisfactory answer yet. A long-range scalar field is currently assumed to play a fundamental role in primordial cosmology; although it decays with the expansion of the Universe, its present remnant would entail not only violations of the two main tests of General Relativity, but also a lack of universality of the constants of microphysics, as assumed in the Equivalence Principle [Damour et al. 1994, 2002].

A claim, based upon quasar absorption lines, that the fine structure constant α was weaker in the distant past has been recently made, thereby violating the Equivalence Principle [Murphy 2001a, 2001b, 2001c, 2001d]; if confirmed, and reconciled with other constraints on the variation of fundamental constants [Damour 2003], such finding would be the first serious challenge to Einstein's paradigm. No detailed theory is available about the expected amounts of these violations, but $\gamma - 1$ should be negative and, possibly, in the range 10^{-5}–10^{-7}. Therefore, our result, with an accuracy not far from this range, places an important constraint on this cosmological scenario.

Solar wind

INTRODUCTION

Before the failure of the Ka-band translator, Cassini's five-link radio system (X-up, X-down coherent with X-up; Ka-down coherent with X-up; Ka-up; Ka-down coherent with Ka-up) allowed a decomposition of the Doppler time series into three components: a non-dispersive component, the uplink-path plasma component, and the downlink-path plasma component [Iess et al. 2003; Bertotti et al. 2003; Tortora et al. 2003, 2004]. Having the up- and downlink plasma time series separately allowed the first localization along the line-of-sight and time of plasma turbulence between the ground station and the Cassini spacecraft.

Before the failure of the Ka-band translator, Cassini's five-link radio system … allowed a decomposition of the Doppler time series into three components: a non-dispersive component, the uplink-path plasma component, and the downlink-path plasma component … .

The idea has its origin in noise budget analysis of precision Doppler tracking experiments [Estabrook and Wahlquist 1975; Estabrook 1978; Vessot and Levine 1978] and is illustrated in Figure RSS-36. The upper plot is a space-time diagram, showing the ground station continuously transmitting a signal to Cassini and continuously receiving a signal from the spacecraft. In the two-way mode, the Doppler time series $y_2(t)$ has its phase perturbed by a localized plasma blob at distance x along the line-of-sight as illustrated, giving rise to two events in the two-way tracking time series separated by a time lag depending on the Earth-blob distance: $T_2 - 2\ x/c$, where T_2 is the two-way light time.

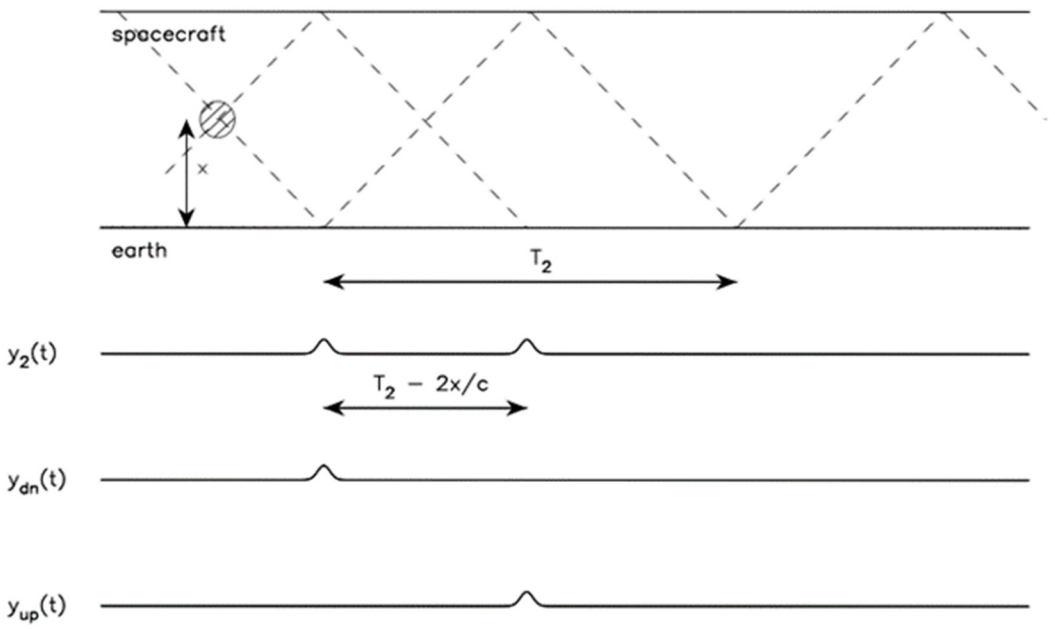

Figure RSS-36. Transfer function of plasma fluctuations to one-way and two-way phase/Doppler scintillation allows localization of plasma blobs along the line-of-sight. Upper plot is a space-time diagram (space vertically, time horizontally). The ground station and the spacecraft are continuously exchanging microwave signals, some of which are shown as dashed lines. If the signals pass through a well-localized plasma blob (indicated by the crosshatched circular area) the phase is perturbed. This perturbation is observed on both the uplink and downlink signals and on the two-way Doppler. The two-way, $y_2(t)$, and the one-way plasma-contribution Doppler time series, $y_{up}(t)$ and $y_{dn}(t)$, are shown in the *lower plot*. The phase perturbation is seen initially on the downlink, and (in the two-way Doppler) latter when the perturbation on the uplink is phase-coherently retransmitted back to the ground. The effect in $y_2(t)$ is two positively-correlated features in the time series, separated in time by $T_2 - 2x/c$, where T_2 is the two-way light time and x is the distance of the blob from the Earth. The one-way up and down Doppler time series detect the blob once each, but also separated by $T_2 - 2x/c$. Cross-correlation or windowed matched filtering between y_{up} and y_{dn} allows an estimate of the time delay thus the location of the blob.

Demonstration with Cassini Data on 2001 DOY 149

As described more completely in Richie-Halford et al. [2009] (from which the discussion and figures here are taken), the proof of concept observations were made with Cassini and DSS25 on 2001 DOY 149 (= 2001 May 29; Sun-Earth-spacecraft angle ≈ 6.6 degrees; $T_2 \approx 6825$ seconds, varying by ≈ 2 seconds over the pass). The full five-link system was used and Figure RSS-37 shows the inferred uplink and downlink plasma scintillation as a function of time. It is usually thought that plasma scintillation arises from distributed scattering along a large fraction of the line of sight. In this case, however, large, similarly-shaped events in the two time series are obvious. The time-offset is indicative of highly localized plasma turbulence in the solar wind on this day. Figure RSS-38 shows the location of this dominant screen in the solar wind as a function of time on DOY 149.

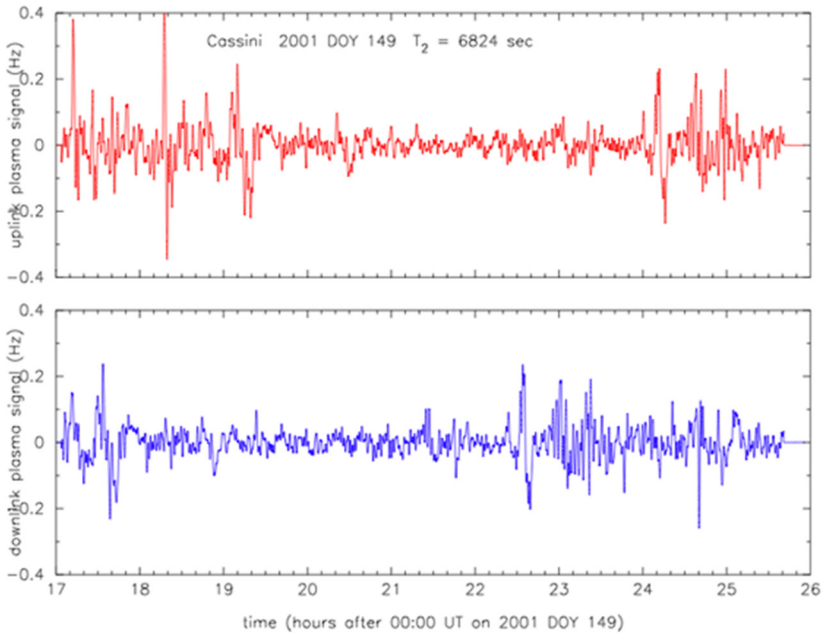

Figure RSS-37. Time series of the plasma contribution to the X-band up- and down links, $y_{up}(t)$ and $y_{dn}(t)$, for DSS25 Cassini track on 2001 DOY 149 = 2001 May 29. The two-way light time T_2 was ≈ 6824 seconds. Several large amplitude features in the downlink time series, for example at about 1730 UT, 2230 UT, 2300 UT, have clear echoes in the uplink time series with time difference ~T_2 − 2∗1.028 AU/c.

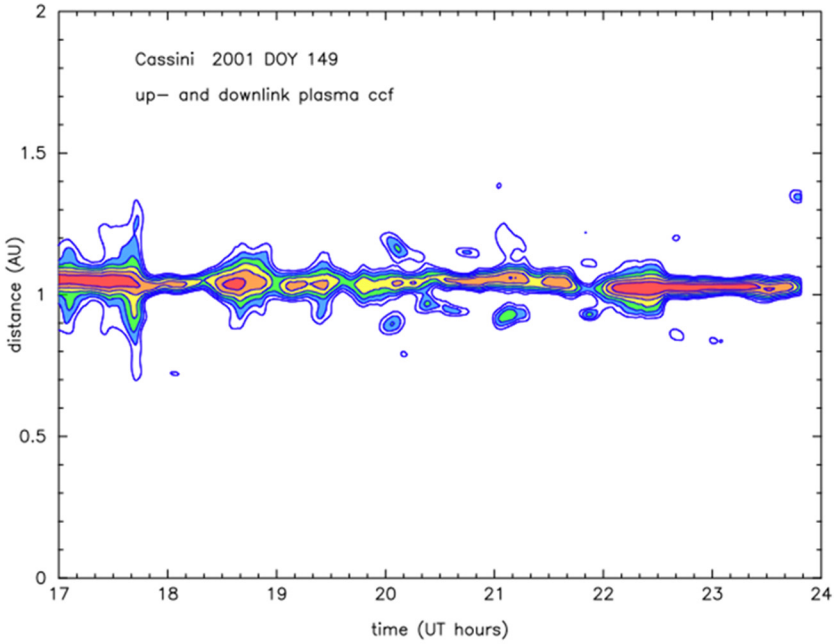

Figure RSS-38. Space-time cross-correlation function of the 2001 DOY 149 plasma up- and downlink time series plotted in Figure RSS-37. Y-axis is the distance from the Earth; x-axis is downlink received time. Contours of cross correlation value are plotted between 0.9 and 0.4, in 0.1 increments. Correlations > 0.9 are shaded red, those between 0.8 and 0.9 in orange, etc.

CONTEXT FROM NEAR-SUN CORONAL DENSITY OBSERVATIONS

Richie-Halford et al. [2009] looked at coronal data to see if there was an obvious plane-of-sky counterpart for the localized plasma on 2001 DOY 149. Figure RSS-39 shows a map of the coronal density structure at a height of four solar radii for Carrington Rotation 1976. Red is high density, black is low. The x-axis is Carrington rotation longitude, the y-axis is solar latitude. The point along the Earth-Cassini line of sight closest to the Sun is shown as a diamond on the map. The three dotted and dashed lines are the position of the heliospheric current sheet, calculated using various models. The positional agreement suggests the highly-localized plasma seen by Cassini is associated with the heliospheric current sheet on DOY 149.

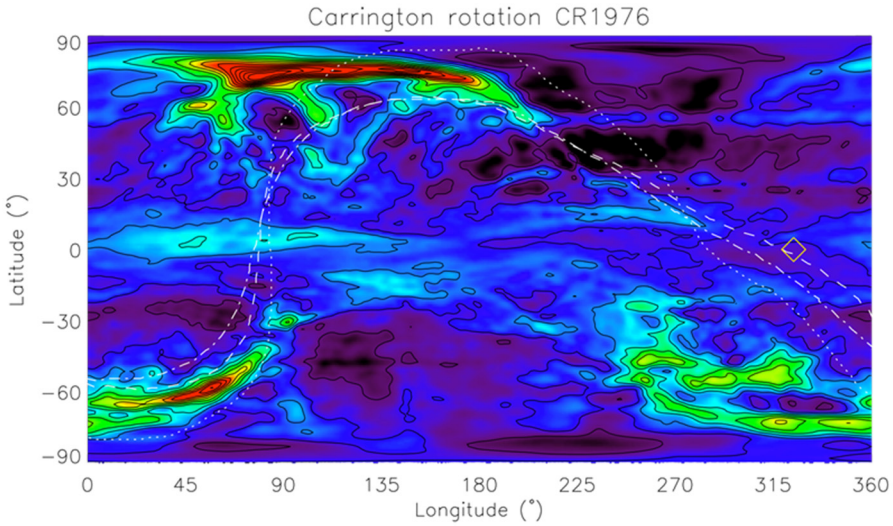

Figure RSS-39. Map of coronal density structure at a height of 4 solar radii for Carrington Rotation 1976, calculated using a solar rotational tomography technique from ~2 weeks of LASCO/SOHO C2 coronagraph observations. Red is high density, black is low. The x-axis refers to Carrington longitude, the y-axis to solar latitude. The point along the Earth-Cassini line of sight closest to the Sun is shown as a diamond. The three dotted and dashed lines are the position of the heliospheric current sheet, calculated using different models. The positional agreement suggests the highly-localized plasma seen by Cassini is associated with the heliospheric current sheet on this day.

LOCALIZATION ON OTHER DAYS

The localization of the dominant plasma turbulence on 2001 DOY 149 is remarkable but perhaps not typical. Figure RSS-40 shows analysis for 2002 DOY 160 = 2002 June 9 (Sun-Earth-spacecraft angle ≈ 9.5 degrees; two-way light time ≈ 8365 seconds). Correlation levels are in general lower than those in Figure RSS-38 for 2001 DOY 149. At the start of the track a scattering region nearer to the Earth than the ray path closest approach point (≈ 1AU∗cos(9.5 degrees) = 0.986 AU) is indicated. In mid-track, the correlation is particularly low, indicative of extended, rather than localized, scattering for much of this day.

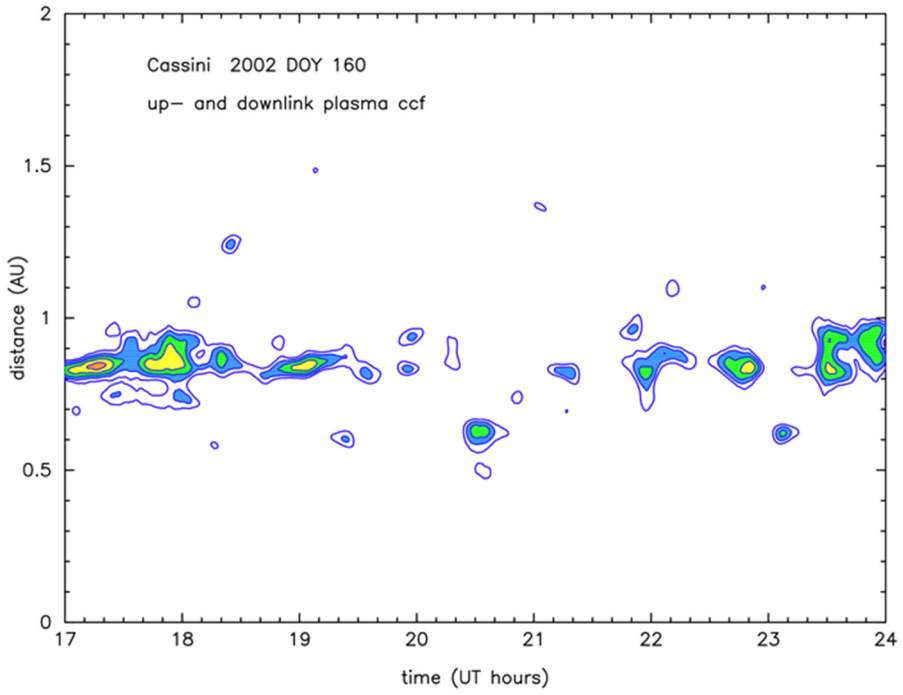

Figure RSS-40. As Figure RSS-38, but for 2002 DOY 160 = 2002 June 9. The Sun-Earth-spacecraft angle was about 9.5 degrees and the two-way light time was about 8365 seconds. Correlation levels in general lower than those in Figure RSS-38. At the start of the track a scattering region nearer to Earth than the ray path closest approach point (≈ 1AU cos (9.5 degrees) = 0.986 AU) is indicated. In mid-track the correlation is particularly low, indicative of extended, rather than localized, scattering.

OTHER SOLAR CONJUNCTION OBSERVATIONS

In addition to the 2001–2002 observations analyzed by Richie-Halford et al. [2009], subsequent solar conjunction data were collected. Full information (including Doppler modes, link information, spacecraft operational modes, exact start/stop times, etc.) are included in Project documentation [Anabtawi 2018]. Table RSS-14, for reference, is an overview of times when data were taken.

Table RSS-14. Overview of data times.

Year	Day-of-Year	Comment	Year	Day-of-Year	Comment
2005	196, 198, 208		2011	270–300	SCE8
2006	203–233	SCE3	2012	279–319	SCE9
2007	219–247	SCE4	2013	297–324	SCE10
2008	233–259	SCE5	2014	308–335	SCE11
2009	245–275	SCE6	2015	322–348	SCE12
2010	261–285	SCE7	2016	330–360	SCE13

SCE = solar conjunction experiment

Open questions

Cassini's principal non-Saturn science investigations were the gravitational wave experiment, solar conjunction relativity experiment, and solar wind plasma localization experiment. In all cases, Doppler tracking between Cassini and the DSN was used as the raw observation. The scientific objectives of future spacecraft cruise experiments would be to improve on current results.

The search for low frequency gravitational waves in space is the goal of the ongoing LISA mission, to be launched in the early 2030. This major undertaking of ESA and NASA confirms the motivations of the Cassini GWE, an attempt to search for gravitational wave sources in the mHz band at distances reaching the Virgo cluster.

The Cassini SCE increased our confidence in the validity of general relativity (GR), pushing possible violations of the metric in the solar system to the fifth decimal place. However, in spite of its apparent success, the Cassini test is just one more step in the quest for the breakdown of GR. Unfortunately, the theoretical framework does not give any clue on the level at which GR could be violated. Every test capable of improving the Cassini results is therefore significant. The BepiColombo Mission, which has a multilink radio system similar to Cassini's, with the additional feature of a pseudo-noise, high accuracy, ranging system, is expected to improve the SCE result by a factor 5–10 [Iess and Asmar 2007; Imperi and Iess 2017]. Remarkably, astrometric measurements of the gravitational deflection with the mission GAIA will reach a similar accuracy.

Here we comment on limiting noises in Cassini's precision Doppler observations and how these might be mitigated in future spacecraft cruise experiments. This section draws heavily on Bertotti et al. [2003]; Armstrong et al. [2003]; Asmar et al. [2005]; Armstrong [2006]; and Richie-Halford et al. [2009].

Precision Doppler tracking: noise in two-way observations

The Earth and the Cassini spacecraft act as separated test masses, electromagnetically tracked using microwaves. The ground stations for the Doppler system are the antennas of the NASA/JPL DSN. In particular, DSS25 was instrumented with Ka-band uplink and an advanced tropospheric calibrations system. The Cassini spacecraft was gravitationally very quiet when its attitude was controlled by reaction wheels and it had a sophisticated radio system. A precision frequency standard provided the frequency reference to both the transmitter and receiver chains. On the transmitter side, the exciter produced a near-monochromatic signal, referenced to the Fourier Transform Spectrometer (FTS) signal but at the desired transmit frequency. This was amplified by the transmitter—with closed-loop feedback around the power amplifier to ensure frequency stability was not degraded—and routed via waveguide to the transmitter feed horn in the basement of DSS25. To correct for aberration the Ka-band transmit feed horn was on a table which articulated in the horizontal plane. This allowed the Ka-band transmitted beam to be pointed correctly relative to the received beam. In a DSN beam waveguide antenna, the transmitted beam is reflected off six mirrors within the antenna up to the subreflector (near the prime focus), then back to the main dish

and out to the spacecraft (passing first through the troposphere, ionosphere, and solar wind). When the signal is received at the spacecraft, it is amplified and phase-coherently retransmitted to Earth. The received beam bounces off the main reflector to the subreflector and then, via mirrors and dichroic plates, to the receiver feed horn. The received signal is downconverted to an intermediate frequency where it is digitized. The digital samples are processed to tune out the (predictable) gross Doppler shift, and reduce the bandwidth of the samples.

For cruise operations, the bandwidth of the predetection data was typically reduced to 1 kHz and those data were recorded to disk along with the tuning information. The phase of the signal was detected in software and, using the tuning information, the received sky frequency could be reconstructed. This and the known frequency of the transmitted signal was used to compute the Doppler time series. Removal of the orbital signature and correction for charged particle and tropospheric scintillation gave Doppler residuals, which were used in subsequent processing steps for cruise experiments.

The main noises, along with the transfer functions of the noises to the two-way Doppler observable, are listed in Table RSS-15—see also Bertotti et al. [2003]; Asmar et al. [2005]; Armstrong [2006]. Cassini's multilink radio system, plus tropospheric corrections using the Advanced Media Calibration system, allowed: a) precise measurement of the PPN parameter γ [Bertotti et al. 2003]; b) improved limits to gravitational wave signal strength in the 10^{-6} to 10^{-1} Hz band [Armstrong et al. 2003]; and c) the first space-time localization of plasma turbulence in the inner heliosphere [Richie-Halford et al. 2009].

Table RSS-15. Cassini Cruise-phase Doppler noises and their transfer functions to two-way observations.

Noise source	Noise level (approx. Allan deviation at 1000s integration) during Cassini cruise phase	Transfer function of raw noise to Doppler observation (T_2 = two-way light time)
Frequency standard	8×10^{-16}	$\delta(t) - \delta(t - T_2)$
Antenna mechanical	2×10^{-15}	$\delta(t) + \delta(t - T_2)$
Ground electronics	2×10^{-16}	$\delta(t)$
Plasma scintillation	$< 10^{-15}$ at Ka-band for Sun-Earth-spacecraft angle > 150 degrees	variable, depending on effective phase screen location
Stochastic spacecraft motion	2×10^{-16}	$\delta(t - T_2/2)$
Receiver thermal	few $\times 10^{-16}$	$\delta(t)$
Spacecraft transponder	10^{-16}	$\delta(t - T_2/2)$
Tropospheric scintillation	$< 3 \times 10^{-15}$ to 30×10^{-15} (raw) $< 1.5 \times 10^{-15}$ to 3×10^{-15} (corrected)	$\delta(t) + \delta(t - T_2)$

Noise Mitigation in Future Precision Two-Way Doppler Observations

This section briefly outlines how future spacecraft Doppler observations might be made with 10x lower noise level, to a few times 10^{-16} Allan deviation at 1000s. In addition to possible innovation in Doppler extraction in the presence of moderate-to-strong interplanetary scintillation (relevant for

near-Sun relativity tracking and the decomposition of Doppler into dispersive uplink and downlink components for turbulence localization close to the Sun), Table RSS-16 shows the required improvements to the various subsystems or other noise contributors for typical tracking conditions—adapted from Armstrong [2006].

Table RSS-16. Required Noise improvement factors to reach ~10^{-16} Doppler noise.

Noise source	Comment/Allan deviation	Approximate improvement required
Frequency standard	currently ~8 × 10^{-16}	~8×
Antenna mechanical	currently ~2 × 10^{-15} under favorable conditions	~20×
Ground electronics	currently ~2 × 10^{-16}	~2×
Plasma scintillation	Cassini-class radio system probably adequate for ~10^{-16} with multilink calibration	~1×
Stochastic spacecraft motion	currently ~2 × 10^{-16}	~2×
Receiver thermal	few × 10^{-16}	~few ×
Spacecraft transponder	10^{-16}	~1×
Tropospheric scintillation	currently ~few × 10^{-15}, under favorable conditions and with calibration	~20×

Improving frequency standards and frequency distribution over what was possible in the Cassini cruise era by 8× is thought to be straightforward. Ground electronics can probably be improved by 2× by even more careful design. Similarly, spacecraft buffeting can probably be improved by 2× by careful design. Thermal noise can be improved by increasing the downlink SNR.

The big problems are antennal mechanical noise and tropospheric scintillation. These enter with the same transfer function: $\delta(t) + \delta\ (t - T_2)$. A possible way to mitigate this noise is to simultaneously track with an additional 3-way link (i.e., with a separate, listen only, ground antenna). As suggested by Estabrook [1978] and Hellings [private communication] in the context of tropospheric mitigation, a linear combination of the 2-way and 3-way Doppler data streams can be used to remove both the antenna mechanical and tropospheric noise of the 2-way station and replace it with those of the 3-way station [Armstrong et al. 2008]. If the 3-way station is located in a favorable tropospheric site and if it is mechanically stiff, this can in principle significantly improve the quality of the observation. Experiments demonstrating proof of concept have been done [Armstrong et al. 2008] and the practical limits of this approached are being investigated [Notaro et al. 2018]. These techniques may be useful in future precision radio science observations, for example BepiColombo, where substantial improvement in selected PPN parameters is possible, as well as future highly-accurate spacecraft navigation determinations [Tortora et al. 2004].

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AACS	Attitude and Articulation Control Subsystem
AMC	Advanced Media Calibration
AO	Announcement of Opportunity
AU	astronomical units
AU	astronomical unit
bps	bits per second
BSR	bistatic radar
C/A	closest approach
CAPS	Cassini Plasma Spectrometer
CDS	Command & Data Subsystem
CIRS	Composite Infrared Spectrometer
CME	coronal mass ejections
DOY	day of year
DSN	Deep Space Network
DSS	Deep Space Station
ELS	Electron Spectrometer
EM	electromagnetic
EOS	equation of state
ESA	electrostatic energy analyzer
FTS	Fourier Transform Spectrometer
GFO	Grand Finale Orbits
GM	gravitational mass
GR	general relativity
GSE	gravity science enhancement
GW	gigawatt
GWE	gravitational wave experiment
HASI–PWA	Huygens Atmospheric Structure and Permittivity, Wave, and Altimetry
HGA	high-gain antenna
ILR	inner Lindblad resonance
INMS	Ion and Neutral Mass Spectrometer
JPL	Jet Propulsion Laboratory
KaT	Ka-band translator
LCP	left circularly polarized
LEM	lower equipment module
LGA	low-gain antennas
LOS	line-of–sight
MHD	magneto-hydrodynamic

MOIF	moment of inertia factor
PLL	phase-locked loop
PM	periodic microstructure
PMS	Propulsion Module Subsystem
PPN	parametrized post-Newtonian
PPS	Power and Pyrotechnics Subsystem
RADAR	Titan Radar Mapper
RCP	right circularly polarized
RFIS	Radio Frequency Instrument Subsystem
RFS	Radio Frequency Subsystem
rms	root-mean-square
RPWS	Radio and Plasma Wave Spectrometer
RS	radio science
RSR	radio science receiver
RSS	Radio Science Subsystem
RSSG	Radio Science Systems Group
RTG	radioisotope thermoelectric generator
SCE	solar conjunction experiment
SEP	Sun-Earth-Probe
SNR	signal to noise ratio
SOHO	Solar and Heliospheric Observatory
SOI	Saturn Orbit Insertion
TCS	Temperature Control Subsystem
TM	Traceability Matrix
TSAC	Tracking System Analytical Calibrations
UEM	upper equipment module
USO	ultra-stable oscillator
UTC	Coordinated Universal Time
UVIS	Ultraviolet Imaging Spectrograph
VIMS	Visual and Infrared Imaging Spectrometer
VLBI	very-long-baseline interferometry
VSR	VLBI Science Receiver

4 PROJECT PUBLIC ENGAGEMENT PROGRAM

Social media did not exist when Cassini launched to Saturn. The interactivity and accessibility enabled by the internet was only just beginning to emerge. Streaming video was limited to pixelated, postage stamp-sized windows that often required great patience to view. But over the years, as the world—and the World Wide Web—changed, Cassini's public engagement activities evolved to embrace an ever-larger audience.

In 1998, JPL communications manager Alice Wessen was asked to lead the reformulation of the Cassini Mission's Education and Public Outreach (EPO) Plan. Then head of NASA's Office of Space Science, Jeff Rosendahl, funded each science mission individually, and each mission was required to have its own communications plan, which included EPO. The charge was to update Cassini outreach for the 21st century—make it more relevant and more impactful nationally. Wessen worked with the project to create a new vision for Cassini public engagement for NASA review. Early versions of the plan included ideas for a public-friendly mission website, a Saturn observing campaign, printed outreach products, and a planetary data access function (which did not survive the development process due to the projected level of effort needed to support it).

From that original 1998 plan, Cassini's public engagement program evolved to embrace the ever-expanding role of digital media.

From that original 1998 plan, Cassini's public engagement program evolved to embrace the ever-expanding role of digital media. Over the mission's final decade, from 2008 to 2018, the project transitioned from primarily dealing in printed outreach products (such as posters, lithographs, trading cards, and educational binders for teachers) to almost exclusively digital outreach. By the mission's end, there were millions of visits to the Cassini mission website per year, and Cassini could boast of 1.6 million followers on Twitter and close to half a million followers on Facebook. (In fact, the mission was an early adopter of social media, in 2008, leading the agency as one of the most followed NASA accounts on Twitter throughout its lifetime.)

The most visible element of the mission (and perhaps most memorable for the public) has always been its dazzling images. Cassini set a new standard at NASA for openness and public access to scientific data by making all of the spacecraft's raw imaging science observations available on the mission website almost as soon as the data hit the ground. This level of access was game changing in public engagement, and allowed a whole community to spring up and evolve over the years as people perused the images, processed them, discussed them, and shared them. This was the most trafficked area of the mission website for its entire history, but it should also be noted that the overall website won two judges' Webby awards ("the Internet's highest honor") for best science website, in 2009 and 2017.

The hallmark of Cassini public engagement was to serve up Saturn's awe-inspiring vistas and to seize on emerging trends in the digital landscape. The mission consistently did this in ways that drew in people from diverse backgrounds and many walks of life, bestowing on them a sense of

personal ownership of the mission as they imagined dancing with the spacecraft among the icy moons of Saturn.

4.1 Formal Education

4.1.1 READING, WRITING & RINGS (RW&R)

"Reading, Writing & Rings" is a comprehensive language arts education program for young learners. The program was developed in partnership by the Cassini-Huygens EPO program; the Jet Propulsion Laboratory education office; the Bay Area Writing Project (an affiliate of the California Writing Project); Project FIRST at the University of California, Berkeley; the Caltech Precollege Science Initiative; and selected classroom educators.

4.1.2 CASSINI "SCIENTIST FOR A DAY" (SFAD)

The Cassini Scientist for a Day essay program challenges students to become NASA scientists studying Saturn. Participants write a short essay about which of three possible Cassini observations they think will yield the best science. SFAD meets U.S. National English and Science Education Standards. Since its 2004 inception, SFAD reached over 10,000 students in over 500 U.S. classrooms; the international version reached tens of thousands worldwide on five continents and 65 countries. See https://solarsystem.nasa.gov/scientist-for-a-day/home/.

4.2 Informal Education

"Ring World" Planetarium Show Content transitioned from original planetarium show (slides, music, and storyboard) for 200 mid-sized planetariums in 2004, to digital slides in 2005, to three updated versions of a DVD video "Ring World." All copies were distributed before end of mission. The Grand Finale video replaced the previous programs, is widely available, and remains on the Cassini Website, which transitioned to the NASA Solar System website in fall 2018.

Ring World won a 2004 Telly award, and has been shown nationally and internationally in hundreds of planetariums in multiple languages. Versions for schools in English, Spanish, Letterbox (for hearing impaired), and Podcast (or "vodcast") are available for download. The third and final Ring World HD video was completed in 2012, and a print run of 50,000 was completed and sent to NASA networks with a Spanish translation and closed-captioning for the hearing impaired.

The "Saturn Observing Campaign" shared the excitement of the Cassini mission with amateur astronomers and public groups around the world. Since 2004, Saturn Observation Events reached more than 750,000 members of the public. The Juno Observing program (JunoCam) gleaned lessons learned from the Saturn Observation Campaign, as did other citizen science programs throughout NASA. The Saturn Observing Campaign was created from U.S. members of the Solar System Ambassador program, and opened to international volunteers to honor the International Cassini-

Huygens mission. At its peak in 2013, the program had over 500 worldwide members in 100 countries, and all 50 states of the U.S.

Now known as "Eyes on the Solar System" (http://eyes.nasa.gov), the application provides 3-D simulations of all of NASAs planetary missions using authentic NASA SPICE navigation data.

The "What's Up?" podcast featured a 2-minute video highlight of a current NASA mission and what is viewable in the night sky. Originally developed by Cassini EPO and featured Cassini and Saturn in many of the monthly episodes, it is now supported by the NASA Planetary Science directorate. In November 2017, NASA Communications selected "What's Up?" as one of four NASA video series to debut on Facebook Watch. As of April 2018, 165,000 users subscribed to the What's Up show, and each episode reached between 800,000 and 3 million views each month. In its 12th year (began by Cassini in April 2007), What's Up's 130 monthly episodes now reach over 10 million views each month on NASA websites, YouTube, Facebook, Instagram, Tumblr, Twitter, and other social platforms, and are imbedded in TV Weather websites, science websites, and used in museums, planetariums, and shown in amateur astronomy club meetings.

4.3 Reaching Underserved Schools

DonorsChoose.org (http://www.youtube.com/watch?v=PUSdjfh2YjM&feature=player_embedded) is a nonprofit organization matching donors with public school educators. Seventy-five percent are high poverty and all were unaware that NASA provides high-quality materials for free.

Through DonorsChoose.org:

- Cassini reached ~3,000 K–12 teachers and ~300,000 students in all 50 states;
- Cassini EPO invited all students to participate in Cassini Scientist for a Day and other NASA networks. This program has been transferred to the Solar System Public Engagement team for continuation.

4.4 Public Outreach: NASA Data Shared with the Public

"Eyes on the Solar System": In 2004, Cassini EPO started a unique visualization program called "CASSIE" (Cassini Internet Explorer), which allowed the public to experience the Cassini spacecraft going into Saturn Orbit Insertion. Now known as "Eyes on the Solar System" (http://eyes.nasa.gov), the application provides 3-D simulations of all of NASA's planetary missions using authentic NASA SPICE navigation data. It has been downloaded millions of times by members of the public. The

family of applications known as NASA's Eyes on the Earth, Eyes on Exoplanets, and DSN now owe their start to Cassini's CASSIE.

Cassini Huygens Analysis and Results of the Mission (CHARM): Teleconferences presented since 2004 by Cassini Mission experts to NASA's outreach networks (NASA Museum Alliance members, Cassini Saturn Observation Campaign volunteers, Solar System Ambassadors, Night Sky Network astronomy clubs, solar system educators. Now hosted on NASA's Museum Alliance website.

4.5 Website

The Cassini website (https://solarsystem.nasa.gov/missions/cassini) was one of the most-visited NASA websites, garnering Webby awards for Best Science Website in 2009 and 2017 for outstanding work highlighting science. In 2009, the site received approximately half a million unique users monthly and is over 100,000 pages deep. The raw images, which were made available to the public eight hours after being downlinked from the spacecraft, continued to receive the most traffic throughout the mission's lifetime.

During 2015–2017, content was created to highlight the Cassini Grand Finale (https://solarsystem.nasa.gov/missions/cassini/mission/grand-finale/overview/) with resources, orbit guides, photo galleries, 3-D interactives, and features such as "Why Cassini Matters," End of Mission timeline, Quick facts and What's Next, and Cassini People, while older content was rewritten or retired. Since October 2017, the website was further streamlined, and in October 2018, the Cassini Legacy Website was transferred to the NASA Solar System website for historic preservation.

Cassini Archive Updates:

- https://saturn.jpl.nasa.gov has been redirected to https://solarsystem.nasa.gov/missions/cassini
- https://solarsystem.nasa.gov/missions/cassini has been expanded
- Cassini pages have been migrated into the new architecture and redirects provided for key content
- The archive site has fewer sections, but content offered in a deeper dive
- News, features, images, videos, graphics, etc., archived in SSE news section, but filterable by mission
- Raw images and search remain intact

The Journey: https://saturn/solarsystem.nasa.gov/missions/cassini/the-journey/

News & Features: https://solarsystem.nasa.gov/news/

Resources: https://solarsystem.nasa.gov/resources/all/

4.6 Social Media

Cassini had a significant presence on social media. Cassini Twitter (@CassiniSaturn) had 1.6 million followers and NASA Cassini Facebook had 450,000+ followers as of April 2018. The accounts are now managed by the Solar System Exploration Social/Web team.

4.7 Other Notable Programs

Wave at Saturn: The EPO team partnered with NASA Media Relations to produce the viral "Wave at Saturn" event on July 19, 2013, which captured a mosaic of the Saturn and Earth/Moon systems. The event was the first time Earthlings were told in advance that their picture was being taken from interplanetary distances. A photomosaic, or collage version of the image features about 1,600 pictures submitted by members of the public, in which they captured themselves waving at Cassini (and Saturn) during the event. Other NASA missions and programs have since used the Wave At Saturn model for their own public engagement campaigns (#EarthRightNow photos and mosaic #HiJuno (in Morse code) and others).

Cassini hosts a regular whimsical gallery of holiday graphics which have their own cult following. No other mission has matched Cassini in this endeavor, and the collection, along with all photo galleries, will remain on the legacy website.

4.8 And the Emmy goes to … NASA/JPL!

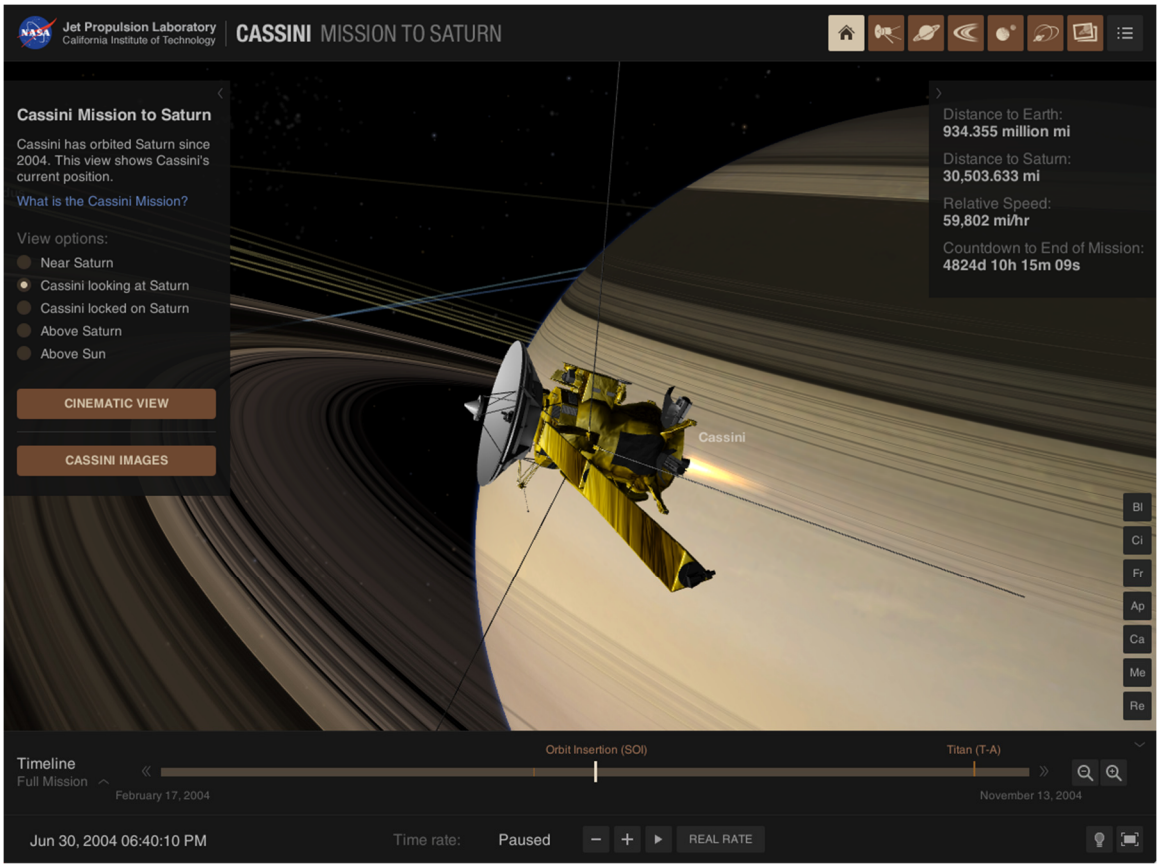
The Cassini team pulled out all the stops for their coverage of the spacecraft's Grand Finale. Mixing traditional media coverage with interactive components, they developed a multi-faceted, multi-platform campaign that allowed them to share the mission's last weeks and hours. Their efforts in showcasing the mission earned NASA/JPL an Emmy for Outstanding Original Interactive Program in 2018, the first such award the agency has ever received.

4.9 Summary

As Cassini winds down, the mission's decades-long public engagement effort continues to pay dividends—its products and programs now influencing the next generation of space missions.

The Saturn Observation Campaign has fed into the ongoing efforts of the NASA-sponsored Night Sky Network and helped inform the Juno mission's JunoCam amateur observation program. Cassini's long-running Scientist for a Day program is planned to continue indefinitely as NASA Solar System Scientist for a Day.

NASA's Eyes on the Solar System application (eyes.nasa.gov), which began life as the Cassini Interactive Explorer, continues to be developed and diversified. The application shows all of NASA's space missions over the period of 1950 to 2050, and (of course) includes a detailed dive into Cassini's Grand Finale. It has branched out into two additional interactives, called Eyes on the Earth and Eyes on Exoplanets. This innovative and groundbreaking visualization tool owes credit for much of its early development to Cassini.

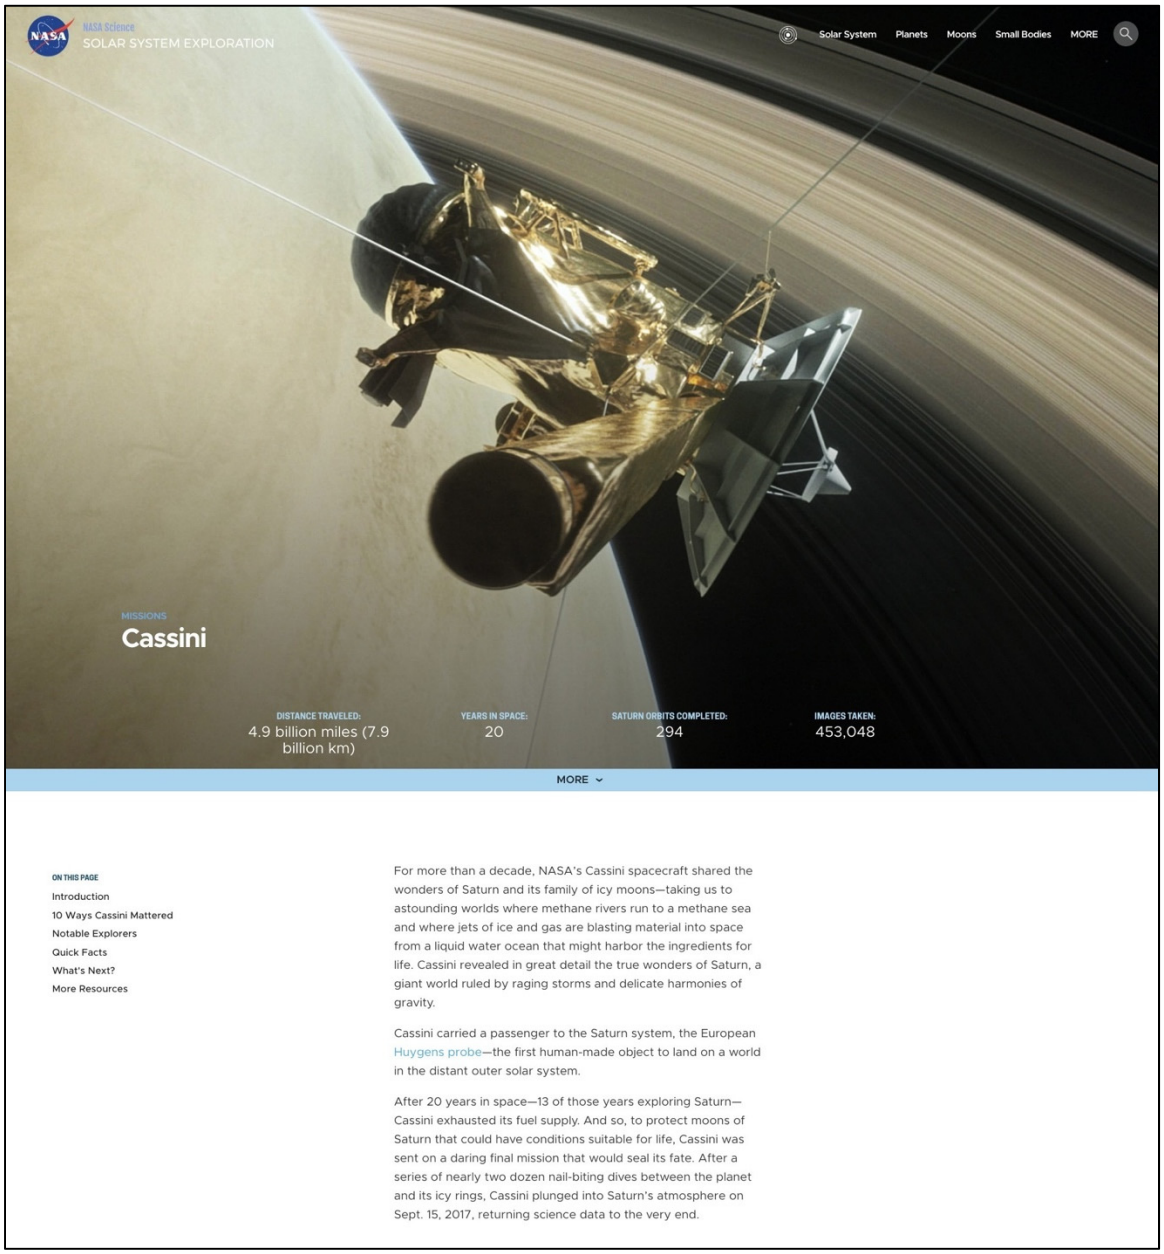


Screenshot from NASA's Eyes on the Solar System interactive application, which began life as a Cassini simulator in 2004.

The Cassini Twitter account, with its >1.6 million followers, was rechristened as the NASA Solar System Exploration account in September 2018. (The account serves the Planetary Science Division's Solar System Exploration website, solarsystem.nasa.gov.) This decision reflects the enormous influence Cassini has had on pivoting planetary exploration toward ocean worlds, and also helps NASA hold onto the huge space-science hungry audience the mission has painstakingly built over a decade.

The mission website is permanently archived as part of the Solar System Exploration website (https://solarsystem.nasa.gov/missions/cassini/overview/), similar to the model employed for Deep Impact and Galileo. A major difference is that the post-mission archiving of the Cassini site was planned for and budgeted well in advance, and the site's final redesign (including the content itself)

was produced with this end-state in mind. Digital storytelling tools and image gallery filtering tools developed for Cassini are also being deployed on the solar system site at large. The website for NASA's next flagship outer planets mission, Europa Clipper, is being directly modeled on key elements of the Cassini site. Examples include: science instrument profiles, which provide accessible, high-level "How It Works and How We Use It" summaries before delving into details; visually rich interactives like Cassini's timelines and short-form digital stories (as seen in "The Journey" section of the website); and the mission's planned raw image gallery, which will follow the same basic design as Cassini.



Screenshot from the Cassini website, now archived on NASA's Solar System Exploration site.

5 PROJECT ARCHIVES

Due to the complexity and amount of information (engineering and scientific) that the Cassini Project acquired and processed, the archive of this information has been divided into the following main systems: the PDS, JPL DocuShare, JPL Records Storage, JPL Line Management Archives, Amazon Web Services (AWS), and the JPL Solar System Exploration Web Presence.

5.1 The Planetary Data System

The PDS is the primary organization within NASA responsible for the archive of planetary science data obtained from NASA sponsored missions and, thus, provides a long-term archive system for Cassini science data. It consists of an Engineering Node located at JPL and several Discipline Nodes located around the country. For Cassini, the Lead Node is the Atmospheres (ATMOS) Node at New Mexico State University in Las Cruces, New Mexico. The full list of Nodes supporting the Cassini Mission, and the corresponding instrument team delivering to them, is shown in the table below.

Table 5.1-1. PDS discipline nodes for Cassini/Huygens data.

Data from:	Delivered to PDS Node:
CAPS, INMS, MAG, MIMI, RPWS	Planetary Plasma Interactions Node (PPI), University of California, Los Angeles, CA https://pds-ppi.igpp.ucla.edu/
CDA	Small Bodies Node (SBN) – Dust Sub-node, University of Arizona, Tucson, AZ https://pds-smallbodies.astro.umd.edu/
CIRS, RSS, UVIS	*Atmospheres Node (ATMOS), New Mexico State University, Las Cruces, NM https://pds-atmospheres.nmsu.edu/
ISS, VIMS	Cartography and Imaging Sciences Node, JPL, Pasadena, CA https://pds-imaging.jpl.nasa.gov/portal/
RADAR	Cartography and Imaging Sciences Node, JPL, Pasadena, CA https://pds-imaging.jpl.nasa.gov/portal/
SPICE (Kernels: SPK, PCK, IK, CK, EK, FK, SCLK and LSK)	Navigation and Ancillary Information Facility (NAIF), JPL, Pasadena, CA https://naif.jpl.nasa.gov/
Huygens probe: ACP, DISR, DWE, GCMS, HASI, SSP	1. Planetary Science Archive, ESA http://open.esa.int/esa-planetary-science-archive/ 2. ATMOS, New Mexico State University, Las Cruces, NM https://pds-atmospheres.nmsu.edu/

* Lead node for Cassini

The Cassini and Huygens probe data sets are archived separately. The Huygens data are housed online at the PDS Atmospheres Node in the U.S. as well as in Europe at the European Space Agency's Planetary Science Archive.

The first scheduled archive delivery took place on July 1, 2005. Data coverage was from launch on October 15, 1997 through September 30, 2004.

After the first data delivery on July 1, 2005, data deliveries were made quarterly and lagged the acquisition of data in operations by 9 months. The final data delivery took place October 2018.

In addition to the data from the Cassini science instruments, the project created the Cassini Science Research Support System (SRSS). The Cassini SRSS is a cohesive set of PDS web pages with links to science research support data and science data. The SRSS is located on the PDS Atmospheres node: https://pds-atmospheres.nmsu.edu/data_and_services/atmospheres_data/Cassini/Cassini.html.

5.2 JPL Archives

Cassini has created two institutionally supported libraries: the Cassini Program Archival Library and the Cassini Software Repository.

The Cassini Program Archival Library consists of the following collections:

- Project Document Archive – contains official project documents, interoffice memorandums, requirements, plans, reviews, and science proposals
- Project Records and Products – contains operational products, such as sequence products, log files, and process documents, and records, such as test reports, and records, such as instrument heating predicts. Files are organized by team.
- Project Discreet Documents and Records – contains project- and business-discreet documents, such as management reviews, program status reports, and program plan
- Science Research Support Products
- Records Storage Requests – contains inventories of storage requests
- Cassini Electronic File Cabinet (EFC) – contains over 18,000 memos, presentations, and documents

The Cassini Software Repository library contains copies of the latest versions of flight and ground software delivered to the Cassini Program Software Library (PSL). It is organized into two collections: Flight Software and Ground Software.

The Project Document Archive collection contains official project documents, such as plans, requirements, test plans, reports, and reviews.

5.3 JPL Records Storage

Hardcopy records and documents are archived with JPL Records Storage. The JPL internal online Paper Records Inventory (PRI) System is used to create a Records Storage Request or to perform a search and request the return of boxes sent to storage.

5.4 JPL Line Management Archives

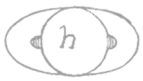
Teams with domain-specific information and data have arranged to archive this data with their JPL Line Management. For example, navigation software, documentation, and data are archived on the Section 392 System for Archival of Navigation Data (SAND).

5.5 Amazon Web Services

Files used and shared in operations that were stored in the Cassini file catalog system, known as the DOM and the project web server, were copied into the AWS cloud storage as a deep archive, or backup, to other archives. A web portal provides a limited, file-name–based search capability to the archive.

5.6 JPL Solar System Exploration Web Presence

The mission's public website (saturn.jpl.nasa.gov)—including the entire searchable raw image gallery—was permanently archived as part of the NASA Solar System Exploration website (solarsystem.nasa.gov) in September 2018 (as solarsystem.nasa.gov/cassini). New Cassini science results are shared by the Solar System Exploration Twitter account (@NASASolarSystem) and are retweeted and amplified by the Cassini Twitter account (@CassiniSaturn).



6 ADDITIONAL INFORMATION

6.1 Quick Facts about the Cassini Mission

6.1.1 MILESTONES

- Launch: October 15, 1997, from Cape Canaveral Air Force Station, Florida
- Launch vehicle: Titan IVB/Centaur
- Venus flybys: April 26, 1998, at 176 miles (234 km); June 24, 1999, at 370 miles (600 km)
- Earth flyby: August 18, 1999, at 727 miles (1,171 km)
- Jupiter flyby: December 30, 2000, at 6 million miles (10 million kilometers); closest approach at 5:12 a.m. EST Saturn arrival: July 1, 2004, UTC (June 30, 2004 PDT)
- Huygens probe: Titan release December 24, 2004; Titan descent January 14, 2005

6.1.2 CASSINI ORBITER

- Dimensions: 22 feet (6.7 meters) high; 13.1 feet (4 meters) wide
- Weight at launch: 12,593 pounds (5,712 kilograms) with fuel, Huygens probe, adapter, etc.
- Weight at end of mission: 4,685 pounds (2,125 kilograms)
- Propellant used: 6,504 pounds out of 6,565 pounds (2,950 kilograms out of 2,978 kilograms)
- Power: 885 watts (633 watts at end of mission) from radioisotope thermoelectric generators
- Orbiter science instruments (12 total): CIRS, ISS, UVIS, VIMS, RADAR, RSS, CAPS, CDA, INMS, MAG, MIMI, RPWS. Details about all of Cassini's science instruments: https://solarsystem.nasa.gov/missions/cassini/mission/spacecraft/cassini-orbiter/.

6.1.3 MISSION

- Commands executed: 2.5 million
- GB of science data collected: 635 GB
- Saturn orbits completed: 294
- Targeted moon flybys: 162
- Targeted Titan flybys: 127
- Targeted Enceladus flybys: 23
- Images taken: 453,048
- Main engine burns: 183
- Oceans discovered: 2 (Titan, Enceladus)
- Titan seas and lakes discovered: 3 seas, hundreds of small lakes
- Named moons discovered: 6
- Science papers published: 3,948
- Prime Mission: 4 years
- Two Extended Missions: Equinox (2008–2010) and Solstice (2010–2017)

- Total distance traveled: At Cassini's end of mission, the spacecraft had traveled about 4.9 billion miles (7.8 billion kilometers) with respect to the Sun. This distance includes its 2.1 billion-mile (3.4-billion kilometer) interplanetary trajectory from Earth to Saturn. With respect to Saturn, Cassini traveled a total of 1.2 billion miles (1.9 million kilometers) from arrival to end of mission.
- Saturn's average distance from Earth: 890 million miles (1.43 billion kilometers)
- One-way speed-of-light time from Saturn to Earth during orbital tour: Varied between 67 and 85 minutes
- One-way speed-of-light time from Saturn to Earth at end of mission: 83 minutes
- Spacecraft speed at loss of signal (relative to Saturn): 69,368 mph (111,637 kph)

6.1.4 PROGRAM

- Partners: NASA, ESA, ASI
- Number of people who worked on some portion of Cassini-Huygens: More than 5,000
- Cost of mission: $3.9 billion*. This figure includes $2.5 billion* in pre-launch costs (including launch vehicle and contributions from ESA and the Italian Space Agency) and $1.4 billion* in post-launch costs (including operations and tracking for 20 years in flight).

**The cost information contained in this document is of a budgetary and planning nature and is intended for informational purposes only. It does not constitute a commitment on the part of JPL and/or Caltech.*

ACRONYMS

Note: For a complete list of Acronyms, refer to Cassini Acronyms – Attachment A.

AACS	Attitude and Articulation Control Subsystem
ACP	Aerosol Collector and Pyrolyzer
AFC	AACS Flight Computer
AMMOS	Advanced Multi-Mission Operations System
ASI	Italian Space Agency (Agenzia Spaziale Italiana)
ASIC	Application-Specific Integrated Circuit
ATMOS	Atmospheres
AWS	Amazon Web Services
BAIL	Backup Assisted Load Format Injection Loader
BIU	Bus Interface Unit
bps	Bits Per Second
C/CAM	collision and contamination avoidance maneuver
Caltech	California Institute of Technology
CAPS	Cassini Plasma Spectrometer
Cassini Internet Explorer	CASSIE
CCL	Channel Conversion Language
CDA	Cosmic Dust Analyzer
CDS	Command and Data Subsystem
CEM	Cassini Equinox Mission
CHARM	Cassini Huygens Analysis and Results of the Mission
CHEMS	Change-Energy-Mass Spectrometer
CIRS	Composite Infrared Spectrometer
CM	Configuration Management
CPT	Channel Parameter Table
CRAF	Comet Rendezvous/Asteroid Flyby
CSM	Cassini Solstice Mission
DGDS	Downlink Ground Data System
DISR	Descent Imager/Spectral Radiometer
DMD	Data Monitor and Display
DOM	Distributed Object Manager
DSN	Deep Space Network
DSOT	Data Services Operations Team
DSS	Digital Subsystem
DWE	Doppler Wind Experiment
EFC	Engineering Flight Computer
EFC	Electronic File Cabinet
EGA	Engine Gimbal Assembly

EPO	Education and Public Outreach
ESA	European Space Agency
ESB	Earth Swing-By
ESS	Energy Storage Subsystem
ESTEC	European Space Technology and Research Center
FIR	Far-Infrared
FOP	Flight Operations Plan
FPW	Fields, Particles and Waves
GCMS	Gas Chromatograph Mass Spectrometer
GCMS	Gas Chromatograph and Mass Spectrometer
GVSC	Generic VHSIC Spaceborne Computer
HASI	Huygens Atmospheric Structure Instrument
HPOC	Huygens Probe Operations Centre
ICD	Interface Control Document
IEB	Instrument Expanded Block
INCA	Ion and Neutral Camera
INMS	Ion and Neutral Mass Spectrometer
IRU	Inertial Reference Unit
ISS	Imaging Science Subsystem
IT	Information Technology
ITSDB	Information Technology Security Database
JunoCam	Juno Observing Program
kbps	Kilobits Per Second
LEMMS	Low Energy Magnetospheric Measurement Subsystem
LV	Latch Valve
MAG	Magnetometer
MAG	Magnetometer
MDAS	Mission Control, Data Management & Accountability, and Spacecraft Analysis Subsystem
MGSS	Multi-Mission Ground Data System and Services
MIM	Mission Interface Manager
MIMI	Magnetospheric Imaging Instrument
MMH	Monomethylhydrazine
MOA	Mission Operations Assurance
MOAM	Mission Operations Assurance Manager
MOS	Mission Operations System
MSC	Magnetic Search Coils
MSS	Mission Sequencing System
NAC	Narrow-Angle Camera
NAIF	Navigation and Ancillary Information Facility
NGSS	National Next Generation Science Standards

NPD	NASA Policy Directive
NTO	nitrogen tetroxide
ODM	Orbiter Deflection Maneuver
OIA	Operational Interface Agreement
OIT	Operational Interface Test
ORS	Optical Remote Sensing Instruments
OTM	Orbit Trim Maneuver
PAR	Perimeter Access Request
PAT	PSG Automation Tool
PB	Playback
PCO	Probe Checkout
PDS	Planetary Data System
PDT	Pointing Design Tool
PI	Principal Investigator
PM	Prime Mission
PPI	Planetary Plasma Interactions
PR	Pressure Regulator
PRI	Paper Records Inventory
PSA	Probe Support Avionics
PSL	Program Software Library
PSLA	Program Service Level Agreement
PV	Pyro Valve
RADAR	Titan Radar Mapper
RCS	Reaction Control Subsystem
RF	Radio Frequency
RFES	Radio Frequency Electronics Subsystem
RFIS	Radio Frequency Instrument Subsystem
RPWS	Radio and Plasma Wave Science
RSP	Remote Sensing Pallet
RSS	Radio Science Subsystem
RTE	Real-Time Engineering
RTG	Radioisotope Thermoelectric Generator
RTO	Real-Time Operations
RW&R	Reading, Writing, & Rings
RWA	Reaction Wheel Assembly
SAND	System for Archival of navigation Data
SAUL	Science and Uplink
SBN	Small Bodies Node
SCAS	Science Calibration Subsystem
SCCM	Standard Cubic Centimeters Per Minute

SCET	Spacecraft Event Time
SCIOP	Science Operations
SCLK	Spacecraft Clock Time
SED	Spin/Eject Device
SEQ_GEN	Sequence Generator
SEQTRAN	Sequence Translator
SFAD	Scientist for a Day
SIS	Software Interface Specification
SOPC	Science Operations and Planning Computer
SPE	Sun-Spacecraft-Earth
SRAM	Static Random-Access Memory
SRU	Stellar Reference Unit
SSI	Space Science Institute
SSP	Surface Science Package
SSPS	Solid-State Power Switch
SwRI	Southwest Research Institute
TCM	Trajectory Correction Maneuver
TDS	Telemetry Delivery System
TT&C	Telemetry, Tracking and Command
UEM	Upper Equipment Module
UVIS	Ultraviolet Imaging Spectrograph
V&V	Verification and Validation
VHSIC	Very High-Speed Integrated Circuit
VIMS	Visible and Infrared Mapping Spectrometer
WAC	Wide-Angle Camera
